Plum breeding at the Horticultural Experiment Station, Vineland, Canada, was started in 1913. From 1913 to 1935, 4,240 seedlings were grown. Seeds were planted from 57 open pollinations and 35 crosses. Out of this number 16 had horticultural value. During the period 1931 to 1933, 860 seedlings were grown from crosses in which Imperial Epineuse was used as the female parent, and Grand Duke, Coe Fellenberg, and President have been used as pollen parents. The object of the cross was to produce a high-quality blue plum for the export trade.

Genetic and Cytological Studies of the Plum [7]

Experiments with plums were begun at the John Innes Horticultural Institution in England by W. J. Backhouse and Crane (*8*) in 1911, to investigate the genetic composition of plum trees by raising selfed offspring. The characters studied were (1) hairiness of shoots, leaf petioles, and fruits; (2) smoothness of bark and size and shape of leaves; (3) habit of growth of tree; and (4) bark and fruit color.

All the varieties of plums studied with hairy wood surface proved to be heterozygous for that character. Serrate leaf character proved to be homozygous in the Pershore variety, and crenate leaf margin homozygous in the Czar family. The irregular margin appeared to be heterozygous in varieties possessing this character.

Flesh color varied. Varieties in which yellow was the predominating flesh color have, when selfed, given seedlings with a green, and a wholly yellow flesh.

As to fruit size and shape, many of the differences were recognized as doubtless quantitative. The oblate fruit of Early Transparent, for example, and the pyriform fruit of the Pershore variety proved to be homozygous for these forms. With some selfed families, length and shape varied in the progeny.

Wellington (*32*) has carried on extensive investigations at the New York (State) Agricultural Experiment Station in breeding and genetic studies with a number of plum varieties and species. He found the oval fruit shape of *Prunus domestica* dominant to oblate. Thick bloom on the surface of the fruit is dominant to thin bloom. Yellow color is recessive to red, purple, and black. The freestone character is recessive to clingstone. Many varieties are heterozygous for the freestone character, freestones being obtained from the cling and semicling parents.

Some varieties of our domestica plums set fruit with their own pollen; others are partially self-incompatible, while a third group fail entirely with their own pollen. Insititia varieties grown in this country are self-fruitful. Nearly all of the varieties of the Japanese group are self-sterile.

Tufts has found the following important varieties of domestica plums to be self-unfruitful in California: Clyman, Tragedy, Imperial Epineuse, President, Standard, Sergeant, Washington, Jefferson, Quackenboss, Diamond, and Silver. Self-fruitful varieties were

Agen, Giant, Pond (partially), Grand Duke (partially), California Blue, Yellow Egg, and Sugar.

The following Japanese and hybrid plums were self-unfruitful in California: Abundance, Burbank, Duarte, El Dorado, Formosa, Gaviota, Kelsey, Prize, Satsuma, Sultan, Upright, and Wickson. Methley, Climax, Beauty, and Santa Rosa are partially self-fertile. Formosa and Gaviota were also found to be interunfruitful. The Tragedy plum will fertilize several Japanese varieties but is not fertilized by them.

Crane and Lawrence (*10*) observed that certain of the domestica plums were completely self-and cross-incompatible, while others, such as President and Late Orange, were reciprocally incompatible but set fruit when pollinated with Green Gage (probably Reine Claude). Early Rivers, when pollinated by Blue Rock, set a full crop, while in the reciprocal cross only a few fruits set. Varieties such as Golden Drop, Coe Violet, and Jefferson, were found to be completely self- and cross-incompatible (*9*).

Incompatibility Due to Genetic Make-up

Experiments by a number of investigators, East (*13*), Lehmann (*24*), and others, have shown that sterility is determined by genes just as are morphological characters. East designated these genes S, and they form a multiple allelomorphic series, S_1, S_2, S_3, etc. As in the case of other allelomorphs, any two may be carried by a given plant. While this concept is based on the results of studies with *Nicotiana*, it fits into the observations made on stone fruits and explains incompatibility in plums and cherries. The essential features of the genetic behavior of incompatibility is that pollen cannot function in the style of a plant carrying the same incompatibility factors as the pollen. Self-pollinations or cross-pollinations among individuals carrying the same sterility genes fail because either the pollen tubes grow so slowly that in normal cases they are unable to reach the ovules in time to effect fertilization, or the growth of the pollen tube is inhibited in the stylar tissue. Consequently, groups of individuals occur within which all cross- and self-pollination fails to effect fertilization. Thus, individuals of the constitution S_1, S_2, cannot be fertilized by S_1 or S_2 pollen. If, however, such individuals are crossed by S_3 S_4, both the S_3 and S_4 pollen can penetrate the style of the mother and effect fertilization. It will be seen that the offspring from such a cross, allowing all combinations possible, will constitute four intrasterile, interfertile groups of the composition S_1 S_3, S_1 S_4, S_2 S_3, S_2 S_4.

With certain of our plum varieties, of either the Japanese or the domestica species, self-unfruitfulness occurs when those varieties carry a gene for incompatibility. Likewise, varieties would be cross-unfruitful if both parents carried the same genes for incompatibility.

Chromosome Numbers in the Plums

In the genus *Prunus* the basic chromosome number is 8. All the varieties examined among the myrobalan plums (*P. cerasifera*), American plums (*P. americana*), and Japanese plums (*P. salicina*)

show the diploid number ($2n$) to be 16. Other species, notably the sloe (*P. spinosa* L.), have the tetraploid number or 32 chromosomes, and a still greater number (48) is found in the important groups of European plums (*P. domestica*) and the damsons (*P. insititia*).

Hybrids of *Prunus domestica* (48) × *P. cerasifera* (16), and *P. insititia* (48) × *P. spinosa* (32) have the intermediate chromosome numbers, 32 and 40, respectively.

According to Crane and Lawrence (*10*), the hybrids that they have obtained between *Prunus domestica* and *P. insititia*, both hexaploid, have always been completely interfertile; but from crosses between diploid and polyploid, and different polyploid forms, such as *P. domestica* × *P. cerasifera* and *P. insititia* × *P. spinosa*, fruits with viable seeds are rarely produced. Crosses between damsons and other varieties of *P. insititia* and *P. domestica* when attempted have always set fruit and developed good seeds freely. Wellington has also made many interspecific crosses. Crosses have been made successfully between *P. domestica* and *P. insititia*. With a large number of other interspecific crosses, however, involving *P. domestica* × *P. armeniaca* and its reciprocal; *P. domestica* × *P. tomentosa*, and *P. domestica* × *P. americana*, few fruits were obtained or the seeds failed to grow. Insofar as is known, triploid varieties of *Prunus* are found only as ornamentals, their degree of sterility being too high to enable them to be grown for their fruits.

TABLE 7.—*Plum introductions of the Minnesota Agricultural Experiment Station*

Variety	Parentage	When crossed or seed collected	When introduced	Descriptive notes (special value and superior characters)	Estimated acreage now planted
Anoka (Minn No 118)	Burbank × De Soto	1913	1922	Hardy, productive	Small
Elliot (Minn No 8)	Probably apple plum × *Prunus americana*	1907	1920	Very hardy, productive good quality, late season	175 acres
Ember (Minn No 83)	Shiro × S Dak No 33	1913	1936	High quality late season long-keeping quality, exceptional adherence to tree	Small
Golden Rod (Minn No 120)	Shiro × Howard Yellow	1913	1923	Vigorous tree, larger firm yellow fruit (Variety a shy bearer)	50 acres
Hennepin (Minn No 132)	Satsuma × *P americana*	1911	1923	Hardy, productive red flesh	Small
La Crescent (Minn No 109)	Shiro × Howard Yellow	1913	1923	Very high quality large, vigorous tree	100 acres
Mendota (Minn No 5)	Burbank × Wolf	1908	1924	Very large fruit, good quality	Small
Monitor (Minn No 70)	Probably Burbank × *P americana*	1912	1920	Large, high-quality fruit, hardy, regularly productive	300 acres
Mound (Minn No 50)	Burbank × Wolf	1908	1922	Large size of fruit productive	[1].
Newport (Minn No 116)	Omaha × Pissardii	1913	1923	An ornamental with purple foliage	25 acres
Nicollet	(*P avium* × *pensylvanica*) [2]	1912	1925	Dwarf, bushlike, fruit similar	50 acres

[1] All in scattered landscape plantings
[2] Open pollen parent is *Prunus besseyi* or a hybrid of this species

TABLE 7.—*Plum introductions of the Minnesota Agricultural Experiment Station*—Con.

Variety	Parentage	When crossed or seed collected	When introduced	Descriptive notes (special value and superior characters)	Estimated acreage now planted
Radisson (Minn. No. 157).	*P. salicina* × *americana*.	1908	1925	Early-maturing high-quality fruit; adapted to northern locations.	Small.
Red Wing (Minn. No. 12).	Burbank × Wolf..	1908	1920	Large high-quality fruit; exceptional freestone.	250 acres.
St. Anthony (Minn. No. 145).	*P. besseyi* (or hybrid) × Satsuma.	1912	1923	Very hardy and productive; red flesh.	50 acres.
Superior (Minn. No. 194).	Burbank × Kaga..	1920	1932	Very productive and early bearing; fruit very large, firm, excellent quality.	100 acres.
Tonka (Minn. No. 21)	Burbank × Wolf...	1908	1920	Very productive; firm flesh; high quality.	300 acres.
Underwood (Minn No. 91).	Shiro × Wyant.	1911	1920	Very vigorous; hardy; productive; early ripening; excellent quality.	500 acres.
Waconia (Minn. No. 10).	Burbank × Wolf..	1908	1923	Hardy; productive; quality only fair.	Small.
Winona (Minn. No. 80).	*P. salicina* × *americana*.	1909	1922	Hardy; productive; high quality; late season.	Do.
Zumbra..............	(*P. avium* × *pensylvanica*).[2]	1912	1920	Dwarf, bushlike; very productive; excellent culinary quality.	100 acres.

[2] Open pollen parent is *Prunus besseyi* or a hybrid of this species.

- Pond
- President
- Primate
- Prinlow
- Purple Gage
- Quackenboss
- Rayburn
- Reuter Early Italian
- St. George
- St. Jean
- St. Martin
- Sannois
- Sergeant
- Sharpe Imperial
- Shipper
- Silver Prune
- Smith Orleans
- Smith Late
- Splendor

[9] This list of variety names is approximately as submitted by the California station. The names are those under which the material is recorded, and not all of them are necessarily intended as authentic variety names. The list apparently contains a considerable number of names representing local strains and other names that do not conform to the generally accepted code of nomenclature. It is impracticable to attempt to bring the nomenclature in all cases into harmony with the code, therefore only a few changes representing obvious differences have been made

Prunus domestica—Con.
- Standard
- Stanley
- Stark Green Gage
- Steward Prune
- Stint
- Stuart
- Sugar
- Super Prune
- Swan
- Sweetest
- Tardeva de Moleta
- Tatge
- Tennant
- Tragedy
- True Blue
- Tulare
- Turkish Prune (synonym of Italian Prune)
- $2000 Prune
- Uncle Ben
- Ungarish
- Victoria
- Voronesh
- Wales
- Washington
- Wilhelmina
- Williamson Tragedy
- Yakima
- Yellow Egg
- Yellow Gage
- Yellow Imperial
- York State Prune
- Zucheriva del Vesuvia

Prunus salicina:
- Abundance
- Alpha
- Amador
- Apex
- Beauty
- Becky Smith
- Best's Hybrid
- Blood Plum
- Blue Gown
- Botan
- Burbank
- Burton
- Chabot
- Clarice
- Collie
- Del Norte
- Earliest of All
- Engre
- Extra Early Satsuma
- Florida
- Georgeson
- Hale
- IXL
- Kelsey
- McRea
- Miss Edith

Prunus salicina—Con.
- Occident
- October
- Ogon
- Pasha
- Purple Flesh
- Raisin
- Red June
- Sachem
- Santa Rosa
- San Francisco
- Satsuma
- Schattenburg
- Sherkey
- Strang
- Tribble Early Beauty
- Ulatis
- Valleda
- Willard
- Wilson
- Wright Early (P. I. 43180)
- Wright Purple (P I. 43181)

Prunus americana:
- Admiral Schley
- Advance
- Desoto
- Golden Queen
- Hawkeye
- Klondike
- Muncy
- New Ulm
- Quaker
- Skuyu
- Stoddard
- Weaver
- Wolf
- Wood
- Wyant

Prunus americana var. *mollis* Torr. and Gray:
- Gloria
- Terry

Prunus nigra:
- Aitken
- Cheney
- Eureka

Plumcots (so-called):
- Francis I
- Poe Royal Cot Plum
- Rutland
- Sharpe
- Smith
- Sparks
- Stanford
- Triumph
- Velvet

Prunus insititia:
- Big Mackey
- California Wild

Prunus insititia—Con.
- Crittenden
- Damson Free
- Damson Majestic
- French damson
- Frogmore
- King damson
- Merryweathers
- St. Julien
- Shropshire
- White damson

Prunus munsoniana:
- Clifford
- Downing
- Early June
- Freestone Goose
- Jewell
- Late Goose
- Monthalia
- Newman
- Oxheart
- Poole Pride
- Pottawattomie
- Wildgoose Improved
- Wooten

Native plum:
- Zekanta

Prunus hortulana:
- Forest Garden
- Golden Beauty
- Minco
- Robinson
- Surprise
- Wayland

Prunus hortulana var. *mineri* Bailey:
- Miner

Prunus bokhariensis:
- P. I. 40224

Species unknown:
- May Queen
- Progressive
- Superior

Prunus cerasifera:
- De Caradenc
- Early Cherry
- Extra Early Cherry
- Myrobalan
- Paragon

Prunus angustifolia var. *varians* Wight and Hedr.:
- Eagle
- McCartney

Prunus orthosepala Koehne:
- *Prunus orthosepala*

Prunus subcordata Benth.:
- Sierra

Prunus simonii:
- Simon

CHERRIES

THE CHERRY is another very important stone fruit, although it is not grown so extensively in the United States as the peach and the plum. The varieties in which we are interested for their value as edible fruit belong to two groups, the sweet and the sour. Varieties of the former

Figure 15.—Eight-year-old trees of Napoleon sweet cherry (*Prunus avium*).

group are used principally for fresh-fruit dessert, while those of the latter make up the great bulk of the frozen and canned cherries of commerce for use in bakeries, restaurants, and homes for pies, preserves, and sauce. In fact, so important is their use for pies that this group of sour varieties is frequently referred to as pie cherries.

Unfortunately, our present-day cherry varieties are not so widely adapted over this country as we should like to have them. While the sweet cherry trees are as hardy in wood as the peach, they do not recover so well from winter injury. They blossom early in the spring, and the flowers are very susceptible to cold and frost injury. The sour cherry tree is as hardy as some apple varieties, but its blossoms are also quite tender to cold, and crops are frequently lost by spring frosts. In more southern latitudes in this country the trees do not thrive in the hot, dry summers, and in the more humid regions the fruits are very susceptible to brown rot. Chiefly because of special climatic requirements, the principal commercial production of sour cherries is limited to districts along the Great Lakes in the East, and of the sweet cherry varieties to the Pacific and Intermountain States of the West.

Classification of Cherries

All varieties of cultivated cherry belong to two species (*3, 18*). The sweet cherries, *Prunus avium* L., (fig. 15) are tall trees with few or no suckers from the roots and with leaves downy on the under side. The sour cherries, *Prunus cerasus* L., (figs. 16 and 17) are small trees with many suckers from the roots and with fruit sour to bitter in taste.

Figure 16.—Six-year-old trees of the Montmorency variety of sour cherry (*Prunus cerasus*).

Wild forms of the sweet cherry found growing in this country and in Europe are also called mazzard, bird, and wild sweet cherry. Some of these have escaped from cultivation.

The native habitat of the sweet cherry species is in southern and central Europe and Asia Minor. This species has been divided by botanists into different groups, but because of hybridization among the varieties it is rather difficult in many cases to classify them. Sweet cherries with soft, tender flesh form one group, known by pomologists under the French group name guigne or the English gean. These are also known as the heart cherries. These sweet, soft-fruited cherries may again be divided into dark-colored varieties with reddish juice, and light-colored varieties with colorless juice. Among the light-colored gean varieties are Coe, Ida, Elton, and Wood. Dark-colored ones are represented by Black Tartarian (fig. 18) and Early Purple The second group is distinguished by the firm, crisp flesh of the fruits and is referred to as the bigarreaus. Windsor, Republican, Bing, and Lambert are representative varieties of the black type, while light types are Yellow Spanish and Napoleon (fig. 15).

The native habitat of *Prunus cerasus* seems to be close to that of *P. avium* in the region about the Caspian Sea to western Anatolia. De Candolle concludes that *P. avium* extended westward more rapidly and was the first to become naturalized. Like the sweet cherry, the sour cherry is also divided into groups based on the color of the juice. Cherries with colorless juice are the amarelles, consisting of pale-red to red fruits more or less flattened at the ends (fig. 19). Common

Figure 17.—Mature trees of Montmorency cherry in bloom. This is the important sour cherry of commerce grown in the United States.

representatives of this group are Early Richmond and Montmorency (figs. 16 and 17). The second group called the morellos, contains varieties with very dark round to oval fruits and flesh with reddish juice. Typical varieties of this group are English Morello, Ostheim, and Olivet. A third type in the species is the marasca cherry, from which is made maraschino, a liqueur used in Europe and the United States in the manufacture of maraschino cherries. The marasca cherry is a native of the Province of Dalmatia, Yugoslavia, where the trees grow wild. The fruits of the marasca varieties are much smaller and darker and somewhat more acid than the common sour cherry. In the United States at the present time some varieties of sweet cherry such as Napoleon, and some sour varieties, are being used for making maraschino cherries.

The duke cherries (fig. 20) are intermediate in type and have sometimes been referred to *Prunus avium*, but more recently have been considered to be hybrids between *P. avium* and *P. cerasus*. In France they are called royals. May Duke, perhaps one of the oldest varieties grown in the United States, Reine Hortense, and Late Duke are important varieties of this group. In the duke cherries

many characteristics of fruit, skin, flesh, juice color, and flavor, as well as of tree growth, are intermediate between the sweets and sours.

Three other species of cherry that have been used by breeders are the Nanking or bush cherry, *Prunus tomentosa* Thunb , an inhabitant of central Asia; the sand cherry, *P pumila* L , of the shores and

Figure 18.—Sweet cherries are more or less heart-shaped and are sometimes referred to as heart cherries. Black Tartarian, shown above, is a variety of the gean type with dark flesh and reddish juice. The bigarreau type is similar in appearance but has firm flesh.

beaches of the eastern United States; and the western sand cherry or Bessey cherry, *P. besseyi* Bailey, of the western United States.

In addition to the wild sweet or mazzard cherry, two other species are important from the standpoint of stocks on which to bud or graft varieties for propagation. These are the small wild, inedible sour cherry of southern Europe, *Prunus mahaleb* L , known as the mahaleb cherry, and the small wild red or pin cherry of the Northern States and Canada, *P. pensylvanica* L. f.

Attempts have also been made to locate pleasant-flavored strains of the chokecherry, *Prunus virginiana* L. Some strains are quite inedible until fully ripe.

Objectives in Cherry Breeding

One of the main objectives in cherry breeding is the production of high-quality sweet varieties that will prove more hardy in tree and blossom characters than many of those now available for planting. The production of such a delicious fruit as the sweet cherry is now

limited to a very few regions of this country. Even in those regions where it can be grown there is need for firm-fleshed varieties that do not crack and that will ripen over a long season. At the present time we have no firm-fleshed early-ripening varieties of the bigarreau type. The unsatisfactory viability and germination of seed of early-ripening varieties impede progress in this direction at the present time.

In obtaining varieties that will be suited to regions where moderately low winter temperatures prevail, the matter of understocks may be of first importance. The chief limiting factor in growing hardy cherries

Figure 19.—Sour cherries of the amarelle group, including pale red to red types with colorless juice: *A*, Early Richmond; *B*, Saint Medard.

in the northern Great Plains area, as well as in certain other parts of the United States, is the relative tenderness of some mahaleb and mazzard stocks used in propagation. Selection of better understocks that will prove more cold-resistant and more widely adapted than those in present use is worthy of further investigation. Selections of native cherries that appear to be better adapted to various soil and climatic conditions, such as hardier strains of our native mazzard and mahaleb stocks, may prove fruitful of results (*21*). Cherries are not grown at the present time in the vast area comprising the southern part of the United States, principally because of the susceptibility of our available varieties to certain diseases. There is need for the development of disease-resistant varieties for this region.

More genetic and cytological studies are needed, particularly of hybrids between the sweet and sour varieties, as a basis for more intelligent choice of desirable parents. Some of the duke varieties

are very excellent cherries but they are not highly productive. Methods of inducing polyploidy in order to obtain greater fertility in cherries has received little attention.

Methods of Cherry Breeding

The methods used in breeding new varieties of cherry are not different from those already discussed for the peach and the plum. Since all of the important varieties of *Prunus avium* have been shown to be self-unfruitful (*28, 30*) emasculation is unnecessary, but with the sour and duke varieties the blossoms must be emasculated.

Figure 20.—Eight-year-old trees of the May Duke variety of the duke group of cherries

One of the important problems confronting the cherry breeder at present is to find methods for growing the seeds of early-ripening varieties.

Improvement in Varieties

Breeding of new varieties of cherries does not seem to have attracted the interest of private breeders to the extent noted with peaches and plums. Interest has always been maintained in a search for new varieties, but progress in obtaining them has been slow. The failure to develop new varieties may be due partly to the fact that the cherry is not at home over such a large area of this country as the peach and the plum. The tenderness of the sweet cherry (*Prunus avium*) varieties, with the resulting loss of trees during cold winters, has largely limited their culture to the more protected areas along the Great Lakes and to the Pacific and Intermountain States of the West. The failure to obtain new varieties, particularly the sweet sorts, may also be due to the failure of the seed to grow.

The success obtained by two private breeders is worthy of mention. The pioneer breeding work of the brothers Henderson and Seth Lewelling in Oregon dates back to 1848 (*18*). In that year Henderson Lewelling carried an assortment of varieties of peach, apple, pear, plum, and cherry by wagon from Iowa to Oregon. These were planted in Milwaukie, Oreg., as a source of material for nursery and variety-improvement work. One of the most important varieties of cherry in this collection was the Napoleon. Apparently the tag had been lost, and the variety was renamed the Royal Ann, the name by which it is known in the Pacific Coast States today. From this stock of Royal Ann and other cherries, three important new varieties of the black bigarreau type were developed, Republican, Lambert, and Bing. Republican, possibly a cross of Napoleon and Black Tartarian, originated as a seedling in Seth Lewelling's orchard in 1860. Lambert originated as a seedling under a tree of Napoleon planted by Lewelling in 1848. From a seed of Napoleon planted in 1875 in Milwaukie, Seth Lewelling grew the promising seedling that later he called Bing. These excellent varieties developed by the Lewelling brothers laid the foundation for the present cherry industry in the Pacific Northwest as well as in California. The Bing, Lambert, Republican, and Napoleon are at the present time the leading commercial varieties of sweet cherry in this region.

At about the time that the Lewellings were working on the development of cherry varieties in Oregon, P. J. Kirkland, of Cleveland, Ohio, was engaged in similar work for the eastern United States. Varieties introduced by Kirkland that have been grown and are still being grown to some extent are the soft-fleshed sweet varieties Black Hawk, Kirkland, and Rockport.

In view of the results obtained by these men it is rather surprising that no enterprising breeder has become interested in more recent times in searching for better varieties and types of sweet cherries adapted to this country.

Cherry Breeding in the United States

The New York (State) Agricultural Experiment Station at Geneva has done the most work on cherry breeding in recent years. The first crosses were made in 1911. To date, about 1,200 seedlings have been planted for fruiting, and in addition there are a few hundred in the nursery for future planting. Sixty-two different sweet, sour, and duke varieties and a few seedlings have been used in the breeding studies. The varieties used most extensively were Abesse d'Oignies 33 times, Abundance 47, Bing 57, Burbank 9, Coe 16, Early Rivers 35, Early Purple 9, English Morello 46, Elton 41, Emperor Francis 45, Early Richmond 21, Giant 82, Gil Peck 15, Hedelfingen (*Géante d'Hedelfingen*) 27, Ida 12, Kirtland 50, Knight 10, Ludwig 27, Lambert 81, Lyons 58, May Duke 72, Montmorency 73, Napoleon 103, Ostheim 26, Olivet 14, Oswego 11, Reine Hortense 25, Royal Duke 9, Republican 32, Schrecken 30, Seneca 74, Schmidt 74, Windsor 59, Wood 24, and Yellow Spanish 54.

Unfortunately, many cherry seeds failed to germinate, and consequently from thousands of seeds comparatively few trees were obtained.

The seeds of early varieties were nearly 100 percent nonviable. The Seneca, a very early black sweet cherry, was produced at the Geneva station by crossing an early unknown sweet with the Early Purple. This variety originated in 1911 and was sent out for trial in 1924. The only other seedling that has been named was derived from a cross made in 1925 between Napoleon and Giant. This seedling was named Gil Peck upon request of the Indian tribes of New York, who were very fond of the late Gilbert W. Peck, a Cornell extension worker in pomology. The Gil Peck was introduced in 1926.

The objectives of the work in New York have been the production of firm-flesh sweet cherries that do not crack or rot and that ripen from early to late season. To secure lateness, large-fruited varieties were crossed with Abundance and with a small, very late, firm-flesh cherry called Oswego. Late-blooming mazzards have also been used in order to secure later blooming varieties that may escape late spring freezes.

In addition to fruit of good quality for commercial purposes, productive hardy trees have been given consideration in this work. Little work has been done with the sour (*Prunus cerasus*) group of cherry, because the present commercial varieties, Montmorency and Early Richmond, have been found fairly satisfactory for New York. The production of desirable duke cherries has also been given consideration, inasmuch as a productive high-quality duke would doubtless meet with favor among cherry producers and consumers.

In South Dakota, N. E. Hansen has been actively engaged since 1900 in breeding cherries suited to the west north central States. He has made many crosses, using the western sand cherry, *Prunus besseyi*, and other species of *Prunus*. The sweet cherries, *P. avium*, which are raised in the Eastern States and so extensively on the Pacific coast, are not hardy in the northern prairie States. The sour cherries, *P. cerasus*, are much hardier than the sweets, but they are not generally planted in this region. The Early Richmond and some other sour varieties are grown to a limited extent in the southern part of the State. Attempts to hybridize sweet and sour varieties with the native cherries have not been successful.

The following have been developed and introduced:

Select South Dakota sand cherries (*Prunus besseyi*): Sioux, Tomahawk, and S. Dak. No. 5.

Sand cherry × Japanese plum: Sapa, Wachampa, Etopa, Eyami, Enopa, Ezaptan (sand cherry × Burbank Sultan plum), Opata, Owanka, Okiya, Cikana (sand cherry × Gold plum), Skuya, Wohanka, Wakapa (probably sand cherry × unknown Japanese plum).

Sand cherry × native plum: Cheresoto, Sansoto (sand cherry × De Soto plum).

Sand cherry × plum: Champa (sand cherry hybrid, a seedling of Sioux open-pollinated), Oka (seedling of Champa open-pollinated, probably with Japanese plum).

Sand cherry × Purple-leaf Persian plum: Stanapa (purple-leaved, semi-dwarf), Cistena (purple-leaved, dwarf).

Sand cherry × European apricot: Yuksa (sand cherry × New Large apricot).

At the Iowa Agricultural Experiment Station cherry-breeding work is being carried on by utilizing greenhouse-grown trees in the same way as in the work at this station with plums and peaches. The varieties consist of six species of *Prunus*, namely, *avium*, *cerasus*,

besseyi, japonica Thunb., *tomentosa,* and *capuli* Cav. Trees of the following crosses are being grown in the nursery: Sapa plum (*P. salicina* Lindl. × *P. besseyi*) × Gold cherry (*P. avium*); *P. serotina* Ehrh. × *P. capuli,* and Zumbra × *P. tomentosa.* The object of this work is to obtain varieties of cherry hardy for Iowa and suitable for the Great Plains region.

At the North Dakota Agricultural Experiment Station, work on cherry breeding is carried on with objectives similar to those in South Dakota and Iowa. The Cooper sand cherry hybrid was introduced in 1935. Because of good quality of fruit and hardiness of tree, it is considered a substitute for the sweet cherry in that State.

In past years about 400 seedlings of open-pollinated Compass cherry have been grown. Only one seedling had horticultural value. About 500 chokecherry selections have been grown, and from this work variety improvement seems possible from the use of these cherries as parents. Fifty F_1 seedlings were obtained from crosses made in 1926 of chokecherry × *P. maackii* Rupr. These seedlings are also of genetic interest and are under study. Seedlings of hardy Russian sorts and of open-pollinated Anoka are also being grown.

At the United States Northern Great Plains Field Station at Mandan, N. Dak., sour and sweet varieties of cherries have been crossed with pin cherries (*Prunus pensylvanica*), western sand cherries (*P. besseyi*), Nanking cherries (*P. tomentosa*), and chokecherries. Seeds have been produced, but in most cases they failed to grow. One tree, a cross between Wragg and pin cherry, seems to be fairly drought-resistant and hardy. It blooms profusely but does not set fruit, probably because of self-unfruitfulness.

Several hundred pin cherry seedlings have borne fruit, but none has been good enough to select.

Several thousand western sand cherry seedlings have been grown. This hardy native fruit shows a decided and varied response to cultivation; there are marked variations in habit of growth and in size and quality of the fruit. A number of promising selections have been made and propagated for further testing. This fruit has also been used in crossing with plums and Nanking cherries. Some of the latter crosses are bearing, and both fruit and bush characteristics are intermediate between the western sand cherry and the Nanking cherry. Second-generation seedlings have been grown.

Large numbers of chokecherry seedlings have been grown, and while they show considerable variation, no real "chokeless" seedling, i. e., entirely nonastringent, has been found. A few of the best have been propagated on *Prunus maackii* stock for further testing.

Thousands of seedlings of the Nanking cherry have been fruited in the testing blocks. This fruit is not entirely hardy and tends to be a shy bearer. It has been used in crossing with standard varieties of cherries, the western sand cherry, and plums. The only viable seeds obtained were from the western sand cherry crosses.

In addition to the breeding work at the various institutions, extensive variety collections are located in a number of States where breeding material may be obtained. Some of these are the New York (State) Agricultural Experiment Station, the Ohio Agricultural Experi-

ment Station at Wooster, the Colorado State College at Fort Collins, the Utah Agricultural Experiment Station at Ogden, the California Agricultural Experiment Station at Davis, and the Oregon Agricultural Experiment Station at Corvallis.

Cherry Breeding in Canada

Cherry-breeding work at the Horticultural Experiment Station at Vineland, Ontario, Canada, was begun in 1915 and has been continued up to the present time. During the period 1915 to 1935, 2,587 seedlings were obtained and planted for study. These seedlings were from 27 variety crssoes and 27 open pollinations. Sixteen have been selected as having horticultural value. Two hundred and eighty-one seedlings were obtained from crosses made in 1931, using Bing as the seed parent and Black Tartarian, Napoleon, and Victor as pollen parents, to obtain large, nonsplitting, black varieties. From crosses made in 1935, 1,040 seedlings have been obtained from Hedelfingen as seed parent and Black Tartarian, Bing, Victor, and Windsor as pollen parents, with the same object in view.

From the early cherry-breeding work the Victor variety was introduced in 1935. This variety was a selection from seed of open-pollinated Windsor, which was collected in 1916 by F. S. Reeves. It is a large, attractive white cherry. Approximately 4,000 trees of this variety have been planted in southern Ontario.

Self-Fertility in Cherry Varieties

Gardner (*14*), in 1911, working in Oregon, failed to get a set of fruit from selfing 11 varieties of sweet cherry. In 1912 he attempted to intercross Bing, Lambert, and Napoleon. These varieties proved to be not only self-incompatible, but incompatible with each other, that is, they would not set fruit when selfed or when cross-pollinated among themselves. In orchards where Napoleon was interplanted with Republican, and away from the influence of other varieties, the Napoleon set a full crop. The same was true where Lambert and Bing were interplanted with Black Tartarian.

The results of early cherry pollination work from 1911 to 1913 in Oregon, as well as later work in that State and in California, show that all varieties of sweet cherry tested were self-incompatible. Republican, Black Tartarian, Coe, Early Purple, Elton, Knight, Major, Francis, May Duke, Rockport, Waterhouse, Willamette, Windsor, and Wood were all self-incompatible. Republican and Black Tartarian were found to be good pollinizers for all the varieties. They, of course, do not set fruit when selfed.

Crane and Lawrence, working in England, have tested 33 varieties and found all of them to be self-incompatible. Important self- and cross-incompatible varieties were Black Eagle, Early Rivers, Knight (Knight's Early Black), and Bedford Prolific, while among cross-compatible varieties were Black Tartarian, Schmidt, Wood, and Windsor.

For all practical purposes, therefore, we must consider all true sweet-cherry varieties of *Prunus avium* to be self-unfruitful, that is,

no fruit will set from blossoms pollinated with their own pollen, since fertilization will not take place. The genetic explanation of self-incompatibility of style and pollen and its relation to failure of fruit to set has already been discussed in the section on plums.

Types of Sterility

Nearly all of the varieties of sweet cherries fail to set fruit when the flowers are pollinated with their own pollen. They are therefore said to be self-sterile. However, the pollen grains and egg cells of these varieties are functional, for the pollen will grow when placed on the stigma of another variety, and in like manner the egg cell will develop if fertilized with pollen of another variety. With most of the stone fruits fertilization is required before the fruit will develop, and a variety that does not set fruit because of the failure of its own pollen to effect fertilization of the flowers is said to be self-unfruitful.

Strictly speaking, sterility may be due to three causes (*23*): (1) Flowers may be sterile because of their morphological development. Failure of the anthers or pistils, or both, to develop, and failure to develop viable pollen or functional egg cells, may result in nonfruitfulness. It is recognized that such situations may be due to genetic causes. (2) Sterility may also be physiological. The pollen grains and egg cells may be normal; fertilization is effected, but the embryo does not grow because of certain nutritional disturbances. (3) Sterility may be due to incompatibility. In this case the pollen grains are normal and will develop in the style of other varieties and bring about fertilization of the ovules, but they will not function in the style of the flower of the same variety. It is this latter type of sterility that is most frequently encountered in the stone fruits. Nearly all of the sweet cherry varieties are self-unfruitful because of incompatibility. Varieties such as Napoleon, Windsor, and Black Tartarian will not set fruit when the flowers of any one of them are pollinated with its own pollen. If, however, Black Tartarian pollen is applied to Napoleon or Windsor, a large percentage of the flowers will set fruit. Likewise, if Windsor pollen is applied to Napoleon or Black Tartarian, fruit-setting will occur.

The genetic basis of incompatibility has already been discussed in the section under plums.

Genetic and Cytological Studies With Cherries [10]

In contrast to the sweet cherries, varieties of sour cherries are self-fertile, and the pollen of sour varieties will also effectively cause fruit-setting on sweets.

In duke cherries varying degrees of self-compatibility occur. Crane and Lawrence (*10*), working in England at the John Innes Horticultural Institution, have obtained the following percentage of set from selfing important duke varieties: 9 percent for Late Duke, 3 percent for Empress Eugenie, 1 percent for May Duke. Reine Hortense set no fruit. The results obtained from cross-pollinations between sweet,

[10] This section is written primarily for students or others professionally interested in genetics or breeding.

sour, and duke cherries have varied considerably. According to Crane and. Lawrence, sweet varieties pollinated by sour varieties generally produce and mature fruits freely, but from reciprocal pollinations fruits are less freely formed. In a similar way fruit production is less when the dukes are pollinated by sweet varieties than when reciprocal pollinations are made.

We have little knowledge about the origin of our present cherry varieties. Three varieties produced by Thomas Andrew Knight, resulting from a cross of a sweet (bigarreau) × May Duke, were Waterloo, Knight (Knight's Early Black), and Black Eagle, and the latter two would pass for sweet cherries. In pollination studies to determine the incompatibility of varieties, it has been observed, both in this country and in England, that individuals of the same variety appear to differ in their pollination requirements, and it is possible that distinct strains of such varieties or types as Black Tartarian or Napoleon have been propagated. Because of the fact that all varieties of *Prunus avium* are self-unfruitful it has been impossible to raise selfed progeny to study the inheritance of characters and determine genetic relationships. In studies made at the John Innes Horticultural Institution in England, Crane observed that in selfed families raised from varieties of *P. cerasus*, seedlings with *P. avium* characters frequently appeared, and in families raised from crosses between varieties of *P. avium*, occasional seedlings occurred which showed marked *P. cerasus* characters. Furthermore, seedlings in families raised from *P. avium* × *cerasus* resembled the dukes in many characters but not in all.

Cytological investigations of the cherries show the somatic chromosome number ($2n$) in *P. avium* to be 16, and it is apparently diploid. In *P. cerasus* and the dukes the number is 32. Darlington (*11*), who has studied the chromosome behavior in a number of cultivated varieties of cherry, considers that *P. cerasus* is a true tetraploid, not derived simply from *P. avium*, but one possessing additional elements probably derived from *P. fruticosa* Pall., another tetraploid. All of the sweet cherries examined by Darlington had extra chromosomes beyond the diploid number. Irregularities occur in chromosome pairing, but it does not appear that there is any correlation between the actual chromosome number and the incompatibilities observed in sweet cherry varieties. Selfed seedlings of sour and duke varieties showed a chromosome number of 32. In crosses between the sour and dukes an examination of the progeny shows that the chromosome number is also 32. However, in crosses between dukes and sweets, and sours and sweets, the progeny showed the intermediate number 24 in some cases, as we might expect, and in others 32. The cultivated duke varieties appear to be tetraploids that have arisen from hybridization between the diploid sweet cherries and the tetraploid sours. In experimental studies, however, crosses between some tetraploid sours and diploid sweets have yielded seedlings with 24 chromosomes that presumably were triploids and proved to be highly sterile.

B. R. Nebel, at the New York Agricultural Experiment Station, has been studying the cytology of interspecific hybrids. From crosses

between sour and sweet cherries, 22 triploid first-generation trees have been obtained, and these are fruiting on the station grounds. In attempting to backcross from these hybrids only 1 fruit was obtained in 700 pollinations. Open-pollinated seed was then used, and this gave nearly 50 second-generation seedlings. Upon cytological examination of this second-generation material there appeared to be a gradation downward in chromosome numbers through loss of some of the supernumerary chromosomes of the sour species. It is possible that the second-generation seedlings will be more fertile than the first-generation, and that backcrosses with firm-fleshed sweet cherries will give diploid dukes that are interfertile with sweet cherries. As already mentioned, if autopolyploidy could be induced, the first-generation triploids could be made fertile directly and much time could be saved.

Crane and Lawrence report from their studies of the inheritance of flesh color in sweet cherries that white is recessive to black. In crosses between white varieties only white was obtained. Bigarreau du Schrechen is considered homozygous for black, since in all crosses where this variety was used as a parent all of the progeny produce black fruits. Other black varieties, such as Early Rivers, Bedford Prolific, Black Tartarian types A and B, Late Black, and Schmidt, are heterozygous for flesh color. It appears, however, that when the different shades of fruit color are considered, ranging from dark to white, through various pinks and reds, a number of genes may be involved in color inheritance.

Selfed sour cherry (morello) varieties with roundish oblate fruit gave seedlings that yielded occasional long fruits. Kentish Red, a variety with roundish oblate fruits, gave a progeny that yielded fruits of variable size and shape.

[11] This list contains, besides well-known varieties, local selections and other sorts the names of which cannot well be made at this time to conform to the code of nomenclature.

APRICOTS

The apricot is prized by all who like the stone fruits, and when eaten fresh it is considered by many to be the most delectable of this group. Unfortunately, however, very few apricots are grown for fresh fruit in the States east of the Rocky Mountains, and most people know the flavor of this fruit only from the canned or dried product. Its production is restricted to a relatively small area in this country where climatic conditions are favorable. Most varieties can withstand winter cold as well as peaches, but the blossom buds develop rapidly under favorable growing temperatures in late winter after the rest period is over, and the crops are frequently lost from late freezes and spring frosts.

The commercial production of the apricot (fig. 21) is confined largely to the Pacific Coast and Intermountain States (*5*, *20*). California leads with a potential average production considerably in excess of 200,000 tons. Of the average crop of 266,000 tons harvested during the years 1931–33, approximately 76 percent was dried, slightly over 14 percent canned, and about 10 percent was shipped or consumed locally as fresh fruit. Because of the great perishability of this fruit and the need for quick handling, fresh apricots are on the market in the Eastern States for only a short time and their distribution is limited to large centers of population.

Botany and History of the Apricot

All of the important commercial varieties of apricot grown in this country today belong to the species *Prunus armeniaca* L. The name of the species, like that of the peach, is a geographical misnomer. The apricot was formerly considered a native of the Caucasus and Armenia, but later studies suggest that China is its native home. It is said that Alexander the Great brought the apricot from Armenia to Greece, whence it was taken to Italy. The Romans cultivated this fruit, and it is described in the writings of Pliny and Dioscorides. It was later carried to France, and there is mention of its being in England in Turner's Herbal, published in 1562. The fruit is now cultivated in all of central and southeastern Asia, and in parts of southern Europe and northern Africa. There seems to be no mention of it in the United States until 1720, when it was said to be growing abundantly in Virginia. It was doubtless among the fruits brought into southern California early in the eighteenth century by the Mission Fathers. Its culture spread to the valleys farther north, where climatic conditions were more congenial. Wickson (*33*) reports that Vancouver found a fine orchard of fruits, including apricot, at Santa Clara in 1792. In 1935, 17 varieties were described as growing in England. Downing (*12, pp. 236–242*) names 26 varieties, and the American Pomological Society (*1*) lists 11 varieties as growing in the United States in 1879.

In tree, fruit, and flower characters the apricot seems to be somewhat intermediate between the plum and the peach. The trees are large and spreading, and in this respect are more like the peach and some of the Japanese plums. The leaves are broad, heart-shaped, dark green in color, and held erect on the twigs. The flowers are

white, resembling those of the plum in color, but are borne not in clusters but singly or doubly at a node on very short stems. Like the peach, the apricot is self-fruitful and will set fruit when its blossoms are selfed. The pit is smooth, somewhat like that of the plum, but broader, somewhat flatter, and more winged. The fruit is nearly smooth, round to oblong, in some varieties somewhat flattened, and in general rather more like the peach in shape. The flesh is typically

Figure 21.—Peach and apricot growing constitutes an important industry in California. The apricot trees, in the immediate foreground, and the peach trees in the rear are a part of a large orchard with rows 3 miles long.

an attractive yellow to yellowish orange. The kernels of some varieties are sweet.

The peach, plum, and apricot may be readily intergrafted. The apricot does well on peach stock, but the peach on apricot stock is not entirely satisfactory.

In addition to the common apricot (*Prunus armeniaca*), which comprises all of the commercial varieties grown in this country, several other species are of interest to the breeder. The black apricot (*P. dasycarpa* Ehrh.) has fruits of small size, dark purple or black in color, and for the most part of inferior quality. The trees more closely resemble the plum and possess considerable hardiness in wood and bud.

The Japanese apricot (*P. mume* Sieb. and Zucc.) is noted principally for the ornamental character of the trees. The flowers and fruits also are very attractive.

Types native in other countries have been described as species but are classed by some authorities as subspecies. The Russian apricot (*P. sibirica* L.), is possibly a strain of the common apricot (*P. armeni-

aca). Trees of the Russian apricot differ from the common apricot in bearing smaller fruit of poorer quality. They are considered very much hardier in their native home, but certain strains brought into this country have not shown superior hardiness under test. The trees have a characteristic upright growth habit, are thickly branched, and possess more thornlike spurs. The small fruits set in clusters.

Another probable subspecies, the Manchurian apricot (*P. mandschurica* Koehne), is a common wild tree in central Chosen. Its fruit is similar to that of the common apricot, but the leaves differ, and its bark is thick and corky. This subspecies may be a selected strain of the common apricot.

The apricot is widely distributed throughout Asia, and a large number of seedlings have been observed growing wild in various localities. In China some travelers report the apricot only as a cultivated tree, but others have found it growing wild in the northern Provinces.

Breeding Material

The apricot is less rich than some of the other stone fruits in species and horticultural varieties suitable for breeding material. The raw material consists of many old varieties introduced from England and France. Among those recognized as of English origin are Blenheim, Early Moorpark, Moorpark, and Hemskirke. These are all varieties, of high quality, with the Blenheim maintaining first importance as a commercial variety. Varieties of French origin are Peach, Oullins Early, Montgamet, Luizet, and Royal. Royal is the most important commercial variety of this group. Like the English varieties, all the French varieties have certain commercial limitations. There is an excellent opportunity for the apricot breeder to combine their desirable characters by cross breeding. Work of this kind is already under way at State and Federal agricultural experiment stations, as will be pointed out later.

A large number of varieties have been introduced from the Union of Soviet Socialist Republics, many of these by J. L. Budd, of Iowa. As a class they are more hardy in bud, later in blossoming, with fruit of smaller size and poorer quality, but they are very productive. Some of the more important varieties of this group are Alexander, Budd, Gibb, Shense (Acme), Superb, and Toyahvale. Little work has been done in combining the qualities of these hardy sorts, which some botanists consider a separate species (*Prunus sibirica*), with the commonly grown varieties from western Europe.

In the last half century a number of promising seedlings and strains of American origin have been selected, but only the Tilton ranks with the older European sorts as an important commercial variety. As might be expected, most of the American varieties originated in Pacific Coast States. Among the more important are Newcastle, Alameda Hemskirke, Routier Peach, Derby Royal, and Sparks Mammoth, from California. Other varieties of more recent origin are Wenatchee Moorpark, which has been reported to be similar to if not identical with Moorpark, Riland, Gilbert, and Sofia, originating in the State of Washington. Among other older American varieties are Early Golden and Superb.

The apricot has been crossed with varieties of plum, particularly the Japanese plum. Luther Burbank produced a number of seedlings by crossing the apricot with this plum. Some of the more promising of these have been introduced under the group name plumcot. Among the more important are Apex, Corona, Rutland, Silver, and Triumph.

The crosses of apricot with plum have apparently been more successful than those with peach. No horticulturally satisfactory peach-apricot varieties have been reported.

Objectives in Apricot Breeding

If apricot culture is to be extended beyond the present restricted areas where climatic conditions are favorable, varieties must be developed that are later in flowering in spring. From material that has been brought into this country, differences in bud hardiness and in blooming have been observed. There is need for the introduction of varieties from countries where apricots are growing and surviving temperatures as low as those obtaining during the winter months in this country. Many of these will doubtless prove worthless from the standpoint of edible fruit quality, but will serve as breeding material for the development of better varieties. In California considerable loss results from the dropping of blossom buds of certain varieties. Varieties that have a short rest period, are needed for those sections of the country where the winter temperatures are not low. Better canning, drying, and shipping varieties are also in demand. Evidence at hand would indicate that the commercial quality of varieties can be improved by breeding.

There is little information about the development of varieties by private breeders. A number of chance seedlings have been discovered by individuals, but it does not appear that any conscious attempt to select or breed new varieties has been carried on to the extent that it has with the other stone fruits. It is likely that many who were interested in better varieties were discouraged in their attempts because the parent material available for crossing was in itself not sufficiently hardy.

In the selection of material for breeding, difficulty may be encountered in establishing the trueness to name of varieties, since the same variety may be grown in two or more localities under different names. Some of the varieties representing desirable types are Moorpark, Royal, Blenheim, Tilton, Montgamet, and some selections of Russian and Japanese origin. For breeding studies in the eastern United States, where hardiness is an important factor, varieties should be used that have been tested and have demonstrated superior hardiness, such as strains of Russian varieties introduced by Budd, and more recent importations made by Hansen, of South Dakota, and the Division of Plant Exploration and Introduction, Bureau of Plant Industry, United States Department of Agriculture.

Apricot Breeding at State and Federal Stations

Apricot breeding was started at the New York (State) Agricultural Experiment Station in 1922. Eighteen varieties, one seedling, and two P. I. numbered seedlings have been used. Eighty-four seedlings derived from definite crosses, 1,424 from open cross-pollination, and 9

from self-pollination have been set in the orchard for fruiting. Varieties used most extensively have been Alexis 6 times, Doty (a local seedling) 15, Downing (late blooming) 5, Montgamet 6, Oullins Early 13, St. Ambrose 5, and Toyahvale 5. A seedling grown from a seed imported by the Department of Agriculture as P. I. 34265 has been considered worthy of a name. This variety was temporarily called "Frascati", as the seed was thought to have been imported from the vicinity of Frascati, Italy, but more recently it has been given the name Geneva.

At the North Dakota station apricot breeding work was started in 1924 in an attempt to develop varieties of sufficient hardiness to stand the winters of the northern Great Plains area. Over 2,000 seedlings are being grown and studied for their hardiness and quality of fruit.

At the South Dakota station, N. E. Hansen has been propagating trees from seeds collected by him in northern Manchuria in 1924. The fruits were taken from trees growing in localities reported to have minimum temperatures of $-47°$ F. Twenty-three selections, called the Manchu group, have been propagated for test. Additional collections made in 1934 in eastern Siberia for propagation at Brookings are expected to give seedlings with greater hardiness than the Manchu.

Breeding work at the California station at Davis, Calif., was started in 1930. The objective is the development of varieties of high quality suitable for shipping as fresh fruits, canning, and drying, but lacking some of the faults of the old varieties now grown commercially. Varieties used as pollen and seed parents have been Tilton, Royal, Hemskirke, Blenheim, St. Ambroise, Peach, Newcastle, Moorpark, Oullins Early, and in addition strains of Moorpark and Hemskirke. In the seasons of 1933 and 1934, one seedling each was obtained from the following interspecies crosses: Royal × *Prunus pseudocerasus*, *P. mume* × Royal, Pringle Late × Rutland plumcot, Diamond Jubilee nectarine × Royal, and Lovell peach × Royal. From the crosses made during 1930–35 there are at the present time over 2,000 seedlings growing in the orchard.

This material should provide a sufficiently large progeny for genetic studies of the varieties used as parents and serve as a source of superior seedlings that may be worthy of naming. A list of the crosses and the number of seedlings in each cross, as well as a list of varieties now being grown, is given in the appendix to this section.

At Palo Alto, Calif., apricot breeding by the United States Department of Agriculture in cooperation with Leland Stanford Junior University has been in progress since 1922. A search for varieties of high quality that would prove more satisfactory for the established apricot districts has been the main objective of this work. About 60 promising hybrids have been selected for further studying and testing. The more common varieties, such as Blenheim, Tilton, Moorpark, Royal, Newcastle, and Hemskirke, have been used as seed and pollen parents, and in addition the less common varieties Bergetti, Montgamet, McKinley, Luizet, Bremner, and Sparks. Hybrids of these varieties have been recrossed, and other combinations have been made by using promising parents introduced from southern Europe, Africa, and Asia in an effort to obtain certain desirable characteristics in the

progeny. In this material from abroad are included Giallo di Tortona, Tunis seedlings, Japanese seedling 26018, Sardinian, P. I. 28954, and P. I. 34272.

A list of the hybrids selected with the parentage and the years the crosses were made is given in the appendix.

Apricot Breeding in Other Countries

A program of apricot breeding has been under way for some time under the supervision of the Department of Agriculture at the Yanco Experiment Farm, Sydney, New South Wales. The work has for its object the production of superior canning varieties, particularly later varieties than Trevatt, to extend the season and thus close the gap of ripening between the latest canning apricots and the earliest canning peaches. Importations of seed have been made from Palestine, Iraq, Syria, and Morocco, and from this material seedlings are now being grown. The varieties used in the crosses and for open pollination are Alsace, Bouche Peche, Mansfield, Moorpark, Lossie Blenheim, Tilton, Campbellfield, Bathurst, Trevatt, Newcastle, and Rose de Vaucluse. From results obtained to date, Moorpark seems to be the best parent variety for giving a useful range of seedlings, while Trevatt cross-bred seedlings have better general quality. A Moorpark × Bouche Peche seedling is being propagated for orchard trial.

In Morocco, work is being carried on at the new State station at Ain Taoujdat, especially designed for research in horticultural genetics. New varieties of high quality are being sought for by hybridization. Ten distinct forms of native apricot (mechmech) have been studied comparatively since 1934 for their value as stocks. Superiority has been shown by E. F. 136, 137, and 139.

Genetic and Cytological Studies With Apricots

There is little published information dealing with the genetics of hybrid progenies of apricot varieties and species.

Cytological studies have been made at the agricultural experiment stations of New York and California, and all apricot varieties examined thus far have 16 as the diploid ($2n$) number of chromosomes, which is the number found in sweet cherry, peach, and some species of plum. At the New York (State) Agricultural Experiment Station, chromosome numbers in exceptionally vigorous seedlings and also in abnormal seedlings from embryo cultures have been counted, but in a total of about 50 cases no deviation from the regular diploid type was found. Unsuccessful attempts have been made to induce polyploidy by selecting giant pollen grains under the microscope, mounting them on hairs, and applying them to the stigmas of flowers. Radiation experiments with stem meristem have also failed. This work is being continued, and other methods to induce polyploidy in apricots are being tried.

Cytological investigations are under way at the California station to determine the true hybridity of the plumcots. This is important in breeding work, to determine whether the characters in segregation will behave as true hybrids or whether they will behave separately as plums or apricots.

IMPROVEMENT OF SUBTROPICAL FRUIT CROPS: CITRUS

HAMILTON P. TRAUB, Senior Horticulturist
T. RALPH ROBINSON, Senior Physiologist Division of Fruit and Vegetable Crops and Diseases, Bureau of Plant Industry

MORE than half of the 13 fruit crops known to have been cultivated longer than 4,000 years, according to the researches of De Candolle (*7*)[1], are tropical and subtropical fruits—mango, olive, fig, date, banana, jujube, and pomegranate. The citrus fruits as a group, the lychee, and the persimmon have been cultivated for thousands of years in the Orient; the avocado and papaya were important food crops in the American Tropics and subtropics long before the discovery of the New World. Other types, such as the pineapple, granadilla, cherimoya, jaboticaba, etc., are of more recent introduction, and some of these have not received the attention of the plant breeder to any appreciable extent.

Through the centuries preceding recorded history and up to recent times, progress in the improvement of most subtropical fruits was accomplished by the trial-error method, which is crude and usually expensive if measured by modern standards. With the general acceptance of the Mendelian principles of heredity—unit characters, dominance, and segregation—early in the twentieth century a starting point was provided for the development of a truly modern science of genetics.

In this article it is the purpose to consider how subtropical citrus fruit crops have been improved, are now being improved, or are likely to be improved by scientific breeding. Each of the more important crops will be considered more or less in detail. Before proceeding to these considerations, however, it is desirable to define the province of subtropical fruit culture and to take a glance at the economic importance of the subtropical fruit industry.

The region where subtropical fruits are produced, as the name indicates, is between the true Tropics, where frost never occurs, and the temperate region, where normally the temperature often falls below freezing and stays below for a considerable part of the winter season. In this intermediate region the temperature occasionally goes below freezing but not as a rule below 25° F., so that when necessary the trees can be economically protected by artificial means. Because of the influence of large bodies of water, the protection of mountain ranges, or planting where the topography gives good air drainage, this type of region may be extended as "islands" considerably beyond the usual subtropical region.

The types of fruit crops grown merge into those of the true Tropics—citrus, avocado, mango, etc.—and no hard and fast division can be

[1] Italic numbers in parentheses refer to Literature Cited, p. 806.

drawn on the basis of fruit types except that forms possessing resistance to low temperature are of major importance in the subtropics. Diverse types are cultivated, of which the familiar citrus fruits are among the most outstanding, followed by the pineapple, fig, olive, avocado, date, persimmon, mango, papaya, guava, pomegranate, lychee, granadilla, cherimoya, loquat, jujube, and other minor types.

In the United States some of the crops, notably citrus and avocado, have become staple dessert and salad fruits. Others, notably the date and the fig, are used primarily as confections. The olive is used in preserved form or for oil. Some of these fruits were recognized as important sources of indispensable vitamins even before the true function of these chemical regulators was fully understood. Limes, for instance, have long been included by the British as a regular part of the diet of seamen as a preventive of scurvy. During the recent Ethiopian campaign, the entire Italian export crop of lemons was reserved for the army of invasion, and it is reported that deficiency diseases were at a minimum. Besides the citrus group, pineapples, papayas, dates, avocados, mangoes, and other subtropical fruits are known to be unusually high in vitamins.

Some of these fruits, for example the mango and the papaya, are extensively cultivated but primarily for local consumption. Higgins and Holt (*30, p. 17*) remark: "Excepting the banana, there is no fruit grown in the Hawaiian Islands that means more to the people of this Territory than the papaya, if measured in terms of the comfort and enjoyment furnished the people." This applies to the papaya in other tropical countries as well; to the avocado in Central America and the West Indies; and to the mango in India, southeastern Asia, Malaya, Puerto Rico, and the West Indies in general.

OUTSTANDING *in the story of citrus fruit improvement was the work of A. D. Shamel, of the United States Department of Agriculture, and his coworkers, in studying bud mutations. In the past 18 years, probably 10 million buds of superior strains of the Washington Navel orange, the Valencia orange, the Marsh grapefruit, the Eureka lemon, the Lisbon lemon, and miscellaneous citrus varieties have been sold to California growers alone as a result of this work. Two special strains produced fairly recently—the Robertson Navel orange and the Dawn grapefruit—are now being widely distributed and seem to have great promise. In addition, the intensive study of bud mutations, backed by careful statistics, was important in teaching growers to keep a close watch for branches mutating toward poor types, so that they could be eliminated from the orchard.*

The subtropical fruit production regions in the continental United States are indicated in figure 1. The annual farm value (1934–35) of the chief subtropical fruit crops grown in the United States for

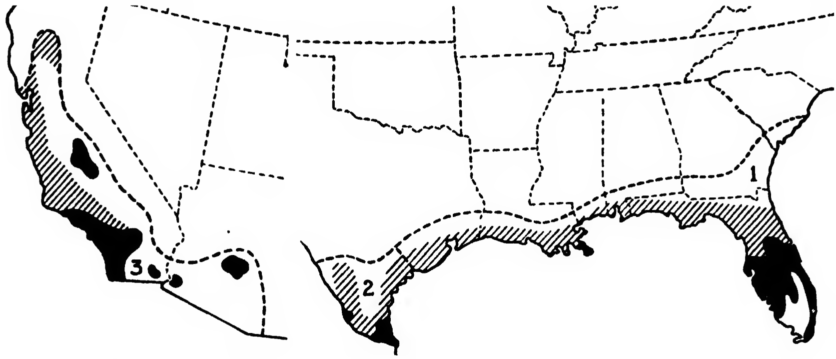

Figure 1.—Citrus-producing areas of the United States. Solid black denotes areas of commercial production of sweet and tangerine oranges, grapefruit, or acid citrus fruits (lemons or limes). Shading denotes areas producing satsuma oranges or minor quantities of other citrus fruits. The dotted boundary lines indicate the approximate northern limits of the three subtropical crop regions: (1) Southeastern humid, (2) central irrigated, and (3) southwestern irrigated.

which figures are available—citrus, fig, olive, avocado, and date—amounts to approximately $140,000,000, distributed as follows: Citrus fruits, $135,000,000; fig, $1,706,000; olive, $1,260,000; avocado, $959,000; date, $390,000.

The distribution of the total return for citrus fruits in the United States in 1934 is given in table 1.

EARLY HISTORY OF CITRUS FRUITS

THE citrus fruits as a class are native to southeastern Asia—eastern India, Indo-China, southern China, the Philippines—and here they were first brought under cultivation. A monograph on the oranges of Wenchow, Chekiang, Nan Yen-Chih's Chu Lu, composed in China during the period 1174 to 1189, is the earliest treatise on citrus culture extant (*26*). Even at this early date three horticultural groups of oranges were recognized and the total number of varieties listed was 27.

Although there are a dozen or more types of citrus fruits, only five or six are of major importance from a commercial standpoint. The most important of these grown for fruits are the sweet orange, *Citrus sinensis* (L.) Osbeck; the grapefruit, *C. grandis* (L.) Osbeck[2]; the acid citrus fruits, including the lemon, *C. limonia* Osbeck, and the lime, *C. aurantifolia* (Christm.) Swingle; and the mandarin orange group, including the tangerine orange, *C. nobilis* var. *deliciosa* Swingle, and the satsuma orange, *C. nobilis* var. *unshiu* Swingle. Other types that are of importance mainly as rootstocks are the sour or Seville orange, *C. aurantium* L.; the rough lemon, *C. limonia* Osbeck; and the trifoliate orange, *Poncirus trifoliata* (L.) Raf. In some foreign countries the sour orange, the pummelo (*C. grandis*),[2] and the citron (*C. medica* L.) are of relatively greater commercial importance than in the United States.

From the Orient the various types and varieties spread to other parts of the world along the trade routes. The citron reached the Mediterranean region at an early date, as it is mentioned by Theophrastus. The sweet orange was apparently not introduced into Europe until the early fifteenth century. The sour orange reached Spain by way of northern Africa. The lemon and the lime were apparently introduced into Europe about the same time as the sweet orange, and several varieties are described by Ferrarius and other writers. Lemon culture first became important in Sicily, Corsica, Genoa, and other parts of southern Europe.

On his second voyage to the New World in 1493 Columbus stopped off for 2 days early in October at Gomera, Grand Canary Island, where he purchased livestock and fruit and vegetable seeds, among which were "seeds of oranges, lemons, and citrons." He reached the island of Hispaniola on November 22, 1493, and in the course of establishing a colony he "set out orchards, planted gardens" (*40*). The historical records of introduction to other parts of the Americas have not been exhaustively searched, but citrus fruits were established at St. Augustine, eastern Florida, by 1579 (*12*) and in Peru before 1591 (*82*). They were introduced into southern California in 1769 by Franciscan monks at San Diego (*43*), and there were undoubtedly many similar introductions into Brazil, Mexico, and other regions settled by the Spanish. In Florida the sour orange, and to a lesser extent the sweet orange and the lime, escaped to the wild.

It is now known, however, that the so-called "wild lime groves" on the lower east coast keys of Florida were in fact planted out by

[2] *Citrus grandis* (L.) Osbeck, as here used, includes the type, the sour shaddock; and two varieties, (1) the commonly known grapefruit and (2) the pummelo, used solely as a salad fruit as explained in the text. The term pummelo should not be confused with pomelo, sometimes used as a synonym for grapefruit.

Henry Perrine, to whom in 1838 Congress had granted a tract of land 6 miles square on Biscayne Bay for the establishment of economic tropical plants. Before his death in the Indian Key massacre of 1840 he had established a nursery of upward of 200 species and selected varieties of useful tropical plants (*53*).

REGIONAL CHARACTERISTICS IN THE UNITED STATES

Commercial citrus growing in the United States presents striking contrasts, due primarily to climatic conditions in the main centers of production (fig. 1). In Florida at an early date the sweet orange, the tangerine orange, and the grapefruit found a congenial home; in California the sweet orange and the lemon have proved the basis for profitable industries, with grapefruit secondary in importance. Texas and Arizona have more recently come into the picture, especially for grapefruit production.

Differences in varieties and seasons of maturity are likewise in sharp contrast. In California two varieties of oranges, the Washington Navel and the Valencia, furnish fruit maturing from November to November, a year-round shipping season. In Florida three or four sweet orange varieties, together with seedlings, are generally required to give a shipping season from October to May. In California lemons are more or less everbearing, affording a supply throughout the year. The Florida and Texas grapefruit crops mature practically during the same season (the fall and winter months), the California and Arizona crops coming in somewhat later. Similar contrasts are to be noted with the rootstocks used in these regions. These and other regional contrasts will be discussed more in detail later.

Thus it will be seen that because of differences in climate and in variety adaptation, citrus fruits, with their highly important vitamins, are available to the American consumer throughout the entire year. In general it may be said that grapefruit has been America's chief contribution to citrus culture, its recognition in Florida as an appetizing breakfast fruit gradually changing this curiosity of the citrus family into a formidable rival of the sweet orange in the national dietary.

Southeastern Humid Region

In the southeastern humid subtropical crops region, citrus development began in eastern Florida in the vicinity of St. Augustine and along the Indian River and in north-central Florida in the general vicinity of Palatka and Ocala as far south as Lake Monroe. On the west coast of Florida the development took place in the vicinity of Tampa Bay and southward. The outstanding pioneers in the introduction of citrus varieties during this period (1870–95) were E. H. Hart (fig. 2); H. S. Sanford, and Lyman Phelps. By the 1880's the industry in northeastern Florida was fairly important, but in the winter of 1894–95 it was practically wiped out by two severe freezes, and the center of the industry was moved farther south to the central ridge section and the southern coastal areas, where most of the citrus growing is now located. Today the industry is based primarily on the sweet orange, grapefruit, tangerine, and lime.

On the upper Gulf coast a citrus industry was established in the Delta district south of New Orleans, based primarily on the sweet

orange. Satsuma growing along the St. Johns River and near Jacksonville began about 1900, spreading thence westward—because of the cold resistance shown by this type during the 1894–95 and 1899 freezes—to the Gulf coast region in western Florida, Alabama, Mississippi, Louisiana, and Texas.

The early plantings of sweet oranges made in various parts of Florida consisted primarily of groves established from seedlings, and it was only later that the practice of budding improved varieties was gradually adopted with the introduction of meritorious early, midseason, and late sorts, beginning in the late 1870's. Since the citrus tree is relatively long-lived, the seedling groves, producing fruit mostly midseason in maturity, are still an important factor in Florida, and they produce approximately 30 to 40 percent of the State's total midseason sweet orange crop. However, budded varieties of recognized merit have been used almost entirely in new plantings and replacements for the last 40 years.

Figure 2.—Edmund H. Hart (1839 98), recognized as a skilled horticulturist and a pioneer in Florida citrus culture. His name is chiefly associated with the Hart's Late or Tardiff orange, now called Valencia, which he first brought to fruiting and introduced into general use in Florida during the 1870's.

Grapefruit first attained commercial importance in the United States. This was between 1880 and 1885, when the first grapefruit were shipped from Florida to the Philadelphia and New York markets. In Florida the industry received a set-back on account of the freeze of 1894–95, but it gradually expanded again, reaching a peak by 1929.

The lemon and the lime, which were classed together in early times, were introduced into the New World by the early Spanish explorers and settlers. The everbearing and rough lemons were among the early introductions into Florida, and the latter had escaped to the wild by the time permanent settlements became common.

Prior to the great freeze of 1894–95 the lemon industry of Florida was of considerable commercial importance. During the year previous to the freeze the annual shipments amounted to 140,000 boxes of lemons. Up to the present the industry has not been rebuilt, but recently attempts have been made to reestablish it. Limes are grown in southern Florida, chiefly on the keys, in Dade county, and in the south-central ridge section.

The mandarin oranges include the King, tangerine, and satsuma types. The tangerine was introduced into Europe from the Orient during the first half of the nineteenth century and was produced on

a commercial scale in Italy as early as the 1840's. It was introduced into Louisiana between 1840 and 1850 and later was brought to Florida, where it is grown as a fancy fruit to a greater extent than in California or Texas. Another member of this group, the satsuma, is outstanding in being the most frost-hardy of all the larger fruited citrus types. It is grown primarily in the upper Gulf coast region, with the chief center of production in western Florida and southern Alabama and Mississippi

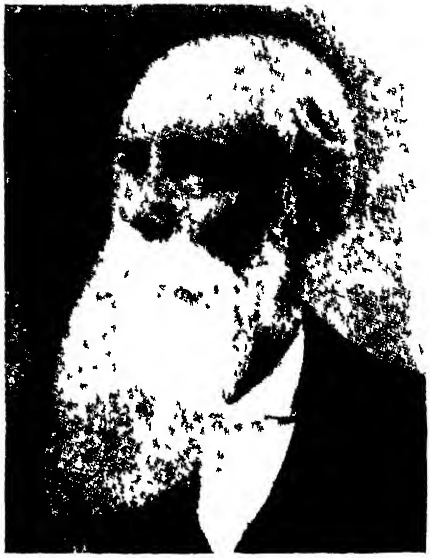

Figure 3.—Thomas A Garey (1830–1909), pioneer California nurseryman, who made extensive introductions of citrus varieties during the period 1868–75.

Southwestern Irrigated Region

In the southwestern irrigated subtropical crops region a citrus industry has been established in California, primarily in the southern coast and interior valley sections. In the southern coast section the industry is based almost entirely on sweet orange and lemon, and in the interior valley section on sweet orange and grapefruit. An extension into the irrigated section of Arizona occurred later, founded primarily on the grapefruit.

Citrus seeds were disseminated from other parts of Mexico to the peninsula of Baja (Lower) California probably in the early 1700's, and later, in 1769, were introduced to Alta (Upper) California by Franciscan missionaries, who established a chain of missions for 400 miles along the coast. According to Coit (*11*), the early settlers secured orange trees from the missions, and a number of small plantings were found in private gardens in the 1830's and 1840's in the vicinity of Los Angeles. These early plantings stimulated further interest, and in 1857, trees were planted at old San Bernardino and Highlands, in 1865 at Crofton, and in 1871 on land now occupied by the city of Riverside. T. A. Garey (fig. 3), of Los Angeles, the outstanding nurseryman of that time, imported large numbers of important varieties during the period 1868 to 1875. His introductions were apparently from Florida, Australia, and southern Europe, as well as from Ellwanger & Barry, of Rochester, N. Y., and Sir Thomas Rivers, of Sawbridgeworth, England. In the southern and central parts of California the industry was only of local importance until after the completion of the Southern Pacific Railroad in 1876, when the first carload of fruit was shipped to St. Louis, Mo., arriving in good condition after a month in transit.

The grapefruit industry in the Southwest—California and Arizona—began after the introduction of the Marsh variety in 1890; the plantings of other varieties previous to that time did not prove profitable.

Great success in lemon culture has been achieved in California, particularly in the southern coastal region, which produces a large proportion of high-priced summer fruit.

Central Irrigated Region

In the lower Rio Grande Valley of Texas, in the central irrigated subtropical crops region, an industry has been established based primarily on the grapefruit and to a lesser extent on the sweet orange.

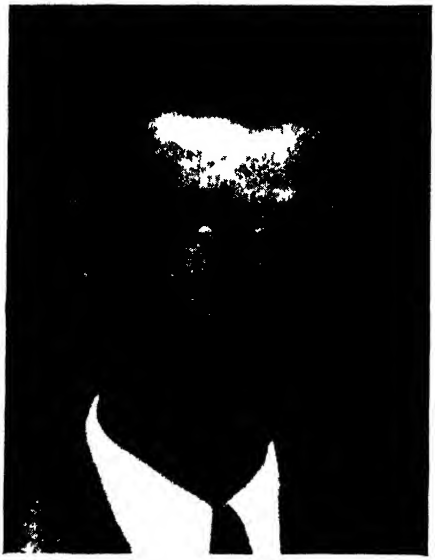

Figure 4.—Charles J. Volz, pioneer Texas citrus grower since 1908, who demonstrated the value of sour-orange rootstock for citrus in the lower Rio Grande Valley of Texas. This demonstration proved to be a turning point in the development of the citrus industry in that section.

As early as the middle of the last century scattered plantings of a few citrus trees could be found along the Texas Gulf coast, particularly from Victoria County southward to Brownsville on the Rio Grande. Experience had demonstrated by the beginning of the twentieth century that regular citrus crops could not be expected in the region above the lower Rio Grande Valley, on account of damage from low temperature (*48*). In the lower Rio Grande Valley—Cameron, Hidalgo, and Willacy Counties—the development of the industry may be grouped into three periods. (1) Up to 1899 citrus fruits were grown for home use and no particular attention was given to the subject of rootstocks. Seedlings and budded trees were planted. During this period, in 1869, the trifoliate orange was imported from northern China by William Saunders, of the United States Department of Agriculture, and it was used to some extent as a rootstock. (2) The resistance to frost shown by trees budded on trifoliate stock during the severe freeze of 1899 led to the extensive use of this stock during the following decade (*87*). Although the stock was valuable from the standpoint of frost resistance and encouraged the pioneer growers to make further attempts, it had the serious defects of dwarfing the scion variety and of being itself subject to foot rot and cotton root rot (*77*). (3) The observations of some of the outstanding pioneers, Charles J. Volz, Harry Banker, J. R. Robertson, F. E. Elliot, Max Melck, and A. P. Wright, beginning after 1900, made possible the growing of citrus fruits in commercial quantities.

Charles J. Volz (fig. 4), from Indiana, settled near Mission in Hidalgo County, Tex., in 1905. He began the planting of citrus in 1908 and clearly demonstrated the superiority of the sour-orange rootstock under the lower Rio Grande Valley conditions. Harry

Banker, from Oklahoma, who settled near Brownsville, in Cameron County, secured similar results with the sour-orange rootstock beginning in 1910 (*87*). With the solution of the rootstock problem the industry showed at first gradual and later rapid development. The citrus shipments from this section, consisting mainly of grapefruit, had reached 13 carlots in 1921 and increased to more than 5,000 carlots annually by 1931. Yields were cut down as a result of hurricane damage in 1933 and damage due to low temperature in 1933–34 and 1934–35, but the crop of 1936–37 reached a total of over 15,000 carlots. Fortunately for this new industry, the seedless type of grapefruit (Marsh variety and its pink-fleshed mutations) has been most heavily planted in Texas, and this has doubtless contributed to its favorable reception in many markets.

HAWAII, PUERTO RICO, AND THE PHILIPPINES

The sweet orange was introduced into Hawaii in 1792, and many citrus varieties have been cultivated there for over 100 years (*54*). The climate is well adapted to citrus culture, but for commercial production the situation is complicated by the presence of the Mediterranean fruit fly, which limits production to local needs.

While citrus fruits, especially the sweet orange, have been grown in a semiwild condition in Puerto Rico for perhaps 3 centuries, commercial planting did not begin until about 1900. The first plantings were largely of Florida orange varieties, but these were soon largely discarded in favor of grapefruit (*29*). The varieties most commonly grown are the Duncan and the Marsh. For budding stocks, rough lemon, sour orange, and seedling grapefruit have all been successfully used, the rough lemon being favored for rapid growth and early production and especially for the lighter grades of soil. Wind damage has caused frequent losses of trees and fruit and has directed attention to the use of such plants as bamboos and casuarinas for windbreaks.

Owing to the fact that the trees bloom intermittently, Puerto Rico is enabled to ship grapefruit over a long season, a summer crop often maturing from a previous fall bloom. Production for several years past has averaged about a million boxes, of which approximately 25 percent is marketed as canned grapefruit. Puerto Rico is credited with having initiated the canning of grapefruit "hearts", a product that has grown rapidly in favor and has made grapefruit available at all seasons and in many localities where fresh fruit seldom is offered. Orange shipments from Puerto Rico, amounting to a half million boxes in good seasons, consist largely of so-called "wild oranges", which come in a considerable measure from seedling trees cultivated as shade trees on coffee plantations.

In the Philippines citrus fruits have been grown for centuries, forms of *Citrus hystrix* DC. (kalpi), *C. mitis* Blanco (calamondin), and *C. grandis* (pummelo) being native to the islands. It is only in recent decades, however, that attention has been given to growing the fruit commercially. Wester (*88*), beginning about 1910, brought together an extensive collection of citrus varieties at Lamao, few of which proved adapted to Philippine conditions. The mandarin oranges as a class have proved best suited to commercial culture,

and a local variety known as Batangas mandarin is being grown on a considerable scale chiefly for the Manila market. The Batangas, the King, and the Szinkom mandarins, several pummelo varieties—including the Siamese—and the Valencia orange constitute most of the recent plantings. Genetic studies and hybridization work have been inaugurated by Torres, and one hybrid variety, Szinbat (Szinkom × Batangas), has been introduced. It is characterized as productive, of good quality, and resistant to wind injury. Further breeding and selection work is in progress, special studies being made of polyembryony—to be discussed later—in scion and stock varieties.

BREEDING MATERIALS

THE citrus breeder is concerned with two kinds of plant materials within the Rutaceae—the citrus group proper, containing the types closely related to the widely known sweet orange, and various species in genera somewhat less closely related. The first or citrus group contains all of the valuable types cultivated for their fruits or used as rootstocks, and the second is of value in some instances as stocks, as breeding material, and in furnishing a clue to the evolutionary development of the branch of the Rutaceae to which the citrus fruits belong.

The citrus group proper is characterized by great diversity in morphological characters, and this has led some systematic botanists to the multiplication of species. The classification of Swingle (*68*), however, is conservative, has been widely accepted, and is used in this report. The only exception made is in the case of *Citrus grandis*, where it has been necessary to recognize two varieties besides the type species.[3] The horticultural differences in a number of cases are so great, as will be pointed out in the discussion of dessert quality later, that the single type designation is quite inadequate.

The following types commonly grown for their fruits or as rootstocks are in the three genera *Citrus*, *Fortunella*, and *Poncirus*:

Sweet orange, *Citrus sinensis* (L.) Osbeck.
Sour orange, *C. aurantium* L.
King orange, *C. nobilis* Lour.
Tangerine orange, *C. nobilis* var. *deliciosa* (Tenore) Swingle.
Satsuma orange, *C. nobilis* var. *unshiu* (Mak.) Swingle.
Shaddock, *C. grandis* (L.) Osbeck.
Grapefruit, *C. grandis*.
Pummelo, *C. grandis*.
Citron, *C. medica* L.
Lemon, *C. limonia* Osbeck.
Lime, *C. aurantifolia* (Christm.) Swingle.
C. ichangensis Swingle.
Kalpi, *C. hystrix* DC.
Calamondin, *C. mitis* Blanco.
Kumquat, *Fortunella* spp.
Trifoliate orange, *Poncirus trifoliata* (L.) Raf.

The citrus breeder is fortunate in possessing material that presents so many diversities—in dessert and keeping quality, season of maturity, resistance to disease, and regional adaptation. All of these will be developed in detail in the following text, but the dessert quality of the types will be discussed at this point.

[3] See footnote 2, p. 752.

Character and Uses of the Fruits

Some of the fruits listed above—sweet orange, grapefruit, lemon, and lime—have become well known to northern readers and need to be only briefly differentiated; a few, however, are little known and will require more detailed descriptions. In general it may be stated that the taste qualities of mature citrus pulp and juice are dependent on various combinations of sugars, acids, glucosides, esters, and peel oil. The first two, the sugars and acids, are the basic matrix and give variations from sour through tart, sweet, and insipid, and the latter contribute bitter and aromatic principles. The bitter principle, furnished by glucosides, is apparent only if it is in solution in sufficient amount in the juice (*5, 78, 79*). This is normally not the case except in such types as grapefruit and lime. The aromatic quality contributed by peel oil is important in some cases.

In most commercial varieties of sweet orange the sensation of sweetness predominates, combined with a slightly perceptible tartness. In most varieties the quality contributed by esters is slight, but in such varieties as Pineapple the suggestive "pineapple" ester is outstanding.

In the mandarin orange or free-peeling group, the tangerine oranges are characterized by the pleasant "tang", which is due to esters. The King and satsuma oranges in this same group have taste qualities similar to those of the sweet orange.

In grapefruit the bitterness of the glucoside naringin gives the sprightly taste added to the mild acidity that makes the fruit outstanding as a breakfast appetizer.

The pummelo, as distinguished from the sour shaddock, is used only as a salad fruit. The large juice sacs are separated from the locular wall tissues and are served like any other salad. The flavor in the better varieties is due to a very slight acidity and the presence of only a very little glucoside, but it is predominantly sweet, and inimitable quality is contributed by esters.

In lemon and lime, acidity is of first importance. A good acid citrus fruit, as pointed out by Traub and Robinson (*80*), should have from 6 to 7 percent of acid. In lime the characteristic glucoside, which has not been studied in detail, lends the "lime" taste. The peel oil of lemon and lime also gives desirable qualities.

The citron is used entirely as a preserve. The kumquat is used both in preserving and in table decorations. It is also eaten entire, out of hand. Two general types are recognized, sweet and sour, in both of which the rind has little of the pungent oil common to most citrus fruits.

In the case of hybrids, intermediates have in some instances been secured, especially in the tangelo oranges—hybrids between the grapefruit and the tangerine orange. In these hybrids, as a rule, the esters are predominant in distinguishing the flavor of the new fruits from the common sweet orange. In the Perrine lemon, a hybrid between the lemon and the lime, there is a mild suggestion of the lime glucoside.

When hybrids between citrus species first appeared it was customary to apply various compound names, such as tangelo, tangor, oranguma, limelo, lemelo, etc., to indicate the parentage. It was soon realized that this would lead to confusion from the horticultural

viewpoint, since some crosses gave rise to more than one horticultural or market type. The grapefruit-tangerine cross (tangelo), for instance, gave rise to forms like the now generally known tangelo orange, and also varieties that resemble the grapefruit in structure and juice quality but with the rind, flesh, and seed color of the tangerine. A strict application of the term "tangelo" would have included both of these forms. The difficulty was overcome by the decision to place hybrids for purposes of horticultural classification with the well-known types that they most resemble, and to use the interspecies compound designations only in their scientific application. On this basis most of the tangelos already introduced, being more like the sweet orange in structure and use, were designated as a group of the sweet orange, possessing relatively high quality with special reference to a pleasing blending of esters, sugars, and acids. Such a class would naturally contain also such hybrids as the Umatilla (oranguma), a cross between the sweet orange and satsuma orange, but very similar to the other tangelo oranges, and also the Temple, apparently a naturally occurring hybrid between the tangerine and a grapefruit variety similar to the Tresca.

Representatives from a great number of related genera, *Glycomis*, *Claucena*, *Chalcas*, *Feronia*, *Feroniella*, *Aeglopsis*, *Aegle*, *Swinglea* (*Chaetospermum*), *Balsamocitrus*, *Lavanga*, *Hesperethusa*, *Triphasia*, *Severinia*, *Citropsis*, *Atlantia*, *Eremocitrus*, and *Microcitrus*, have been introduced by the United States Department of Agriculture during the last 25 years. These are listed in table 6 in the appendix. Some of these may prove of value in citrus breeding and as rootstocks. Although certain species have entered to some extent into hybridization work, no hybrids of immediate value have been secured up to the present. The material, however, is valuable to the breeder from another standpoint, for it presents an opportunity for an evolutionary approach to the study of relationships within the group.

GENERAL TRENDS AND PROBLEMS

The early history of citrus improvement in the United States is concerned almost entirely with the introduction of varieties from other citrus-producing regions, mainly through private initiative. This period extended to the 1870's in this country. Toward the end of the nineteenth century, in the United States, the number of varieties was increased by the addition of those originating as chance seedlings and possibly by bud mutations accidently propagated. Still later, improved types appeared as the result of artificial cross-pollination. Breeding work was undertaken by the Department of Agriculture in 1892, and the the State agricultural experiment stations in California in 1910, in Florida in 1924, in Alabama in 1933, and in Texas in 1934.

Problems Peculiar to Citrus Breeding

The breeding of citrus fruits presents two problems not met with in the case of the usual annual crops such as grains, which can be grown in great numbers on a relatively small area at small expense.

First, as a rule it takes from 6 to 10 years to fruit a seedling citrus tree unless the variety is top-worked on an older tree, in which case the time will be cut in half. The trees are expensive to produce and to

test out in orchard formation on various soil types and under various climatic conditions. It is necessary, therefore, to plan breeding experiments so that only progeny are grown that promise varieties of immediate value or additions to the knowledge of citrus genetics With such a handicap, the work has not progressed at a very rapid rate.

The other difficulty is due to the phenomenon of polyembryony—meaning "several embryos per seed" (fig. 5). In the case of plants reproducing by seeds, each single seed as a rule gives rise to one seedling, which is the result of the union of the male gamete (reproductive cell), contributed by the pollen grain, and the female gamete (egg cell), contained in the ovary of the flower. In each of these gametes the number of chromosomes has been normally reduced by half preparatory to reproduction (the haploid number of chromosomes), and the union of the two results in a complete complement of chromosomes, called the diploid number, which is characteristic of all of the body cells of the individual plant as distinguished from the sex cells. In the case of the citrus seeds, however, a normal embryo produced by the union of the male and female gametes may be present, and in addition one or more—sometimes as high as 15—additional embryos that have arisen from projections into the embryo sac of the surrounding maternal tissue (nucellar tissue). When these projections develop into embryos they have the full chromosome complement (diploid) of the mother plant without the union of two gametes. Citrus types and varieties may vary greatly in the number of nucellar

Figure 5 — Nucellar embryony in citrus, showing four seedlings sprouting from single seeds (McCarty grapefruit): *A*, One vigorous seedling and three relatively less vigorous; *B*, four vigorous seedlings; *C*, similar to *A* after separation. (See also fig. 17, showing cytological details)

embryos produced. Seedlings that develop from nucellar embryos are called apogamic seedlings (literally, "without marriage").

Unless the parents have unlike vegetative characters, it is not possible to distinguish the sexually produced or hybrid embryo from those that arise by nucellar budding, though in the latter, of course, only the characters of the female parent will appear. This means that a great many more seedlings must be grown to the point where they can be distinguished than in the case of crops producing only normal or seminal seedlings. Citrus breeding, therefore, will continue to be even more costly than ordinary tree-fruit breeding unless a method can be worked out to achieve practical control of nucellar embryony.

Thus it is natural to expect relatively slow progress. The results from cross-pollination followed by inbreeding and selection, and from back-crossing on the parent types, will not be available in a few seasons but only after a considerable period of time. However, the earlier pioneers in this field have laid the foundation, and in the future it is probable that the rate of progress can be considerably accelerated.

Methods of Breeding

Fortunately no problem is presented with reference to controlling pollination in citrus. The flowers are relatively large and the ordinary bagging technique with brown-paper bags has proved sufficient. In practice the flowers are emasculated before pollen is shed and then bagged. They are pollinated soon after opening, and the bags, which were removed for pollination, are replaced and left on until the petals have fallen and the fruit begins to grow. To protect from loss by dropping, the fruits are usually covered with cheesecloth bags.

Pollen is gathered from flowers that have been bagged when still closed and is used immediately unless flowering of the parents desired does not overlap, in which case the pollen is stored for later use. Kellerman (*35*) has shown that citrus pollen dried over concentrated sulphuric acid and sealed in glass vacuum tubes at about 0.5 mm pressure can be kept in a viable condition for more than 2 months.

When the seeds are removed from the harvested mature fruits secured as a result of artificial pollination, they are thoroughly washed and are planted at once in flats, for the germination percentage usually decreases if they are allowed to dry in the air. The flats containing the seeds are placed in a coldframe to prevent damage by heavy rains. When seedlings are 6 to 18 months old they are planted in nursery rows, usually 12 by 6 feet apart, and given good culture. As soon as the fruiting stage is reached, usually in 5 years, or sooner if top-worked on old trees, detailed records are taken of tree and fruit characters, and all seedlings that show no immediate promise or appear to be of no value for future breeding are destroyed. These records determine the apparent worth, if any, of the plants as varieties for cultivation, and also serve as a basis for working out genetic principles.

The seedlings are tested for vigor, including disease resistance, bearing capacity, and regional and rootstock adaptation. The fruits are tested for size, shape, juice percentage, season of maturity, number of locules and seeds, rind thickness, percentage of "rag", percentage of sugars and acids, effective acidity (pH) of the juice, and the

flavor of the juice. Out of a great number of seedling individuals only a very few are finally selected for introduction, and these are released only after favorable performance in preliminary fruiting tests in a number of locations.

Objectives of the Breeder

The first consideration in citrus breeding is excellent dessert quality. What constitutes high quality has been previously discussed, and we pass to the consideration of tree and other fruit characters that the breeder has in mind when making his crosses and selections.

The tree (scion variety) should be compact in habit, but a vigorous grower and a prolific bearer. It should be resistant to the common citrus diseases and to low temperatures, and congenial with the rootstock or rootstocks used in the region. The fruit should mature at the proper season or seasons to suit market needs. There are also other characters of importance, such as thornlessness.

The fruit should have excellent dessert quality and contain few or no seeds; the shape and size should be suited to commercial requirements and to ease in packing; shipping or keeping quality, including resistance to storage diseases, should be good; the exterior, including texture and color of rind, should be attractive; and, in particular, the vitamin C content should be up to the standard. With the rapid growth of a new industry in canning "hearts" and juice of both grapefruit and orange, special attention may need to be given to the requirements of this promising industry. For instance, it has already become evident that the pulp of Marsh grapefruit lacks the firmness necessary in a good canning grapefruit. With the growing tendency to utilize citrus fruits in juice form and in mixed drinks, the high color of the juice characteristic of the tangelo group of hybrids is proving a decided advantage.

The tree used as a rootstock should be adapted to the soil and climatic conditions, be free from or resistant to trunk and root diseases, and produce a high percentage of nucellar embryos, and it should not be so vigorous in growth as to make the fruit of the scion coarse, of poor texture, and comparatively low in total solids (sugars and acids) and therefore insipid in taste (*6*, *80*).

As the margin between production costs and sales returns becomes narrowed with increasing supplies of citrus fruits, any adaptation that might lessen the cost of production becomes vitally important. This places emphasis on disease resistance in any breeding program, to reduce both expense for grove sanitation and losses due to infected trees and fruit. In citrus the list of such diseases is quite extensive and varies with citrus types and varieties.

The task of breeding for resistance to injury from insect and other animal pests on plants presents the major difficulty of developing a practical technique.

In Florida the chief citrus diseases are melanose, affecting tender twigs, leaves, and immature fruits, and stem-end rot, affecting mature fruit, both caused by *Diaporthe* (*Phomopsis*) *citri* (Fawc.) Wolf; sour orange scab (*Elsinoë fawcetti* Bitancourt and Jenkins), affecting leaves and fruits; key lime anthracnose (*Gloeosporium limetticolum* Clausen); foot rot (*Phytophthora parasitica* Dastur); and psorosis, cause undetermined.

In the Southwest, brown rot gummosis and foot rot (*Phytophthora citrophthora* (Sm. and Sm.) Leonian and *P. parasitica*); psorosis; and shell bark (*Diaporthe citri*) are of major importance; and in the lower Rio Grande Valley gummosis, scaly bark, and stem-end rot (melanose).

Achievements and Future Possibilities

In spite of the peculiar difficulties encountered in citrus breeding, definite achievements can be recorded, and the outlook for the future is most encouraging. The work in the past has shown that worthwhile results may be secured from appropriate crosses and that important strains and varieties may arise by bud mutation. In addition a beginning has been made in laying a foundation of genetic principles.

The work in citrus hybridization carried on by the Department of Agriculture workers since 1893 has shown that the combinations of grapefruit and tangerine and of lemon and lime give the most promising results. The first have given rise to high-quality fruits known as the tangelo oranges, and the latter to a high-quality lemon, the Perrine. The work of Frost, of the California Agricultural Experiment Station at Riverside, has shown that crosses within the mandarin orange group give worth-while results.

Apogamic seedlings from crosses have also given rise to important varieties in grapefruit and in sweet, sour, and satsuma oranges. Bud selection has given superior strains of known varieties and has served to stabilize standard varieties. Crosses with more distantly related relatives of citrus, *Citrus* × *Poncirus*, citrange × *Fortunella*, citrange × calamondin, etc., have proved interesting from the genetic standpoint and have also given some concrete types of possible value in horticulture—citrange, citrangequat, and citrangedin. Reference to particular hybrids in which definite objectives have been attained are found in the text and in table 6.

Thus the ground work has been laid by the earlier workers. With the wealth of breeding material and the increase of interest in this field, research in citrus breeding may be expected to show greater progress in the years to come.

Some idea of what the future holds in store as a result of citrus breeding can best be gained from the following quotations contained in the report made by H. B. Frost, actively engaged in citrus breeding at the Citrus Experiment Station, Riverside, Calif., in connection with the cooperative survey of plant and animal breeding:

> If we wish to produce a variety or strain that is very similar to a standard variety, such as the Valencia, but superior in some important feature, such as eating quality, generative seedlings from either selfing or narrow crossing are very unpromising, for two reasons: (1) they are usually weak and very unproductive, and (2) they are usually very unlike the parent or parents. The best chance of success, although a very uncertain one, seems to lie in the discovery of superior bud-variation forms. Such forms may be found, of course, either as "limb sports" or as whole trees which have happened to be budded from variant branches. They may also be found as seedlings derived from nucellar embryos that happen to be formed on a variant branch; in this case the seedlings are likely to be indistinguishable from other nucellar seedlings until they produce fruit. On the basis of the time and expense required, the search for bud variations in commercial orchards seems more promising than the growing of seedlings. A good new bud-variation type may in some cases, however, be variable because of

mixture with the parent variety in the same shoots to form a chimera, and the growing of seedlings may then be the best method of getting the new type separated from the parent variety. Variability may in some cases be inherent in the constitution of a new form, however, so that it will never become stable.

X-ray treatment probably can be used, as it has been with other plants, to increase greatly the frequency of new genetic variations. It seems most likely to be useful by producing variations in nucellar seedlings.

For the production of new varieties of superior quality but with flavors very unlike those of the present varieties, the great variability of hybrids offers much promise, since we can use wide crosses, which commonly give vigorous hybrids. Various hybrids of the tangelo and tangor groups, which are hybrids of mandarins with grapefruit and with sweet orange, that have been introduced by the United States Department of Agriculture, offer unique and very pleasant flavors. It is now probable, however, that the best opportunities for securing superlative quality are to be found in crossing within the mandarin species or group of species, and therefore, it is very fortunate that certain crosses between mandarin-group varieties produce vigorous hybrids.

It is advisable to make some further trial of the production of triploid hybrids by pollinating tetraploids by diploids of other species (or of other sections of the mandarin "species"). The only tetraploid form which at present seems to have much promise for such use is the tetraploid Lisbon lemon, which combines good seed production, comparatively low chromosome irregularity, and high proportion of generative progeny.

The evidence on which these suggestions are based has only partly been secured at the Citrus Experiment Station, and that on the results of selfing has very largely been obtained in Dr. H. J. Webber's root stock experiments. The nature of the work has ranged from chromosome counts and systematic records of various tree and fruit characters, to the determination of the agreeableness of fruit flavors. Any extensive gene analysis is clearly impracticable in citrus, yet certain evidence has been obtained which seems to have definite significance for general genetic theory, when interpreted on the basis of gene analysis made on more favorable organisms.

The problems that most concern the citrus breeder have been listed by Frost as the determination of—

(1) The generality of the reduction of vigor with selfing and narrow crossing. (2) The extent to which the proportion of nucellar seedlings can be predicted from counts of total embryos. (3) (*a*) The extent to which triploids are unproductive of fruit, as compared with diploids of the same ancestry. (*b*) The extent to which triploids can be produced by crossing diploids with tetraploids. (*c*) The frequency with which triploids occur from crosses between diploids. (4) The extent to which the prospects of high vigor, productiveness, good flavor, and other horticulturally desirable characters in crossing can be inferred from knowledge of the species or smaller taxonomic group to which a variety belongs, on the basis of trial of other varieties of the same group. (5) The frequency with which new genetic types arise by bud variation, and the extent to which this process can be speeded up by X-ray treatment of seeds, pollen, etc. (6) The best methods of modifying physiological conditions to secure high seed production in crossing, and, if possible, high proportions of generative embryos.

With the present facilities, problems named under 1 to 4 above may be solved partially, and to a much smaller extent those under 5 and 6 in the list.

IMPROVEMENT OF CITRUS VARIETIES

The improvement of citrus varieties will now be briefly discussed on the basis of citrus types—sweet orange, mandarin oranges, grapefruit, acid citrus fruits, and minor citrus fruits. In each case the varieties will be considered by regions. Following this, citrus bud selection and citrus rootstocks will be considered under separate headings.

Sweet Orange Improvement

Florida

In Florida the bulk of the citrus crop is produced between October and June. Good early-maturing and very late-maturing varieties are of most importance from the breeding standpoint. The sweet orange varieties of Florida have been described by Hume (*32*).

EARLY VARIETIES

Early-maturing sweet orange varieties for Florida are relatively scarce, and it is desirable to give this fact due weight in any citrus-breeding project.

The Hamlin is one of the early varieties usually recommended. It was discovered in a grove planted in 1879 near Glenwood, which later came into possession of H. E. Hamlin. Under the best cultural conditions the acidity and sweetness are well blended, giving it excellent flavor; the rind is smooth and glossy; seeds are none too few; the season is October and November and later. Recent reports indicate that it is sensitive to overfeeding and other unfavorable growing conditions, which may lead to fruit splitting, riciness of pulp, and poor juice quality.

The Parson Brown variety was introduced by C. L. Carney, of Lake Weir, about 1878, having originated at Webster in a seedling grove owned by Parson Brown. Acidity and sweetness are fairly well blended if the fruit is picked early; seeds, 10 to 19; season, October and November.

Early sweet oranges usually have poor rind and flesh color when harvested at the beginning of the season. This is a deficiency that might be remedied by breeding methods.

The results thus far look promising. A hybrid, the Orlando tangelo orange (fig. 6), introduced by the Department in 1931 and resulting from a cross of the Bowen grapefruit pollinated by Dancy tangerine, is early in maturity and can be harvested over a long season. The variety is highly resistant to citrus scab. When first harvested in late September or early October the rind color after degreening with ethylene is a beautiful light yellow, but later in the season it takes on a natural deep reddish-orange color. It is medium in size, and the flesh color is deep orange. Its main defect is its seediness. Such a defect can apparently be overcome in future breeding work, as will be pointed out later.

MIDSEASON VARIETIES

A large number of midseason varieties were named and introduced beginning in the 1870's. Among these the outstanding ones are the Homosassa and Pineapple. The Homosassa is a variety of excellent quality, with a sprightly, rich, vinous flavor; seeds, 20 to 24; season, December to February. The Pineapple is the outstanding midseason variety, having a glossy rind of deep orange color, vinous and sprightly in flavor; seeds rather large and numerous. It originated near Citra, Marion County, and received its name from the fine aroma reminiscent of the pineapple. It is today the most important midseason sweet orange in Florida.

The navel type of sweet orange is not suited to the Florida climate. Although a number of varieties have been introduced, they have not proved successful as the Washington Navel has in California.

Two midseason tangelo oranges, of the same parentage as the Orlando variety, introduced by the Department in 1931—Minneola (December–January) and Seminole (February–April)—are outstand-

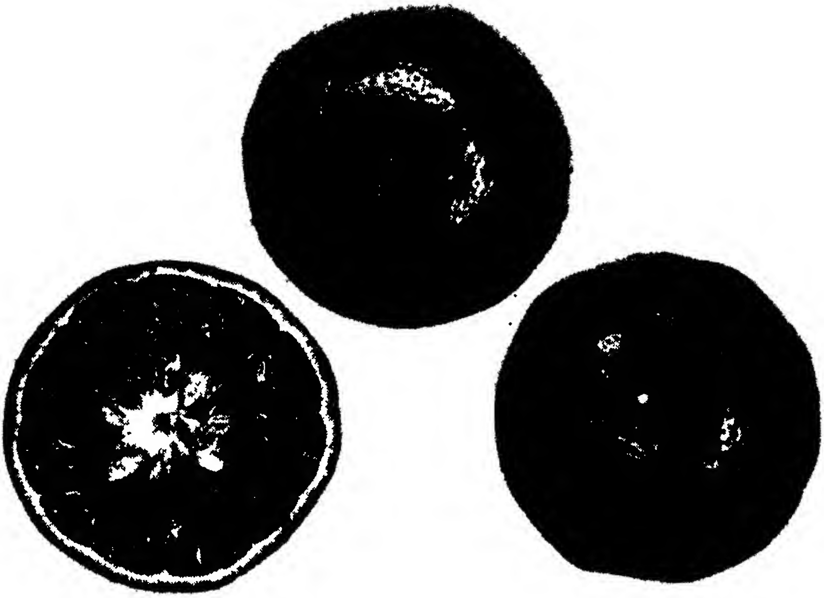

Figure 6.—Typical fruits of Orlando tangelo orange (originally introduced as the Lake variety), a hybrid between grapefruit (♀) and tangerine (♂); remarkable for earliness, maturing in October and November; highly resistant to scab. Introduced by the United States Department of Agriculture.

ing from the standpoint of dessert quality, the Minneola especially having the most delicate blending of esters, sugars, and acids. These fruits have deep tangerine rind and flesh color, and their shipping quality is good. Like the Orlando tangelo orange, the Seminole (fig. 7) is highly resistant to citrus scab, the Minneola partially resistant. The fruits are somewhat seedy.

LATE VARIETIES

The sweet orange industry up to the 1870's was based on seedlings and clones producing early and midseason fruits. An event of great importance took place when, early in the 1870's, the late type of sweet orange, now called Valencia (fig. 8), was introduced into Florida by S. P. Parsons, a nurseryman of Long Island, N. Y., and Palatka, Fla. Parsons had secured it from Thomas Rivers in England, who had imported it from the Azores and had cataloged it under the name "Excelsior." Parsons gave trees to E. H. Hart (fig. 2), of Federal Point,

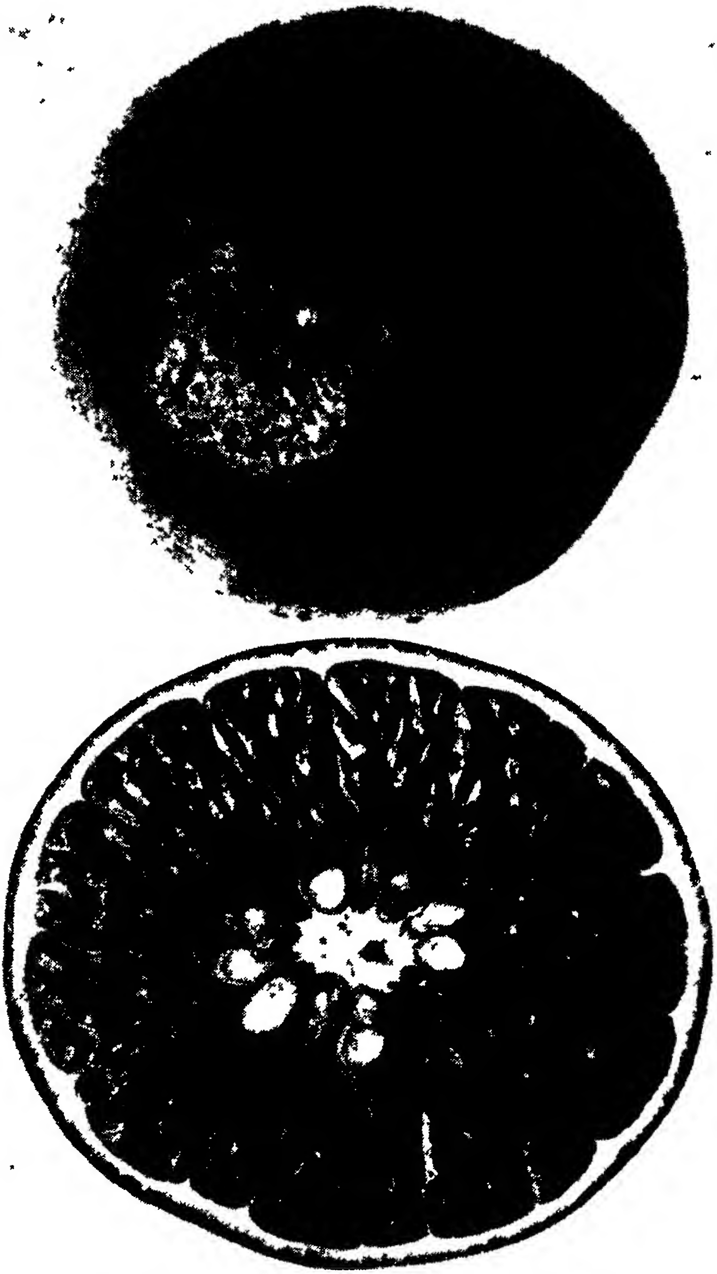

Figure 7.—Typical fruits of Seminole tangelo orange, a hybrid between grapefruit (♀) and tangerine (♂); midseason to late in maturity; replacing the older Sampson variety because of its high color and flavor, resistance to scab, and good shipping quality. Introduced by the United States Department of Agriculture. (Natural size.)

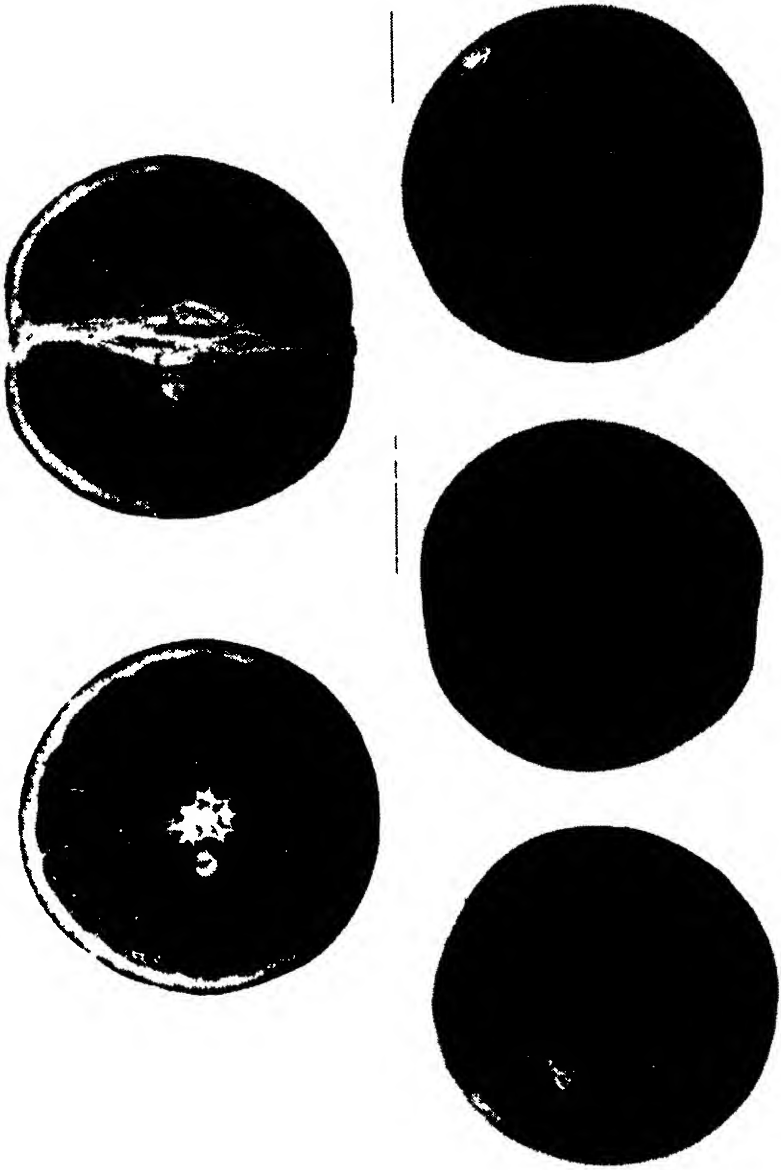

Figure 8.—Valencia orange, typical of the variety as grown on sour orange rootstock in Orange County, Fla. It is characterized by late maturity (March to June in Florida), firm flesh and rind, and fairly high content of citric acid, contributing to its good holding and shipping quality. It is commercially seedless, having normally two to five seeds.

Fla. Having lost the label, Hart distributed the trees under the name of Hart's Late or Hart's Tardiff. The variety was exhibited before the Florida Fruit Growers Association on April 25, 1877. The outstanding characteristic of this variety is its late maturity. Its season extends from March to June.

The variety was also imported into California, in a lot of citrus varieties from Thomas Rivers, by A. Chapman, of San Gabriel, Calif., between 1870 and 1872. One of these varieties, labeled as a navel, turned out to be a late-ripening nonnavel variety that fruited after the other varieties were off the market. The variety was named Valencia at the suggestion of a Spanish laborer, and Chapman sold it under the name of Valencia Late. Nurserymen in California had purchased stocks of Hart's tardiff, and a great many trees had been set out. By the time it was discovered that the Valencia and Hart's Tardiff were identical, the variety had attained commercial importance in California, and the name Valencia was retained.

A variety similar to the Valencia, named Lue Gim Gong, for the originator, and introduced in 1912 by the Glen St. Mary Nurseries, is described as very late in maturity. It is now generally regarded as a strain of Valencia, from which it originated as a seedling.

The production of a tangelo orange (Umatilla), which resulted from the pollination of the satsuma by the Ruby sweet orange and was introduced by the Department in 1931, indicates what may be accomplished by breeding methods in the creation of late-maturing varieties. In contrast with the parents—satsuma, early maturing, and Ruby, sweet midseason—the hybrid matures its fruit in late February, March, and April. The variety is highly resistant to citrus scab; the fruits are medium to large in size; the rind and pulp color is deep orange, and the quality is excellent. Seed content is variable.

To sum up: At the present time the sweet orange industry in Florida is based primarily on two early varieties, Hamlin and Parson Brown; on midseason seedlings and two midseason varieties, Pineapple and Homosassa; and on one late variety, Valencia.

California

In California one early and midseason navel and one late nonnavel variety have proved sufficient to produce an orange crop every month in the year.

Contrary to popular opinion, the navel type of sweet orange is not a modern product. It was described and pictured by John Baptisti Ferrarius in 1646 and is apparently of early origin. As early as 1820 the Bahia form of the navel orange had made its appearance in Brazil, where orange trees had been introduced by the Portuguese settlers. Its excellent qualities were soon recognized, and the variety was extensively propagated in the vicinity of Bahia. Even at this early date the variety seems to have been subject to bud mutation, and inferior types appeared that were unintentionally propagated and introduced in South Africa and Australia. Those that reached Australia also included desirable types.

The Bahia type of navel orange was first introduced into Florida in the 1830's, but the trees were killed during the freeze of 1835. A shy-bearing form of Bahia navel was introduced into California in the

early 1870's. The strain was secured from S. B. Parsons, Flushing, N. Y., who had received it from Thomas Rivers in England. In the early 1870's an inferior type of navel orange was imported from Australia into California, which set the precedent for referring to inferior strains as the Australian navels to distinguish them from the superior Bahia strain.

The story of the Washington Navel orange is a dramatic illustration of the value of superior varieties of economic plants. In 1870 the citrus industry had begun in California, but there was no outstanding early and midseason variety of sweet orange generally adapted to the climate. The early mission seedlings and varieties introduced after the middle of the nineteenth century were being tested out by various growers, but there was a lack of standardization in quality. The value of alertness in using the plant material that has been produced as a result of centuries of selection is nowhere better illustrated than by the timely action of the late William Saunders (fig. 9), then superintendent of gardens and grounds of the United States Department of Agriculture, Washington, D. C.

Figure 9.—William Saunders (1822–1900), superintendent of gardens and grounds of the United States Department of Agriculture at Washington, D. C., through whose efforts the Bahia navel orange was successfully introduced from Brazil in 1870. Three years later trees propagated by Saunders were planted in California and, under the name of Washington Navel, became the basis of an epoch-making industry.

In 1870, through the kind assistance of a missionary stationed at Bahia, Saunders imported from Brazil 12 navel orange trees in tubs. These were housed in the Department greenhouse at Washington, and propagations were made for distribution to the regions adapted to citrus culture. The first propagations were sent largely to Florida and California, but at least one of this lot is still maintained by the Department at Washington. Mr. and Mrs. Luther C. Tibbets were attracted to the settlement at Riverside, Calif., and early in 1873, before starting her journey, Mrs. Tibbets visited the Government propagation gardens at Washington, where Mr. Saunders gave her two Bahia navel trees. These were carried to California and planted beside the Tibbets' cottage in Riverside (fig. 10). In February 1879 the fruit was awarded first prize over other navels exhibited from Orange County, and these two trees were used as the source of extensive plantings. The variety was referred to as the Washington Navel to distinguish it from the Australian importations. An attempt was made to change the name to Riverside Navel, but this proved

unsuccessful. The great superiority of the Washington Navel (fig. 11) was soon recognized, since it apparently was ideally adapted to the climatic and soil conditions of California and produced a fruit of high quality with the highest market appeal. The best strain of Washington Navel, according to Shamel and associates (*61*), is characterized by an—

> open and somewhat drooping habit of growth and dense foliage with large, oval, dark-green leaves. * * * Under normal conditions no pollen is produced by the anthers of the flowers. * * * The fruits * * * are obovoid in shape and generally of medium to large size. The rind is of medium thickness, and the texture is smooth and grained. The color of the fruit is bright orange; the rag is tender and comparatively small in quantity; the juice is abundant and of superior quality, having a pleasing and sprightly subacid flavor. The fruits are seedless, and the navel usually is small, sometimes rudimentary, with no development except in the rind.

By 1885 enterprising nurserymen had introduced most of the important varieties of the world, which were tested in comparison with the local seedlings of special merit. Less profitable varieties were rapidly eliminated, and by 1900 the area planted to the Washington Navel was larger than that of all other varieties in the State. It is now generally recognized that one of the outstanding events in the economic and social development of California was the introduction of this orange in 1873. During the period of more than 60 years following, a great industry has been built up from the two small trees planted by Mrs. Eliza Tibbets.

The Valencia variety of sweet orange, introduced into California and Florida between 1870 and 1872 as already detailed, is the other outstanding orange variety in the State. These two varieties are grown almost to the exclusion of others. Climatic conditions vary widely because of differences in rainfall, protection by mountain ranges, the moderating influence of the ocean, and other factors. These affect the ripening period of fruit varieties so that the same variety matures at different times in various regions. When this is coupled with "tree storage" in the case of the Valencia, which holds its fruit in good condition for several months, the combination results in a marketable fruit crop throughout the year. This tree storage is made possible by the dry summer climate with comparative freedom from fruit-destroying fungi, together with other climatic factors contributing to a long ripening season. The movement of Washington Navels begins in November and ends in May. The Valencia crop is marketed from May to November and, as a rule, overlaps by several weeks the period when navels are shipped.

Frost (*21*) reports that the Citrus Experiment Station of the University of California, at Riverside, has recently introduced a good early nonnavel variety, Trovita, which has pollen and a few seeds. This variety originated as one of three seedlings grown from Washington Navel seeds accidentally found. It is pointed out that this may be a promising variety in the hotter citrus districts because of its seeding tendency, since the seedless Washington Navel often fails to set fruit under these conditions. The fruit of the new variety is much like that of Washington Navel, but the navel structure is usually absent or rudimentary.

Figure 10.—Tree of the Washington Navel orange at Riverside, Calif., the lone survivor of the original budded trees of this variety sent to California in 1873, propagated from the introduction made in 1870 from Bahia, Brazil, by William Saunders, Washington, D. C. A tablet in memory of Mrs. Eliza Tibbets, who first planted this navel orange and brought it to fruiting, stands near the tree.

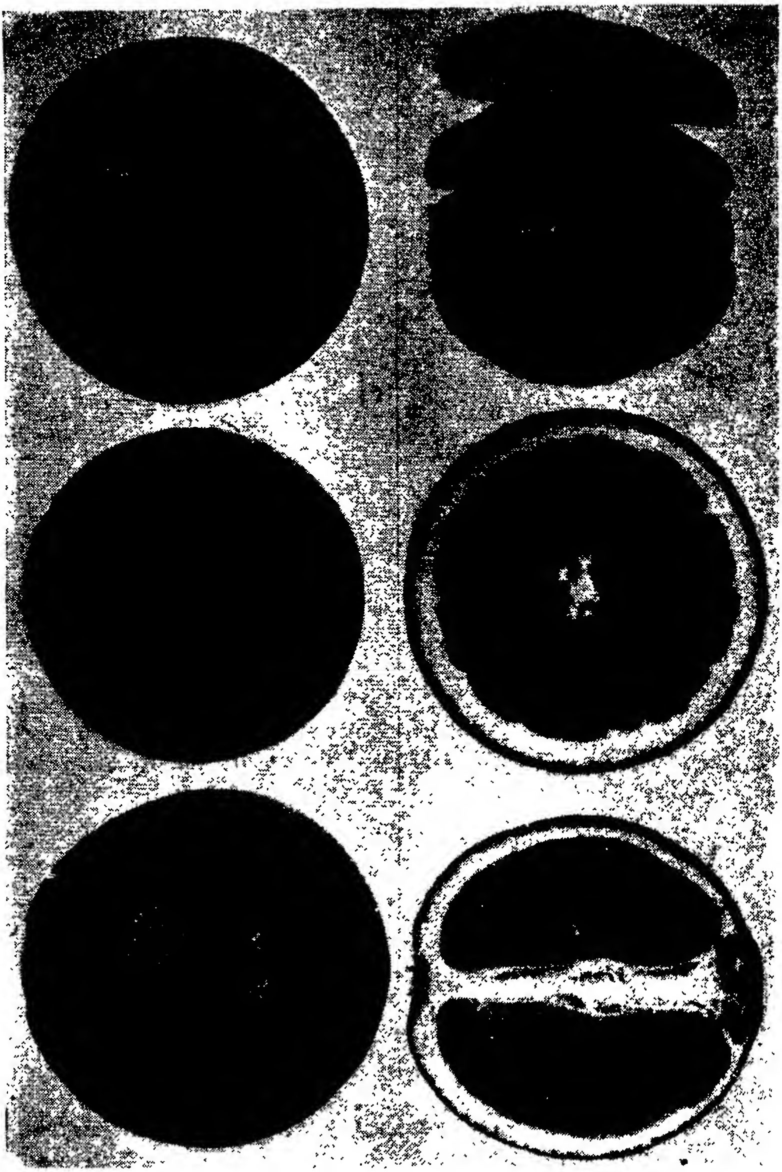

Figure 11.—Washington Navel orange fruit, typical of the variety as grown at Riverside, Calif., showing solid but juicy pulp, locules separating easily, firm, rather thick rind, small navel, and absence of seeds.

Texas

The commonly grown varieties of sweet oranges, along with other varieties of citrus, were brought into the lower Rio Grande Valley of Texas early in the twentieth century, but in general these are not as

well adapted to the climate as the grapefruit. The most desirable early to midseason variety of orange is the Hamlin. The trees are prolific, regular bearers under lower Rio Grande Valley conditions, maturing their fruit in October. Although the Pineapple is the most widely planted early variety, the Weslaco substation of the Texas Agricultural Experiment Station recommends that Hamlin and Joppa should replace varieties such as Pineapple, Parson Brown, and Ruby, which are characterized in Texas by the production of undersized fruit and by erratic bearing habit (*16*). Even the desirable strains of Washington Navel are not satisfactory, being "rather erratic in their bearing habits" and producing juice "variable in flavor, often being quite insipid (devoid of acid)." A recent introduction, one of several navel oranges brought by the Department from Brazil and now under test at the Weslaco substation, is very promising. It has been named Texas Navel (fig. 12) and is being tried extensively by growers. The tree is vigorous and somewhat more productive than the strains of Washington Navel under Texas conditions. The fruit is typically navel in structure, of medium size and good quality.

The Valencia, which matures its fruit from December to January under lower Rio Grande Valley conditions, is the "most profitable commercial variety at the present time, since the trees are productive and fairly regular in bearing, but a large proportion of the fruit, which are of good quality, is undersized."

The Temple orange, which belongs to the horticultural group of high-quality hybrid fruits (tangelo oranges) and is similar to the sweet orange, is promising under Texas conditions, but the rind texture is unattractive and the tree is not hardy. In this same group the Orlando, Seminole, Minneola, and Umatilla varieties are under test.

As far as the standard varieties of sweet oranges are concerned, none is entirely satisfactory under lower Rio Grande Valley conditions.

Louisiana

In the extreme southern tip of Louisiana on the Delta of the Mississippi, south of New Orleans, in the vicinity of Buras, a type of high-quality nonnavel sweet orange of local origin has been grown for a great many years along with some navels of recent introduction. The annual output is usually about 300 cars, marketed primarily in New Orleans.

Grapefruit Improvement

The origin of the grapefruit as a horticultural citrus type is obscure. It is apparently intermediate between the large acid shaddock and the mild salad citrus type commonly referred to as the pummelo. It was brought to Florida from the West Indies and does not correspond to any type in the Orient. It was not appreciated until it was brought to the attention of the consuming public in the 1880's by enterprising Florida citrus growers. It represents a most important horticultural achievement, for it is now found on the breakfast table in either the fresh or the canned state not only in the United States but also in Europe, South Africa, and Australia.

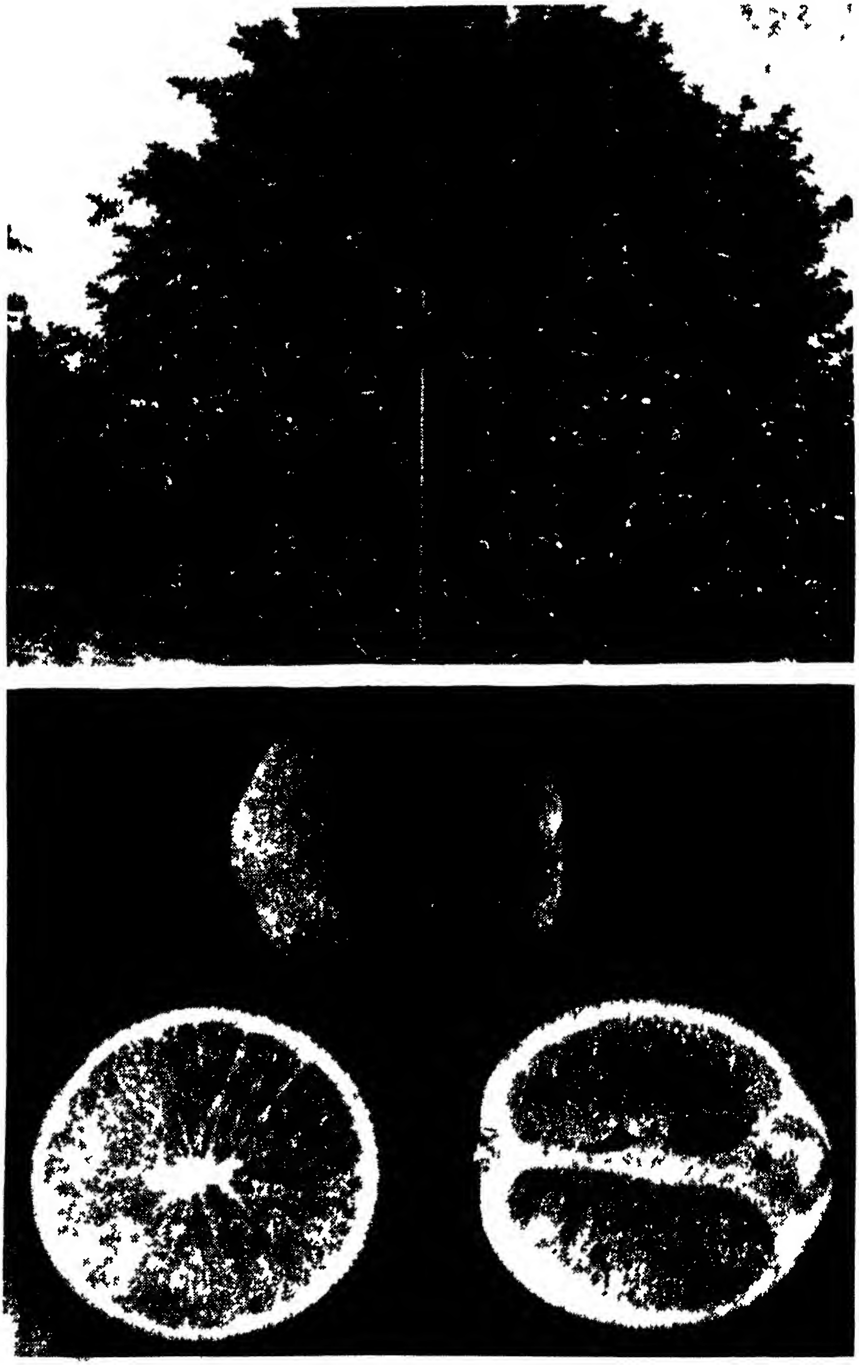

Figure 12.—See legend on opposite page.

Florida

The grapefruit industry in Florida was founded originally on seedling trees, which are very much like the Duncan variety in structure and quality and are now known as Florida Common. The original Duncan tree, over 100 years old in 1926, according to Hume (*32*), was still living in the planting known as the Snedicor Grove near Green Springs, in Pinellas County, where it originated as a seedling from a grapefruit tree grown by a Spanish settler, Don Philippe. Later reports are not available. Duncan (*14, p. 136*) stated in 1892 that Don Philippe brought grapefruit and orange seeds from Cuba 50 years previously and made his planting at Safety Harbor in "Philippe Hammock", and that the orange trees died out from neglect while the grapefruit trees remained in a thrifty condition. The variety was introduced and propagated by A. L. Duncan, of Dunedin, about 1892. It is a very superior variety. Although 17 or more main varieties were later introduced, Duncan remained the favorite among the seedy varieties. Duncan and other seedy varieties are now being top-worked to Marsh in some instances because of the demand for a seedless fruit.

Figure 13.—Egbert N. Reasoner (1869–1926), pioneer nurseryman of Florida, active in the introduction and propagation of many subtropical fruits. He introduced Foster, Thompson, Pernambuco, and Royal grapefruit varieties and the Oneco tangerine, initiated the commercial propagation of the lychee, and was active in testing and disseminating new varieties of mangoes and avocados.

Because of its seedlessness and other desirable qualities the Marsh variety has been gradually replacing the seedy varieties in plantings within the last 15 years. This variety originated in the William Hancock grove at Socrum, near Lakeland, and was first cataloged by C. M. Marsh in the Catalogue of the Lakeland Nurseries for Fall 1896 and Spring 1897, with the statement that the parent tree was a seedling that had been a prolific bearer for 30 or 40 years. Propagation evidently began some years before, as the parent tree was killed in the freeze of 1894–95. A story receiving credence in

Figure 12.—The Texas Navel orange. *A*, Tree showing vigorous habit of this navel variety, an introduction from Brazil made by the United States Department of Agriculture in 1917 when the Washington Navel proved poorly adapted to lower Rio Grande Valley conditions. The tree has a height of 20 feet and a spread of 21 feet. *B*, Fruit of the Texas Navel orange, which resembles the standard Washington Navel in physical characteristics and quality but is more prolific under conditions in southern Texas. Fruits average 2¾ inches in diameter.

138904°—37——50

recent years that the variety originated as a broken root sprout from a common seedy type tree has been definitely disproved by the testimony of members of the Hancock family and other local residents who were thoroughly familiar with the original seedling tree (*56*).

The Marsh variety has given rise to two pink-fleshed bud mutations. A. D. Shamel has described one of these that originated near Riverside, Calif., and was brought to his attention in July 1919 by L. V. W. Brown. The mutation that occurred in Florida, in the grove belonging to W. B. Thompson near Oneco, was discovered by S. A. Collins and introduced under the name of Thompson by Reasoner Bros. (fig. 13), of Oneco, in 1924 (*55*). Both of these mutations are identical with Marsh except in flesh color. The Thompson variety, although not extensively planted in Florida, has become an important variety in the lower Rio Grande Valley of Texas.

The Foster, another pink-fleshed variety, originated as a branch mutation on a tree of the Walters grapefruit. This occurred in the Atwood Grove near Palmetto, and was first observed in the season 1906–07. It was named and introduced by Reasoner Bros. in 1914. Aside from the color, the fruit has much the same quality as the parent variety, though it is sometimes regarded as earlier maturing. The color of the pulp, as well as that of the Thompson, tends to fade as the fruit reaches full maturity.

Another seedless grapefruit, the Davis, originating from a cross between a seedling type of grapefruit and a tangerine (in the attempt by Department workers to secure a tangelo) is receiving favorable attention. In shape and size it resembles the Marsh, though it is more rounded in form, but it has the taste quality of the seedy grapefruit, with apparently less glucosidal flavor than the Marsh. Its outstanding character, however, is the fact that it has proved satisfactory for canning, the pulp remaining firm, while the Marsh tends to become soft from processing (*34*).

In the improvement of grapefruit there has been a steady trend toward the use of fewer varieties, and Marsh, largely because of its seedlessness, has become the standard for new plantings, gradually superseding the 17 or more other varieties—Aurantium, De Soto, Excelsior, Hall, Josselyn, Leonardy, Manville, May, Bowen, McCarty, McKinley, Inman, Pernambuco, Royal, Triumph, Walters, etc.

Texas

The Florida grapefruit varieties were introduced into California, Arizona, and the lower Rio Grande Valley of Texas.

The grapefruit is apparently well adapted to the lower Rio Grande Valley, and it has served as the basis of a citrus industry built up since 1910. As grown in the valley it has "a pleasing, mild flavor that has met with favor in most of the markets where the fruits have been offered for sale" (*16*).

Such varieties as Duncan, Conner, McCarty, Inman, and Walters, all seedy varieties, are grown to a limited extent for the early market, but they are at a discount after the seedless variety, Marsh, is ready for market.

The pink-fleshed varieties Foster (seedy) and Thompson (seedless) have pink flesh early in the ripening season and usually sell at a

premium. The Ruby, a local mutation from Thompson, has both pink flesh and pink rind and is receiving some attention in recent plantings.

California and Arizona

The grapefruit industry in the Southwest began after the introduction of the Marsh grapefruit in 1890; the plantings of other varieties previous to that time did not prove profitable. In the Arizona citrus districts and in the Coachella and Imperial Valleys of California, grapefruit matures fairly rapidly and is marketed in late fall and early winter; in other California grapefruit districts it does not reach full maturity until the following spring or summer.

Mandarin Improvement

In the mandarin orange group the tangerine and satsuma oranges are grown to supply special markets, primarily early in the season. The chief breeding problem is in connection with the production of high-quality early-maturing varieties.

Tangerine Orange

The only variety of tangerine orange extensively planted in Florida is the Dancy, a prolific variety that was originated as a seedling by George L. Dancy, of Buena Vista, St. Johns County, and was introduced in 1871 or 1872. This variety is of great interest, since it is the pollen parent of most of the tangelo oranges, and it imparts to the best tangelos the deep orange rind and flesh color and the aromatic and pleasing ester qualities. In Texas, although the earlier plantings are mostly Dancy, the Clementine (Algerian) is decidedly superior to this variety, as is also the Warnuco (Ponkan) under lower Rio Grande Valley conditions.

In California the Dancy is grown to a limited extent for special markets, but apparently the small size and higher acidity developed when it is grown in this section has retarded extensive planting. Recently three mandarin varieties, developed by Frost (*21*) at the Citrus Experiment Station, Riverside, have been introduced for preliminary trial. They were originated as a first-generation cross between the King orange and other mandarin oranges. In the case of the Kara, the Owari satsuma was the seed parent, and in the case of the Kinnow (fig. 14) and Wilking, the King orange served as the seed parent and the Willowleaf mandarin was the pollen parent. These varieties produce fruits of good size and excellent quality, but, as pointed out by Frost, only orchard tests can determine their ultimate value in citrus culture.

Satsuma Oranges

The satsuma orange was first introduced into Florida by George R. Hall in 1876. In the upper Gulf coast region, from western Florida to eastern Texas, it has been grown commercially since 1910, and the industry is based primarily on the Owari satsuma. Although there are apparently two or more strains of this variety, they do not differ widely. The fruit is harvested early in the season, October and November. It is desirable to harvest as early as possible for two reasons—to secure the early market before many high-grade sweet

oranges are shipped from peninsular Florida, and to remove the fruits early enough to allow for the storage of maximum food reserves in the tree before the onset of winter. In an attempt to meet this need, the Department of Agriculture imported over 50 strains of the early-maturing satsuma from Japan, and these are under test at the Gulf Coast Substation at Fairhope, Ala., in cooperation with the

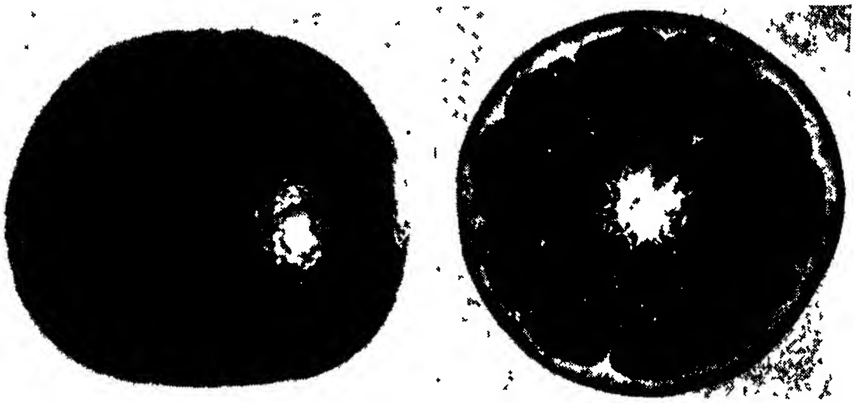

Figure 14.—The Kinnow mandarin, a hybrid of King orange and Willow leaf mandarin, the King serving as the seed parent. The fruit is excellent in appearance and flavor, remaining firm when fully ripe; desirable for local consumption but shipping quality undetermined. Fruits shown are natural size, about 4½ months after ripening. Introduced by Frost, of the California Agricultural Experiment Station.

Alabama Agricultural Experiment Station and with growers in various parts of this section. So far the Kawano variety has shown some promise, but it does not uniformly mature earlier than the Owari. Some of the other strains may prove more regular in this respect.

A selection from extra vigorous apogamic seedlings following cross-pollination of the satsuma orange with the sweet orange is promising from a commercial standpoint. The Silverhill variety, originated in this manner, has now been tested for a number of years and appears to be a superior strain of the Owari. It has shown somewhat more resistance to cold than the other satsuma varieties, but the evidence is not conclusive.

Improvement of Acid Citrus Fruits

The chief center of lemon culture is in California, and lime production is confined primarily to Florida.

Florida

The introduction of the citrus scab proved a serious drawback to lemon culture in Florida. There is also great difficulty in properly curing lemons in the humid summer climate. In 1931 the Department introduced the Perrine lemon (fig. 15), a hybrid between the Genoa lemon and the Mexican or Key lime. It is highly resistant to citrus scab and anthracnose and has given a new impetus to the industry.

The Perrine lemon is a rapid-growing, vigorous, and productive tree. The fruits are borne singly or in clusters and are of medium size, with a high acid percentage, ranging from 6.2 to 7.2 percent, ranking with standard commercial varieties in this respect (*71*, *80*).

The Meyer lemon, an introduction from China named for the introducer, the late Frank N. Meyer, famous plant explorer for the Department of Agriculture, is chiefly noteworthy for its frost resistance.

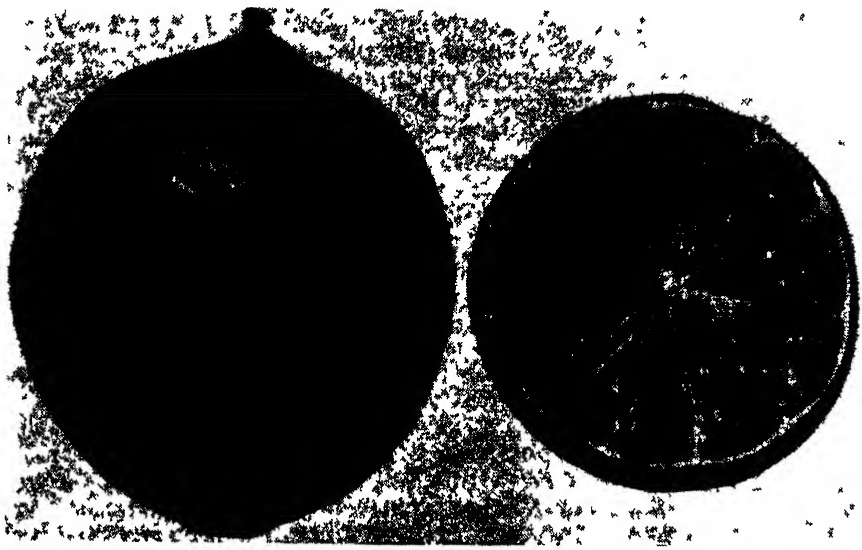

Figure 15.—Typical fruits of Perrine lemon, a hybrid between the lemon and the lime; remarkable for its resistance to scab and anthracnose, vigor of growth, and heavy bearing. Resembles the true lemon in shape, size, and acid content. Introduced by the United States Department of Agriculture.

Its low acid content (4.3 to 4.8 percent), large size, and round shape preclude its general popularity as a commercial lemon, though it is well suited to local needs where true lemons have proved too tender

The Key, Mexican, or West Indian lime has long been cultivated primarily on the keys, but recently the industry has declined because of hurricane damage. The Tahiti (also called Persian or Bearss) lime has recently been planted to a considerable extent in Dade County and the southern ridge section. It has high quality, and in addition the aromatic properties of the rind are highly valued by the consumer The Lakeland and Eustis limes, hybrids of lime and kumquat, introduced by the Department, although of high juice quality, are of small size and have a thin rind, which may prove disadvantageous for storing and shipping.

California

In the early development of the industry a large number of European varieties of lemon were grown and also many seedlings were raised, most of which were not promising. The present plantings are practically limited to Eureka and Lisbon. The former originated from a seed planted in 1870 by C. R. Workmen in Los Angeles. The Lisbon

variety originated in Europe. Shamel and coworkers (*64*) state that the Lisbon lemon was introduced into California in a number of importations, the first of which was made as budded trees in 1874 and 1875 from Australia. It has been pointed out that the advantages of the Eureka are its comparative freedom from thorns, its tendency toward early bearing, and its prolific bearing qualities. The tendency to bear fruit on the tips of the branches and the inclination to grow long canes with but few laterals and to drop its leaves on the long canes or branches, leaving the limbs and fruit too much exposed to the hot rays of the sun, are disadvantages.

The Lisbon has heavy foliage, which protects the fruit from sunburn, and the fruit is borne uniformly throughout the tree. This variety has a tendency to bear one large crop maturing in winter, with only a small amount of summer fruit.

MINOR CITRUS FRUITS

In the United States the pummelo, citron, kumquat, and sour orange are not grown to any appreciable extent for their fruits. Of these minor citrus fruits the pummelo is the most promising. The citron is grown mainly for exhibition purposes, although a beginning has been made in California with preserving it on a commercial scale. The sour orange is grown as an important marmalade fruit in some other citrus-producing countries, notably in Spain

The pummelo in its better varieties is a most delicious salad citrus. The juice does not possess the sprightly acid and naringin (bitter) properties of the grapefruit, but when the juice sacs are served as a salad the inimitable flavor is relished by all who have had the good fortune to sample them. In times past only the sour shaddock was known in the citrus-producing districts, but since 1915 the Department of Agriculture, through its collaborator, G. Weidman Groff, in China, has introduced an important collection of pummelos. These are not as yet well known but are being distributed to those interested in the culture of the fruit. One of the outstanding varieties is named Siam. Reference to this collection will be found in table 5.

The Department has also imported a valuable collection of citron varieties, including practically all of the important ones. Corsican, the chief variety of commerce, was one of the first citrus introductions made by Fairchild, who was for many years in charge of the plant introduction work of the Department.

Kumquats were introduced into Europe as recently as 1846 by Robert Fortune. Importations into the United States were made by Taber in 1885 and Reasoner in 1885 and 1890. The varieties Nagami (oval) and Marumi (round) were first introduced, and later the Meiwa or sweet kumquat. The Nagami predominates in all plantings made thus far. About 1910 the Department introduced the Hong Kong or wild kumquat, which produces very small round fruits and is of interest from the breeding standpoint in that it has the double haploid chromosome complement. (See the later section on cytology in this article.)

The Department has introduced a superior variety of sour orange named Oklawaha. It originated as an apogamic seedling when pollen of the shaddock (sour pummelo) was used to pollinate the sour orange.

In habit the tree appears as a vigorous sour orange. The fruit is similar to the ordinary sour orange but averages larger in size, 3 to 4 inches in diameter, and it is superior to the ordinary seedling sour oranges as a marmalade variety.

CITRUS BUD SELECTION

WITH the general acceptance of De Vries' mutation theory (1901), the improvement of varieties by the selection of bud mutations soon became a recognized mode of procedure in plant breeding. Conversely, the elimination of inferior bud mutations became of equal or even greater importance in many clones especially subject to mutations.

That the Washington Navel orange is subject to bud mutation was recognized at an early date, and by 1910 the problem was so serious that at the California State Fruit Growers Convention of that year Coit (*10*) proposed to "keep individual tree records for 2 years and these trees with records to be offered nurserymen for propagation as pedigreed trees." At the same meeting Coit, in discussing the application of the De Vries mutation theory to the problem, said:

> If you go out into the average navel orchard to select a dozen perfect navel oranges true to old standards, you will be surprised at the amount of searching necessary. * * * It is my belief that by far the greatest part of the divergence is attributable to mutation * * *.

He added that propagators—

> must be quick to see and cut out all branches sporting toward poor types. In the second place, we must be exceedingly careful in cutting budwood. * * * Select buds from those branches which produce your ideal of the navel orange.

The problem was so serious that the Department of Agriculture detailed A. D. Shamel to study it in 1909, and he began his work in cooperation with the California Citrus Experiment Station at Riverside and with citrus growers. In his first report entitled "Bud Selection in Citrus Fruits", given at the California State Fruit Growers Convention at San Bernardino, March 8, 1911, Shamel set forth the problem clearly. His work began with the Washington Navel and was extended to include other sweet oranges, the lemon and grapefruit types, as well as other crop plants.

Over a period of 27 years the work of Shamel and his coworkers (*57, 58, 59, 60, 61, 62, 63, 64*) has been characterized by consistent, painstaking research, which has included a study of the source of strains originating as bud mutations and unintentionally propagated by nurserymen and growers. This was followed by efforts to eliminate the inferior trees in established plantings by top-working with carefully selected buds. Further efforts were made to avoid the propagation of undesirable strains arising from bud mutations by systematic selection on the basis of individual plant performance and an intimate knowledge of the plants. Finally, a systematic search was made in cooperation with growers for superior plants originating from commercially valuable bud mutations, and these were tested in progeny plantings to single out the ones inherently superior to the parent forms for utilization by the industries concerned.

In the case of Washington Navel orange it has been shown (*61, p. 67*) on the basis of individual performance records made in several California groves since 1909 that—

these groves consist of at least 20 strains of commercial importance with five or more others of less economic consequence. The trees of each of these strains have fruit or vegetative characteristics, or both, which serve to distinguish them from all other trees of the variety.

About 25 per cent of the total number of trees studied in the original orchards in which these investigations have been conducted were found to be of undesirable strains having consistently low yields, or bearing fruits of poor quality, or both, such as those of the Australian, Unproductive, Corrugated, Pear-Shape, Sheep-nose, Flattened, Dry, and other inferior strains.

The extent of the commercial use of superior strains selected for the production of more uniformly good fruit is indicated by the sale of selected buds by the Fruit Growers Supply Co. for the period 1917–35. These data, given below, include only a part of the supplies of such buds used by nurserymen and growers-- probably not more than 50 percent; but because they are conservative they will the better convey some idea of the value of this kind of work.

Name of strain	*Number of buds sold*
Superior strain of the Washington Navel orange	1, 402, 950
Superior strain of the Valencia orange	2, 338, 004
Superior strain of the Marsh grapefruit	1, 262, 757
Superior strain of the Eureka lemon	766, 950
Superior strain of the Lisbon lemon	86, 215
Superior strains of miscellaneous citrus varieties	66, 886

Two special citrus strains originating as bud mutations, the Robertson Navel orange in 1925 and the Dawn grapefruit in 1929, are now being introduced, and the indications are that they will be widely grown in certain citrus districts of California and Arizona. In the Robertson Navel orange strain the fruits are resistant to June drop on account of their very rapid early growth. They mature about 1 month earlier than those of the Washington Navel orange under comparable conditions, and the trees are more productive than the normal Washington Navel. Otherwise the mature fruits of the Robertson strain and those of the parent variety are very similar and cannot be distinguished even by those who have grown and studied them.

The Dawn is a strain of the Marsh grapefruit in which the fruits mature about 1 month earlier than those of the parent variety, and the trees are unusually productive. Otherwise the Dawn and the Marsh trees and fruits have similar characteristics. The indications are that this strain will be a particularly valuable one for growing in the desert grapefruit-growing districts.

Many other citrus bud mutations are under test in cooperation with growers in California and Arizona, and some of these promise to be of commercial importance in the near future.

In the history of subtropical fruit breeding the work of Shamel, his coworkers, and the California Agricultural Experiment Station cooperators is inspiring. It is characterized by consistent, painstaking research and unwavering purpose. In the earlier years, although the work was fully appreciated by the growers in the region, scientific workers elsewhere did not give entire credence to the remarkable evidence uncovered. As time went on, Shamel and his coworkers answered their critics by applying statistical methods to the data, which gave convincing proof of the conclusions. Later, numerous bud mutations were also discovered in other fruit types, including apple, and by the time the work was no longer challenged the results

achieved stood out as monumental in this particular field of research. The practical benefits to the industry can be gaged by the millions of selected buds that have been used by the citrus growers in California and elsewhere. A summary of the bud mutations and strains isolated by Shamel and his coworkers is to be found in table 8.

In Florida a bud-selection project has been in progress since 1921. The mode of procedure differs somewhat from that followed in California and was developed cooperatively by the Florida Agricultural Experiment Station and the Department of Agriculture. At the Lake Alfred Citrus Experiment Station a progeny grove has served as the basis of variety improvement. In this progeny grove standard varieties of oranges and grapefruit are represented by rows budded from parent trees of known production, several such selected parents being included for each variety. Production records have been kept, and a detailed study of fruit characteristics has been made as the basis for reselection among the original progenies. For purposes of comparison a few offtype progenies have been included, which have served well to illustrate the importance of careful bud selection in nursery propagation. Growers and nurserymen have gradually come to realize the value of such true-to-type budwood, which has been made available through the experiment station for several seasons past at a cost not greatly in advance of common commercial rates.

Other bud mutations of value to the citrus industry are Foster, Thompson, Ruby, and Davis grapefruit (described above), Silverhill satsuma orange, and Oklawaha sour orange, the three latter being seedling or nucellar mutations

ROOTSTOCKS

A NUMBER of citrus types and varieties are of major importance because of their value as rootstocks for the varieties grown commercially. In the early development of the citrus industry, especially in Florida, seedling citrus trees were extensively planted, but gradually this practice was discontinued, as it was realized that certain rootstocks were better adapted to the soil conditions. This advance was made by the expensive trial-and-error method, and the stage reached by the 1890's was recorded by Van Deman (*81*). Planned experiments with rootstocks have been relatively rare. In California, Mills (*46*) has reported results secured at the experiment station at Pomona, and Bonns and Mertz (*3*) described the experiments carried out at the Citrus Experiment Station at Riverside. The important work of Webber (*85*) at the citrus station is an illuminating piece of research into the seedling variation of the types commonly used as rootstocks. Unfortunately, the work of Taber (fig. 16) quoted by Hume (*31, pp. 209–218*) at the Glen St. Mary Nursery in Florida was discontinued too soon. Traub and Friend (*77*) have reported on preliminary experiments in the lower Rio Grande Valley of Texas. Akenhead, Feilden, and Hatton (*1*) have recently summarized the investigation on citrus rootstocks.

As indicated, the horticultural utilization of rootstock types is based at present mainly on the knowledge accumulated through many years of trial and error. The final results are very valuable, though they were secured at great economic expense. The entire field has not been exhaustively explored.

In general it may be stated that in Florida, as pointed out by Camp (4), the rootstock problem is more complex than in the lower Rio Grande Valley of Texas, in California, or in Arizona.

Three major considerations are necessary in the choice of suitable rootstock—congeniality between stock and scion, resistance to diseases, and adaptation to the soil and climatic conditions. Rootstocks have been tested over a considerable period by commercial growers, and at the present time only three are extensively used—sour orange, rough lemon, and the trifoliate orange. The Cleopatra mandarin has recently received some attention as a rootstock. In Florida, trees on grapefruit stock grow vigorously in the early stages but usually prove to be shy bearers and show decline after a number of years. Sweet orange is susceptible to foot rot, and both grapefruit and sweet orange are less cold-resistant than sour orange. The commercial lemon is susceptible to diseases, and trees on it are short-lived. The citrange has been tried as a substitute rootstock in place of the trifoliate orange for the satsuma orange, but recent observations have shown that the citrange is not reliable in the Gulf coast region, since it is evergreen and does not go dormant sufficiently during the winter season. This has resulted in the loss of the scion variety in some seasons.

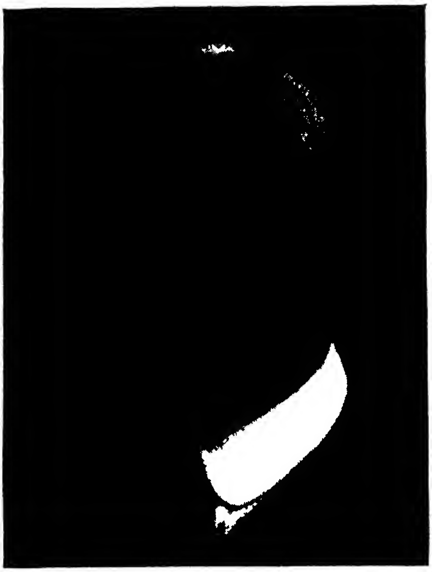

Figure 16.—George Lindley Taber (1854–1929), pioneer nurseryman of Florida, who demonstrated the limitation of the satsuma orange to trifoliate orange stock, founding a new industry; introduced Duncan grapefruit, Lue Gim Gong sweet orange, and varieties of persimmons, and cooperated with the United States Department of Agriculture in the production of early citrus hybrids.

The sour orange is a useful stock in all citrus-growing regions except South Africa, where all attempts to use it so far have failed. It is compatible with most citrus types except satsuma, kumquat, and lime. In California, lemon trees on this stock may show decline after 10 to 20 years, which has been attributed to the stock. For this reason many of the recent lemon plantings in California have been budded on the sweet orange. The sour orange is highly resistant to cold and to root and crown bark diseases, but highly susceptible to citrus scab. Roots are deeply penetrating, and the stock is well adapted to clay subsoils and wet or heavy soils. In Florida it is successful on moist hammock as well as on moist flatwoods soils and on the heavier soil types in general. In California, Arizona, and the lower Rio Grande Valley of Texas it tolerates irrigation conditions. This, together with its adaptability to southwestern conditions, has made it the rootstock almost universally used in these regions. Its

main drawback is its relatively slower growth on light soils as compared with rough lemon, but on heavier soils the rate of growth is satisfactory.

The rough lemon (*Citrus limonia*) makes a satisfactory growth even on very light and sandy soils. This makes it valuable in certain sections of peninsular Florida. It is highly susceptible to citrus scab and susceptible to foot rot and other root and crown diseases, but this apparent handicap is minimized, for on sandy soils these diseases are less troublesome than on the heavier ones. It is extensively used as a rootstock for citrus on soil types not suitable for sour orange in Florida. It is not well adapted for use with the satsuma orange, producing coarse, raggy fruit.

The trifoliate orange was once recommended as a rootstock for citrus in the lower Rio Grande Valley of Texas (*48*), chiefly on account of cold resistance; but it proved susceptible to foot rot and cotton root rot and was later discarded in favor of the sour orange (*77*). In the upper Gulf coast region it is universally used as a root stock, since it is deciduous and goes more dormant during the winter season than evergreen citrus types. It is the hardiest of the citrus types.

Recently the Cleopatra mandarin has been recommended as a rootstock in place of rough lemon, chiefly on the basis that it is more cold-resistant than the rough lemon and tends to produce better textured fruit, holding fruit later in the season in good condition. It is immune to scab and resistant to gummosis. However, experimental work has not been carried out extensively enough to warrant unqualified recommendation.

It has already been pointed out that most citrus seeds produce more than one seedling, and that any extra seedlings not of seminal origin are produced by budding from the mother plant tissue. On the surface it would appear that this is an ideal condition from the standpoint of seedling rootstock production, since it would give a large percentage of plants like the original stock, and this is true in the main. Webber (*85*) and Frost (*20*) have shown, however, that variations may occur even among such nucellar seedlings. Frost points out the influence of mutations in this connection. The work of Webber is of special interest. His experiments, which were started in 1914, show that—

> citrus seedlings of the species and varieties most commonly used as rootstocks exhibit a wide range of variation. In any lot of seedlings grown from seed of the same variety and from the same source, the great majority usually are of the same general type, but from 5 to 40 per cent of them are highly variable types which apparently differ in genetic constitution from the prevailing type and from each other.

These variants may include both apogamic and seminal seedlings. They are usually small and lacking in vigor and when used as stocks induce dwarfing of the tree. His experiments show that small seedlings and "small budlings tend to produce small, low-yielding orchard trees; and that large seedlings and large budlings tend to produce comparatively large, high-yielding orchard trees." In order to secure the desired uniformity in orchard trees, Webber advises "a moderate culling of small seedlings at the seed bed, followed by a careful roguing and destruction of all variants and small seedlings in the nursery just prior to the budding."

CITRUS IMPROVEMENT IN FOREIGN COUNTRIES

This section, like the similar sections in connection with other subtropical fruit crops, is based almost entirely on replies received to the questionnaire dealing with the Cooperative Survey of Plant and Animal Improvement. The information received mainly concerns the present and future objectives of breeders.

Mexico

Citrus studies are carried on at experiment stations of Montemorelos, Nuevo Leon; El Yaqui, Sonora; and Emporio Macuspana, Tabasco. Infestation of fruit by the orange maggot, *Anastrepha ludens* Loew, constitutes the most serious problem. Methods of attack are being studied, but without practical results thus far.

South America

At the Instituto Agronomico do Estado de São Paulo in Brazil, work with citrus under the direction of C. A. Kruge, head of the genetics department, is being confined primarily to the improvement of varieties by bud selection and to the improvement of the sour orange rootstock by making extensive progeny tests. The disease resistance of rootstocks is also being studied.

In Chile no breeding work with subtropical fruits is under way at the experiment stations, but Salvador Ezquierdo at Santiago has for many years introduced varieties of citrus, avocados, etc., to test their adaptability to Chilean conditions.

At the Estacion Experimental de Concordia, Argentine Republic, Signor Ruben Bence Pieres, director of the station, is conducting experiments with citrus which concern the selection of sour orange seedlings, with a view to obtaining strong, vigorous, fast-growing plants. A naturally occurring hybrid mandarin named Malvasio, with a large fruit, fine rind color, excellent quality, and late maturity, is being tested and shows promise of commercial value. The main introduced varieties, which have been selected from a large number and are being extensively cultivated, are the Marsh and Qurian grapefruit and the Valencia and Lue (Lue Gim Gong) sweet oranges. The cultivated area of grapefruit and sweet oranges approximates 5,000 acres, with about half devoted to each type. The main problem that confronts the citrus industry is the ravages of foot rot. Work is in progress for the selection of resistant stocks, as indicated above.

Europe and North Africa

At the Estacion Naranjera de Levante at Burjasot, Valencia, Spain, work has been carried on in sweet orange breeding since 1927 under the direction of Manuel Herero. The work has been confined mainly to selection from open-pollinated seedlings of Washington Navel. Two improved varieties have been selected, one round and the other oval in form. These are being cultivated to the extent of about 375 acres. Hybridization work was begun in 1932 and is being carried on to the second generation after crossing. The crosses made are those between the sweet orange and the mandarin.

A. Biraghi, pathologist, Italian Department of Agriculture, Rome, reports that the chief problem with citrus culture in Sicily is in con-

nection with the disease mal secco, chiefly affecting lemons. Attempts are being made to breed varieties resistant to this disease. Two resistant lemon varieties of unknown origin and not desirable for quality have been found locally, and promising varieties have been imported from India (*2*) and the United States for use in breeding experiments.

At the Superior School of Agriculture, Laboratory of Horticulture, Athens, Greece, P. Th. Anagnostopoulos has gathered together a collection of citrus species for selection and breeding work.

In Morocco, under the leadership of F. Lacarelle, director, and Ch. Miedzyrzecki, geneticist, Experimentation Fruitière et Maraichère, Rabat, citrus fruit improvement is being studied through several methods: (1) Bud selection, (2) hybridization to secure improved varieties and varieties resistant to disease, and (3) selection of stocks. The varieties receiving the most attention are Washington Navel, Valencia Late, and Clementine. A special study of the seed content of the Clementine led to the conclusion that seed production is largely dependent on the proximity of other varieties, especially of mandarin oranges, to furnish pollen to the flowers of the Clementine, self-fertilized flowers being almost seedless (*38*, *39*).

Asia and Malaya

At the Jewish Agency Agricultural Research Station, Rehoboth, Palestine, the experimental work was started by J. D. Oppenheim and is now being continued by Ch. Oppenheimer. The work is confined primarily to improvement by bud selection, which was begun in 1934, and by hybridization, begun in 1933. The first-generation hybrids have not reached fruiting stage. The hybrids are from crosses of the Jaffa orange with other early and late varieties, of the blood orange with the tangerine, and of the sour orange with the sweet lime. The station has gathered together a collection of about 70 citrus varieties.

Theoretical studies are under way on the inheritance of peel thickness in citrus and on the effect of pollination on number of seeds.

At the Imperial Horticultural Experiment Station at Okitsu, Japan, T. Tanakawa is carrying on investigations in bud variation in early- and late-maturing satsuma oranges. Sixty-one late strains and 42 early strains are being tried out. The work was started in 1925 and is still in progress. Citrus hybridization work was begun in 1909.

Tyozaburo Tanaka, professor of horticulture at the Taihoku Imperial University, Taiwan, Japan, is engaged in citrus breeding. Kimijiro Noro, pomologist at the Shizuoka (Japan) Agricultural Experiment Station, has made a collection of 80 bud mutations of the satsuma orange.

At the Department of Horticulture, Lingnan University, Canton, China, G. Weidman Groff, professor of horticulture, and Pui-Man Lei, Qu-Nin Shiu, and A. N. Benemerito, pomologists, have gathered together a comprehensive citrus collection for use in the selection of desirable types of citrus and citrus relatives, particularly from the south China area, with numerous introductions from abroad. Some of the systematic work on this collection has been carried out in collaboration with the United States Department of Agriculture.

R. D. Fordham, deputy director of gardens, United Provinces, Saharanpur, India, reports that citrus rootstock trials are under way, including Khatta (Karna lime), *Citrus limonia*, Sylhet, Bijori, Sadaphal, Jamberi, Bilhari, Galgal, Sweet Galgal, Turanj, and sweet lime.

B. Nazareth, superintendent, Modibag Garden, College of Agriculture, Poona, India, reports that studies of mutations occurring in the principal citrus varieties, Santra Mosambi and Ladoo, have been made, and many well-marked sporting forms have been recognized. Breeding work thus far has been confined to mass selection both for rootstocks and for scion varieties. Collections of scion and rootstock varieties are being made to initiate systematic breeding of fruit crops adapted to different soil and climatic conditions. Attempts at hybridization made in 1912, 1914, and 1918 gave negative results. Polyembryony in citrus has been studied, showing varying percentages, from none in the pummelo to 60 percent in the Ladoo orange. The Marsh (seedless) grapefruit has been introduced for culture in the Bombay region.

South and Central Africa

The Department of Agriculture, Zanzibar, East Africa, is studying local and imported varieties of citrus in a series of plots. This work is being carried out by A. Q. Findley, director.

Australia and New Zealand

At the Department of Agriculture and Stock, Brisbane, Queensland, bud selection of citrus has been practiced for many years and Government certified budwood is available for nurserymen. The chief sweet orange varieties grown are Washington Navel, Valencia, Jaffa, Sabina, and Joppa. The lemon varieties are Lisbon and Villa Franca. The mandarin varieties are Beauty of Glenn Retreat, Emperor of Canton, Scarlet, and Fewtrel Early. The grapefruit variety is Marsh, and Seville sour orange is grown for marmalade. Sour orange and rough lemon rootstocks are used for citrus except that mandarin is grown on mandarin.

At the Department of Agriculture, Division of Horticulture, Melbourne, Victoria, J. M. Ward, superintendent of horticulture, has carried on work in bud selection since 1931, and up to the present one variety has been propagated—a thin-skinned early navel orange, which has not as yet been named. The department also supplies buds of selected strains of the Washington Navel and Valencia to growers and nurserymen. No work in hybridization has yet been carried out.

At the Department of Agriculture, Division of Horticulture, Wellington, New Zealand, J. A. Campbell, director, has gathered together a representative collection of citrus species and varieties for intensive study.

H. Wenholz, director of plant breeding, Department of Agriculture, New South Wales, Australia, reports that citrus breeding is being carried on at the Grafton Experiment Farm and the Hawkesbury Agricultural College with the object of producing "a late hanging navel orange" and a late Valencia of fine texture. A cross has been made between Valencia and a very fine-textured seedling variety.

TECHNICAL PROBLEMS AND RESULTS IN CITRUS BREEDING [4]

PROGRESS in genetic research has been greatly retarded on account of the common occurrence of polyembryony in most citrus types, which makes it necessary to grow to the fruiting stage large numbers of

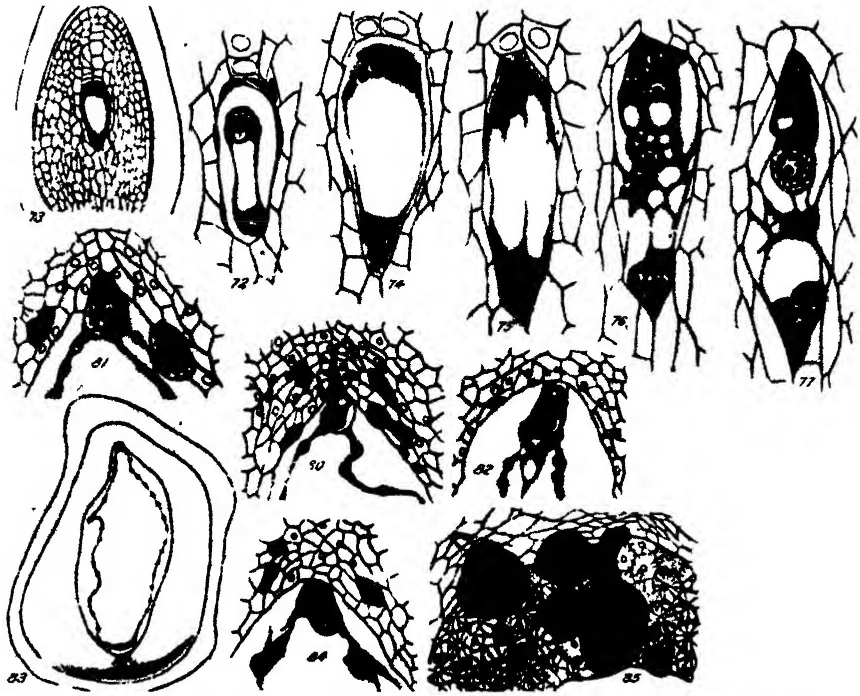

Figure 17.—Embryo development and "nucellar embryony" in *Citrus* and *Poncirus*, after Osawa (*50*): Nos. 72, 80–85, trifoliate orange; 73–76, satsuma orange; 77, Washington Navel orange. seedlings that have arisen asexually. That this section is not more complete is due in the main to this one cause. Even the grouping of citrus species (*68*) is complicated by this condition.

[4] The following sections are written primarily for students and others professionally interested in genetics or breeding.

Cytological Basis for Citrus Genetics

A study of the chromosome numbers and chromosome behavior in citrus is basic to a consideration of citrus genetics. According to Frost (*20*), it may be assumed that bud-variation types originate primarily either as gene (point) mutations or as chromosomal aberrations, and an understanding of these fundamental facts may also throw some light on the great variability of F_1 hybrids between species.

Figure 18.—Howard B. Frost, associate plant breeder, California Agricultural Experiment Station, since 1912, has made important contributions to the cytology and genetics of citrus and is the originator of the Kara, Kinnow, and Wilking mandarins and the Trovita sweet orange.

Strasburger (*66*) determined the haploid chromosome number as 8 in the sweet orange (*Citrus sinensis*), the sour or bigarade orange (*C. aurantium*), and the citron (*C. medica*). Osawa (*50*) reported that the haploid chromosome number in the satsuma orange (*C. nobilis* var. *deliciosa*) was probably 8 (fig. 17).

In 1924–25 both Frost (fig. 18), at the Citrus Experiment Station, Riverside, Calif., and Longley, of the Department of Agriculture, reported important work on the cytology of citrus. Frost (*18*) determined the chromosome numbers in two varieties of sweet orange (*Citrus sinensis*) and one variety of grapefruit (*C. grandis*), and in each case the haploid number was 9. He observed neither polyspory nor polycary.

Longley (*45*) made chromosome counts in 24 citrus species and citrus relatives and verified the basic chromosome number of citrus as 9, but he also found 1 tetraploid species, the Hong Kong kumquat (*Fortunella hindsii* (Champ.) Swingle). He observed both polyspory and polycary in many forms. He states that "irregularities in chromosome pairing at diakinesis and in their distribution at meiosis were frequently noticed. The outcome of such irregularities was the presence of tetrads containing more than the expected four pollen grains." In grapefruit, limes, and limequats polyspory was often observed. He points out that there may be "a relation between irregular chromosome numbers and the production of citrus with supernumerary chromosomes." According to Longley, two factors, however, may hinder the spontaneous appearance of such polyploid forms—the possibility that only sex cells with 9 chromosomes are viable, and the infrequent use of seeds as a means of propagation. However, in the early history of citrus culture, seedlings were commonly used in planting groves, and the disappearance of polyploid forms is apparently because they are of little or no value in horticul-

ture, as Frost points put. Longley emphasizes the possible value of the tetraploid *Fortunella hindsii* in hybridizing with closely related diploid forms to increase the chances of obtaining forms with unusual chromosome complexes.

Later, in 1925, Frost (*19*) reported on the discovery of certain "thick-leaved" apogamic seedlings of sweet orange (*Citrus sinensis*) and lemon (*C. limonia*) which proved to be tetraploids. He had observed such types to the extent of several percent of the total progeny in some cases in 12 horticultural varieties of citrus, representing 4 species, and in 2 botanical varieties, and he points out that they also may prove to be tetraploids.

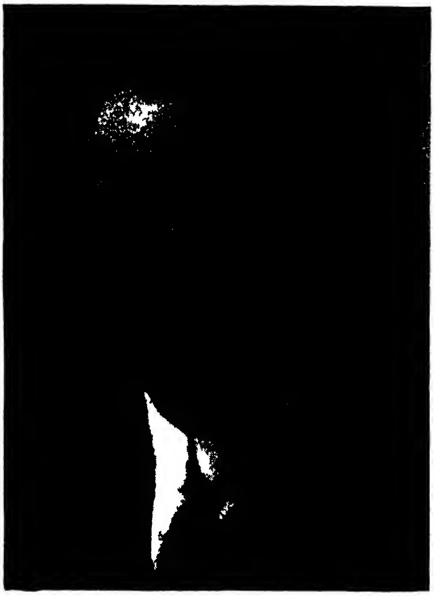

Figure 19.—Herbert J. Webber, pioneer worker in breeding citrus and other crops; United States Department of Agriculture, 1892–1907; Cornell University, 1907–12; California Agricultural Experiment Station, since 1913. He has carried on important work on rootstock variation as influenced by polyembryony.

As to the cause of these forms, Frost postulated the possibility of "islands" of tetraploid tissue in the parent trees, so that not all tetraploid seedlings represent distinct doubling of chromosome number. Against this view he found that the thick-leaved forms have not been found in mature trees by Shamel and his coworkers, and stated that this might be due to "the slower growth of tetraploid cells which might keep them from multiplying sufficiently to dominate the apical meristem, rather than to failure of tetraploidy to originate outside the nucellus." He further supported the hypothesis by citing the fact that in many cases a thick-leaved seedling has developed from a seed giving two or more nonhybrids, and in such cases the other apogamic seedlings from the same seed have almost always been normals.

In connection with these thick-leaved forms, Frost pointed out that they have not given promise of direct horticultural value, but they may be an aid in producing triploids or modified triploids by crossing with ordinary diploid forms, and that triploids would probably be practically seedless.

In 1926 Longley (*45*) reported his findings with reference to a triploid trigeneric hybrid, produced by Swingle and coworkers of the Department of Agriculture. This is a cross of the limequat (*Fortunella margarita* Swingle × *Citrus aurantifolia*) with *Fortunella hindsii*. Longley found 13 bivalent and a single univalent chromosome as the reduced number, and he found indications of only slight irregularity in chromosome distribution during meiosis in the triploid plant.

These findings led him to believe that triploids may be produced by appropriate crosses, and that in the case just cited or similar crosses there is a possibility of producing a seedless kumquat. More recently Longley [5] has found a second triploid, a sister hybrid of the first triploid found. Since most triploid plants are sterile, such crosses, it is hoped, may lead to developing seedless fruits. Longley later (April 1928) found an individual of *Triphasia trifolia* P. Wilson having 18 chromosomes.[5]

Polyembryony

In 1719 Leeuwenhoek noticed two embryos in orange seed, but it was not until 1878 that Strasburger (*65*) explained the true nature of the phenomenon of polyembryony in citrus as sporophytic budding from nucellar tissue. Frost (*19*) in 1925 found that in a minor portion of nucellar embryos—less than 1 percent—two hybrids were produced from one seed. Instances have been noted of three and even four—only two cases of the latter—apparently true hybrids produced from a single seed.[6] In one instance (lemon × trifoliate orange) out of 782 seeds, 16 produced 2 hybrids from 1 seed, with 1 producing 3 and 1 producing 4 hybrids, which is slightly more than 2 percent of "doubling."

Webber (*83*) (fig. 19), Frost (*20*), Toxopeus (*74*), and Torres (*73*) have shown that citrus types vary widely in the percentage of nucellar embryos produced (fig. 17). In a recent study made by Torres in the Philippine Islands, based on 50-seed samples, only the pummelo type did not exhibit polyembryony (table 2).

Table 2.—*Polyembryony in citrus in the Philippine Islands*

Citrus type	Average embryos per seed (range within type)	Embryos per seed (range—minimum and maximum)	Citrus type	Average embryos per seed (range within type)	Embryos per seed (range—minimum and maximum)
	Number	*Number*		*Number*	*Number*
Pummelo	1.0	---- ---	Sour orange	1.00 to 1.18±0.18	1 to 3
Grapefruit	1.16±0.23 to 2.86±0.89	1 to 6	Lime	1.0 to 1.20± .16	1 to 2
Sweet orange	1.32± .002 to 4.88±1.12	1 to 12	Tangelo	1.92± .45 to 2.32± .42	1 to 4
Citrus nobilis	1.02± .07 to 2.72± .44	1 to 6	Calamondin	5.32± .88	1 to 10
Lemon	1.30± .28 to 2.90± .88	1 to 6			

After summing up the evidence with reference to the effect of pollination on polyembryony, Frost (*20*) stated that it appears "very probable that citrus seeds do not develop without pollination, although seedless fruits sometimes develop without pollination even in varieties normally seedy." This would indicate that nucellar budding, which produces apogamic embryos, is at least very largely dependent on some growth stimulus due to the fertilized egg, as suggested by Strasburger (*66*) and Webber (*84*).

Frost (*20*) has shown that in interspecific crosses there is a negative correlation between the total number of seedlings and the percentage of hybrid seedlings, which shows the possible effect of competition among the embryos within the seed. During such developmental

[5] Unpublished work.
[6] Unpublished results of Swingle's crosses in 1909.

selection acting within the soma of the parent, the fertilized egg may be crowded out by the apogamic embryos, depending on the number of apogamic embryos that start and on the position and relative age and vigor of the two classes of embryos. Evidence as to selective elimination during germination was secured by noting the difference between the number of dissected embryos and the germination percentage in similar lots. During germination, survival may be determined by the "difference in size, vigor, position, morphological completeness, and susceptibility to infection." It was also noted that albinism causes the early death of many seedlings from some parents.

The variation in the number of nucellar embryos produced within a variety, and the possible effect of environmental conditions on such variation, led Traub (*76*) in 1936 to offer the hypothesis, based on preliminary experiments, that the number of nucellar embryos produced might be artificially varied by difference in food supply. If the preliminary results can be firmly established by experiments now in progress, an effective method for use in breeding work would be provided.

Swingle (*69*) postulated that citrus varieties propagated as clones are subject to senescence with age, and he cited the supposed disappearance or reduction in size of spines in well-established clones as one of the clearest indications of such senescence. He claimed that such clones might be at least partly rejuvenated, that is, become more spiny and vigorous, for instance, when seedlings from nucellar embryos were used as a method of establishing a new clone. This supposed nutritional effect of the embryo sac on the nucellar embryo developed within he named the "new-life" or "neophyosis" hypothesis.

However, there are no facts to prove that citrus clones are subject to senescence, and it is questionable whether the supposed rejuvenation is explainable as a permanent genetic factor change due to a nutritional effect or may be better explained by Frost's (*20*) theory of "islands" of mutating tissue in the nucellus.

Evaluation of Breeding Methods

Mass selection from open-pollinated seedlings was the method of citrus breeding followed by the early citrus growers It has yielded important results over long periods, but it is not now followed by any of the United States workers in this field. The search for bud variations and the use of hybridization are so much more promising that the method will be revived only for use in special cases.

The practical bearing of a rapid mutation rate in citrus has already been discussed in detailing the improvement of varieties. The question of the cause of such variations remains to be considered. It has been pointed out that Frost had postulated islands of tetraploid nucellar tissue as a possible explanation of the variation in apogamic seedlings, and the little that is known as to the cytological basis of citrus bud mutations has been ably discussed by Frost (*20*). The worker in this field does not have a background of abundant experimental data and must make use largely of the principles established by workers with more facile plant material such as maize, *Nicotiana*, etc., in developing useful theories.

On this basis Frost summarized the situation. Bud variations presumably originating in single cells by gene mutation or by differential mitosis are frequent in citrus. Frost says:

In the former case, at least, their somatic expression is doubtless favored by the presence of numerous heterozygous recessive genes. The production of recognizable bud variations, then, requires bud formation in an area of variant tissue, and may often be due to irregular tissue development in periclinal chimeras. The abundance of bud variation with some citrus forms apparently depends upon a permanent chimeral condition of the types in question.

The selection of bud mutations as a tool in citrus breeding has yielded some important results. Apogamic seedlings following interspecific crossing have given rise to the Davis grapefruit, the Silverhill satsuma orange, and the Oklawaha sour orange. In this group may be included the Everglade and Palmetto limes and Weshart and Trimble tangerines, although the supposed difference in these strains from the parental varieties has not warranted their continuance as distinct varieties. Evidence as to the behavior of the Lue orange indicates that this variety is apparently a nucellar seedling of the Valencia variety. A group of unnamed navel orange seedlings derived from seed of the Washington Navel pollinated with trifoliate orange pollen but showing no hybrid characters offer promise in securing new navel varieties adapted to Gulf coast conditions. In the same series, crosses made on the Thomson Navel gave only worthless fruits of the dry type, while a large percentage of the apogamic seedlings of the Washington Navel are vigorous growers and produce juicy fruits of more or less merit. If some of these prove to fruit satisfactorily under Florida and Gulf coast conditions, a navel variety may be found to meet the need in this section.

The work of Shamel and his coworkers in bud selection has preserved the original strains of commercial varieties and also yielded some superior new ones, as already detailed.

Chace, Church, and Denny (*8*, *9*) studied the inheritance of fruit composition in 18 mutant strains of Washington Navel orange and several mutant strains of Eureka and Lisbon lemons isolated by Shamel, Scott, Pomeroy, and Dyer (*63*, *64*). Chace and coworkers concluded that differences in the chemical composition of fruit exist between mutant strains, and that these are heritable. In Washington Navel strains some of these differences were closely connected with physical differences and others not. The differences generally found were in quantities of peel, oil, insoluble solids, and acids. Less variation was found in the specific gravity of the fruits and in the soluble solids and sugars of the juice. Strains of fruit with smooth skin were found to contain only small quantities of oil. In the Lisbon lemon mutants significant differences were found in specific gravity of fruit, proportion of rind, and percentage of acids; and in the Eureka lemon, in percentage of acids.

Haskins and Moore (*27*) observed premature flowering, albinism, fasciation, twisting, and peloric leaf formation in citrus seedlings grown from X-rayed seeds.

Selection within self-fertilized lines as a tool has little or no value in citrus breeding on account of polyembryony in most citrus types. The experience of Frost (*20*) at the Citrus Experiment Station has

shown that there is great loss of vigor and fertility with selfing. Toxopeus (*74*) and others have shown that the pummelo has no nucellar embryony and is usually self-pollinated. The progeny are usually quite uniform, and in such cases it is possible to develop more highly homozygous races by selection within self-fertilized lines.

Hybridization as a means toward the improvement of citrus varieties was undertaken by the Department in 1892 and has been continued ever since, and the progenies produced are being extensively tested in cooperation with the California, Florida, Texas, and Alabama experiment stations and many citrus growers (*70*, *71*, *84*, *86*). Some concrete results of definite value have been achieved as a result of this cooperation, as detailed under the improvement of citrus varieties above. Frost, in California, has carried on valuable work in this field since 1914, which has recently yielded promising citrus varieties. The work in Florida carried on by Camp and Jefferies, in Alabama by Yates, and in Texas by Yarnell and Wood was begun quite recently, and not enough time has elapsed to yield any definite results.

United States Department of Agriculture Breeding Results

Breeding work by the Department was initiated by Webber and Swingle and is carried out on the cooperative testing basis with the agricultural experiment stations and citrus growers in the subtropical fruit regions. The major part of the work is concerned with interspecific hybrids in which (1) the mandarin orange type is crossed with other citrus types with the object of securing high color of rind and flesh and also the "bouquet" of the tangerine in hybrid forms; (2) the lemon and lime are crossed with each other and with other citrus types; (3) bigeneric crosses of the trifoliate orange are made with species in other genera, primarily to increase the hardiness of the offspring; and (4) various crosses are made to explore the possibilities in other directions. The practical results from this work have been previously considered in the text and are summarized in table 7 of the appendix.

Mandarin Crossed With Other Citrus

Among the interspecific crosses that have given the most interesting results is the cross of the mandarin orange species on the grapefruit. In no case were hybrids produced when grapefruit pollen was transferred to the mandarin orange stigma, but the reverse operation has yielded abundant results.

The first crosses of this nature were made by Swingle in 1897 and by Webber in 1898. Webber and Swingle found wide variation in the F_1 progeny. Out of the first crosses two varieties were introduced, as already indicated, but in these the susceptibility to scab of the grapefruit parent was apparently dominant, and in addition the fruits were of such character that the keeping and shipping quality was unsatisfactory.

During the period 1908–12 Swingle, E. M. Savage, and F. W. Savage made a second series of crosses of a similar nature. The results were similar to those already stated, except that a number of the progeny were highly resistant to citrus scab and also possessed good shipping quality. An attempt was made to proceed a step farther through

selection from segregating seedlings in the F_2 generation, but on account of excessive nucellar embryony only one seminal seedling of merit was secured, which gave rise to a tangelo variety of promise, the San Jacinto. This was introduced in 1931.

A further attempt was made to secure desirable types by backcrossing the tangelo on the grapefruit, and in this case a fair number of seminal offspring were secured. In growth habit these resembled the pollen parent, the Sampson tangelo, but they were less vigorous. The fruit of two such backcrosses proved to be small, round, pink-fleshed, of low acidity and high sugar content, characters not present in either parent. One variety of the pink-fleshed backcross has been introduced as the Wekiwa.

Crosses made between the satsuma orange and the sweet orange have given rise to types somewhat similar to those secured by the tangerine-grapefruit cross with the flesh color and shape of the satsuma and the tight rind and size of the sweet orange (Ruby), but with high acidity and late maturity not found in either parent.

The third series of grapefruit-tangerine crosses were made by Traub, Robinson, and Savage, 1934–36, with the object of producing "seedless" tangelos. Marsh and its mutation, Thompson, and Davis, all "seedless" varieties, were used in place of Bowen, a seedy variety, which was chiefly utilized in previous crosses. These so-called "seedless" varieties are highly self-sterile and intersterile and produce few or no seeds even in mixed plantings.

Crosses between the tangerine and the sweet orange generally gave types similar to the latter but of small size.

Lemon-Lime Crosses

Among crosses between the lime and the lemon, the Perrine lemon, a promising variety, was found to be immune to citrus scab and lime withertip. It has already been mentioned and will be discussed more fully under disease resistance later.

Trifoliate Orange Crossed With Citrus and Fortunella Species

Citrus hybrids involving trifoliate orange (*Poncirus trifoliata*) as one parent have given rise to interesting results. The crosses were made by Swingle and Webber beginning in 1893 and at several times subsequently. In the first series 212 crosses were made and 13 hybrids (citranges, i. e., trifoliate × sweet orange) were secured. Most of these had the trifoliate orange as the seed parent, but in one case (Rusk citrange) the sweet orange produced the seed. There was wide variation in the characters of the hybrids. In most cases the leaves were of the trifoliate type, but unifoliate types were also secured. All were evergreen in habit; in fruit character there was also great variation in size, color, etc. In all cases the rind oil character was inherited from the trifoliate parent, and in most cases the juice character was intermediate. In none of the fruits was the juice character sufficiently like that of the sweet orange to give these fruits any prospect of commercial usefulness. Most of the progeny produced only nucellar embryos when an attempt was made to secure an F_2 generation by self-pollination, except in the case of the Sanford and Phelps citranges, which showed hybrids with segregation for leaf

characters. Seedlings of these segregating varieties were distributed for trial but thus far have produced nothing of special merit.

Hybrids were later secured by crossing the citrange and the kumquat. As a result the objectionable oil content of the fruit was reduced and an acid fruit type secured which has been called the citrangequat. One of the progeny, the Thomasville, shows high resistance to citrus canker, which was inherited apparently from the kumquat ancestor. The citrange crossed with calamondin has given an acid fruit type in which the disagreeable oil is eliminated. It has been called the Glen citrangedin. This type is relatively frost-resistant. Attempts made to secure the F_2 generation have been unsuccessful, since only nucellar embryos were secured.

Other Citrus Crosses

The lime crossed with the kumquat has given rise to small acid-fruited progeny which are immune to lime withertip and decidedly more frost-resistant than the true limes.

Various other crosses were made involving pummelo, sour orange, and other citrus species. The most interesting is the cross between the Eustis limequat, with a haploid chromosome number of 9, and the Hong Kong kumquat (*Fortunella hindsii*), with a haploid chromosome number of 18. This has given rise to a triploid hybrid, as reported by Longley, resembling the Hong Kong kumquat but larger and of greater vigor. It is of potential value in further crossing to secure seedless kumquat types, since many triploids are self-sterile and intersterile.

Inheritance in Citrus and Related Species

A number of hypotheses have been advanced to explain the wide variation in the progeny secured in the F_1 generation citrus crosses. Webber (*84*) in 1905 suggested that there must be some influence, either direct or indirect, of male parent on nucellar embryos, that the male element imparts the tendency to the segregation of characters that exist in the mother parent—characters that as a rule are probably of very mixed origin—but does not transmit any characters of the male parent. The Mendelian principles of unit factors, dominance, and segregation seemed inadequate to Swingle to account for his observations, and in 1913 he proposed the hypothesis of zygotaxis (*67*).

Swingle defined his hypothesis of zygotaxis as—

> the arrangement in syngamete (zygote) of the chromatin and other hereditary substances derived from the parental gametes and the persistence of this arrangement in the cells produced by the subdivision of the syngamete.

In further explanation of his hypothesis he states:

> It is assumed that the particular zygotactic arrangement taken up by the chromosomes of the parental gametes usually persists with little or no change throughout the life of the organism * * *. The fundamental idea underlying the term zygotaxis is that the architecture of the zygote with reference to its idioplastic particles, as well as its mechanisms for transmitting hereditary tendencies into expression, is determined to some extent at the moment of fusion of the two parental gametes and that this arrangement of parts is transmitted to the cells of the organism to which the zygote gives rise.

The hypothesis of zygotaxis was vigorously opposed by Hagedoorn and Hagedoorn (*25*) and by White (*89*). The former workers sug-

gested that variable F_1 progeny in citrus crosses apparently are due to habitual self-sterility and the sexual production of seeds. White points out that the F_1 variation in citrus hybrids, in the light of the data at hand, apparently results from differences in the gametic composition of the heterozygous parents.

Frost (*20*) sums up the evidence for and against the theory of zygotaxis and states that—

> enough is known of the production of new characters by new combinations of genes in crossing to warn us against setting any narrow limits to the probable results of recombinations in crosses between two highly heterozygous species. * * * It is concluded, from the available evidence, that citrus forms are in general extremely heterozygous. * * * This conception seems highly significant. * * * In the evolution of heterozygosis, polyembryony probably was an important factor.

Frost suggested that lethal and sublethal effects in selfing and crossing may be the result of homozygosis of inevitably unfavorable genes and may also be in part a result of incompatible recombinations. Heterosis, however, according to Frost, is probably more often secured in crossing.

Inheritance of Disease Resistance

The various citrus types and varieties show great variation in inheritance of resistance or susceptibility to various diseases. The summary given in table 3 is based largely on the text by Fawcett (*15*).

Winston, Bowman, and Bach (*90*) studied the resistance of citrus types and varieties to sour orange scab, *Sphaceloma fawcetti*, and found the following not susceptible: Kumquat; citron; Kansu orange (*Citrus junos* Tan.); Mexican, Woglum, and Tahiti limes; Royal and Triumph grapefruit; Cuban shaddock; Bergamot orange; most sweet oranges; and Cleopatra mandarin. The work of Peltier and Frederich (*52*) has shown that citrus scab cannot survive under California conditions, indicating that susceptibility under certain conditions may not be apparent.

Fulton (*22*) made a study of the susceptibility of citrus types and varieties to Key lime withertip or anthracnose (*Gloeosporium limetticolum*). He found that the West Indian (Key) lime and the Dominican (thornless) lime are highly susceptible. Other lime varieties have not given undoubted evidence of susceptibility. Hybrid West Indian limes, sweet orange, grapefruit, lemon, *Citrus nobilis*, and others have proved immune. Since only two types are highly susceptible, it is suggested that other closely related varieties might be substituted in culture. It is interesting to note that susceptibility seems not to be a dominant factor in F_1 hybrids.

Peltier and Frederich (*51*) made extensive studies of the susceptibility of *Citrus* and related genera to citrus canker (*Pseudomonas citri*) under greenhouse and Gulf coast conditions. Lee (*41, 42*) made similar studies in the Orient. Although there is no immediate need for varieties and stocks resistant to citrus canker, since the epidemic in the upper Gulf coast and in Florida has been practically eradicated since 1925, it is of advantage to select resistant types where possible as an insurance in case the disease should be inadvertently reintroduced. Grouped in order of susceptibility, varieties of grapefruit and pummelo (shaddock) proved extremely susceptible (except two pummelo varieties, Hirado and Siam, and the Triumph grape-

TABLE 3.—*Relative susceptibility of citrus species and varieties and related species to principal diseases*

[++ indicates high, + medium, and ± slight susceptibility, − indicates high degree of immunity or practically complete immunity]

[1] Some pummelo varieties resist brown rot gummosis; others are very susceptible.
[2] Anthracnose of citrus other than Key lime.

fruit). Lemon varieties and the trifoliate orange (*Poncirus trifoliata*) are only slightly less susceptible than grapefruit. Classed as moderately susceptible are the sweet oranges, sour oranges, citrons, and limes, except that the Tahiti lime is much less susceptible than the Mexican lime. The mandarin group (*Citrus nobilis* varieties) as a whole is only slightly attacked, as is also the calamondin. The outstanding resistant members of the edible citrus fruit group proved to be the kumquats (*Fortunella* spp.), except the susceptible Hong Kong kumquat (*F. hindsii*), resistance in kumquats amounting to practical immunity under field conditions.

The extensive citrus canker tests made by Peltier and Frederich (*51*) afforded opportunities for testing the numerous hybrids developed by the Department, these hybrids involving reciprocal crosses between numerous species and varieties ranging in their reaction to canker infection from extremely susceptible to very resistant. The results of these tests may be briefly summarized as follows. All the trifoliate orange first crosses proved quite susceptible to canker, like the parent, *Poncirus trifoliata*. In the second cross, that is, citranges crossed with other parents, those hybrids with the mandarin orange or the kumquat as one parent proved decidedly resistant; in fact, the citrangequat (Thomasville variety) proved practically immune, fully as much so as the kumquat. Likewise the limequat and the orangequat can be regarded as similar to the satsuma in resistance. The calamondin, while somewhat resistant itself, does not carry this resistance into the hybrid, with one exception, the citrangedin (citrange × calamondin). Most of the grapefruit hybrids have proved quite susceptible, although certain of the tangerine and satsuma crosses with grapefruit (tangelos) show enough canker resistance to place them beside the mandarin oranges in their resistance to canker. Peltier and Frederich conclude: "In the search for promising canker-resistant plants the results of over 4 years' investigations seem to point to the fact that our best plants will come from the hybrids."

Gummosis, a disease caused by *Phytophthora citrophthora*, has been studied by Klotz and Fawcett (*37*), who tested 78 species and varieties for resistance. The sour oranges proved very resistant, while the lemons were most susceptible. Klotz (*36*) has shown that the resistance apparently is due to some cellular product of the host that has an inhibiting action on the fungoid enzymes.

Toxopeus (*75*) reported that the factor or factors for resistance to foot rot (*Phytophthora parasitica*) might possibly be recessive, and in that case he suggests that selection for individuals resistant to this disease be made in the second generation (F_2) after crossing

Inheritance of Capacity to Produce Vitamins

Preliminary tests have been made indicating how capacity to produce vitamins is transmitted in citrus hybrids. The only published report (*71*) has to do with tests made in 1928 with the Sampson and Thornton tangelos, comparing the vitamin B content of these hybrids with that of the parental varieties, grapefuit and tangerine. These tests, made by the Bureau of Chemistry and Soils of the Department, were summarized as follows:

Both charts are in agreement in showing tangerine juice to be a better source of vitamin B than the juice of the other fruits fed, and also that tangelo juice is approximately equal in vitamin B potency to grapefruit juice. Therefore, with respect to vitamin B production the tangelo has inherited the characteristics of the grapefruit (*71, footnote, p. 3*).

With respect to vitamin C, which is of still more importance in the citrus fruits, tests are in progress and some indications as to inheritance have already been secured. These preliminary tests (*13*) were made during the 1935–36 season by Esther P. Daniel, Bureau of Home Economics, in cooperation with Traub and Robinson, Bureau of Plant Industry, of the Department. In these tests the ascorbic acid content of fruit samples at maturity was determined by the titration method. The figures below indicate milligrams of ascorbic acid per cubuc centimeter of juice:

The Thornton and Orlando tangelos (range 0.33 to 0.35) gave results approximating those of the Bowen grapefruit parent (average 0.35); the Sampson, Minneola, and Seminole (range 0.18 to 0.28) proved more like the Dancy tangerine parent (average 0.24). One variety that was grouped with the tangelos, the Umatilla, but that in fact is a hybrid between satsuma and Ruby oranges, gave a much higher content of ascorbic acid (0.40) than the true tangelos. The Clement tangelo, which has the Clementine as the pollen parent, had the highest content (0.64). The Clementine is reputed to be a natural hybrid between the sour orange and the tangerine and has a higher content of ascorbic acid (0.37) than the Dancy (0.24).

The Perrine lemon—a hybrid of lemon and lime—appears to inherit from the lemon parent rather than from the lime, having an ascorbic acid content of 0.40 as compared with 0.22 in the lime.

The limequat (Lakeland) ranks low (0.17), like the lime parent. It is interesting to note that the sweet lime (often called sweet lemon) has a fairly high ascorbic acid content (0.33), despite its almost complete lack of citric acid. Apparently there is no positive correlation between citric and ascorbic acid content.

Results at State Stations

California

The hybridization work at the Citrus Experiment Station at Riverside was begun by Frost (*17*) in 1914, and since that date pollinations were made mainly in 1915, 1916, 1928, 1929, and 1931. More work of this nature is planned for the next 2 or 3 years. The work consists of selfing and crossing and the study of genetic variation in nucellar seedlings.

In general the work is confined to crosses between species and within the mandarin orange group, *Citrus nobilis*. In all cases selfing of the parents is carried along as far as practicable with the work of crossing. In all, six varieties of sweet orange, three of grapefruit, and four of lemon have been used in crossing. Within the mandarin group four varieties were used in crosses. The chief results so far have been secured by selection within the first generation (F_1), but promising F_1 hybrids have been selfed, and crosses have been made between promising hybrids and standard varieties.

The F_1 hybrid combinations represented by at least one individual include the following: Lemon and mandarin (tangemon), mandarin and mandarin (of distinct botanical varieties), orange and mandarin (tangor), grapefruit and mandarin (tangelo), grapefruit and orange (orangelo), lemon and orange (oramon), and grapefruit and lemon (lemelo). The most promising hybrids not yet introduced seem to

be the following: One each from King mandarin × Dancy tangerine (fruit of very good size, fair shape, and very good flavor); from Mediterranean Sweet orange × Dancy tangerine (very good fruit color and flavor, extra early); and from satsuma (Owari) × Lisbon lemon (fruit rough, very juicy, seedless, high in acid, excellent in aroma).

The most promising results have been secured by crossing within the mandarin group. Three varieties already mentioned have been introduced, and at least two or three more are under consideration as candidates for introduction. The earliest work at the Citrus Experiment Station led to the use of the King mandarin as the main seed parent in these crosses.

During the last few years certain hybrids from crosses of lemons with grapefruit and of "hedge bergamot" with grapefruit have been studied as possible stock types for lemons. On the basis of tree characters, seed production, and resistance to inoculated phytophthora gummosis, several hybrids have been selected for further trial, and a preliminary study of seedlings has been made. At present one hybrid from Imperial grapefruit × hedge bergamot and one from Eureka lemon × Imperial grapefruit seem most promising, although it is not certain whether they have enough nucellar embryony to produce adequately uniform seedlings for rootstocks.

A general survey including 3,800 trees is under way in a search for genetic differences from the seed parent. Tetraploids are listed and studied, and a special study is being made of a few other progenies showing unquestionably variant characters (dry fruit from one parent tree, nonnavel fruit and pollen production from two navel parent trees without pollen, late-ripening fruit from one parent tree). A study of possible genetic differences in fruit shape (satsuma) and pulp color (blood orange) among progeny of the same seed-parent tree has also been undertaken.

The related specialized studies carried on by Frost include:

(1) *Polyembryony.*—Counts of total embryos and counts of generative and nucellar seedlings have been made for horticultural varieties, tetraploid and diploid nucellar progeny, and F_1 hybrids. Among about 1,200 hybrids, 10 cases of duplicate hybrids (two identical hybrids from one seed) have been found, obviously the result of embryonic fission. Nucellar embryos seem to be somewhat less abundant with tetraploids than with corresponding diploids.

(2) *Triploidy and tetraploidy.*—About 2 percent of about 3,800 nucellar seedlings were tetraploid and have been especially studied. These are of no horticultural value. A few hybrids have recently been produced by crossing a tetraploid with diploids as pollen parents; the reverse combination failed to produce seed. About 1½ percent of about 1,200 hybrids have been proved to be triploid, none tetraploid; several times as many are suggestive of triploidy, but their chromosome constitution has not been determined.

(3) *Chromosome behavior.*—Preliminary studies have been made on chromosome conjugation and segregation in diploids, triploids, and tetraploids, and on irregularities at the microsporad stage.

(4) *Clonal senescence.*—Studies are in progress on various juvenile characters of young seedlings and clones, especially thorniness, scarcity of flowers, and general vigor of growth, and on their decline with increasing age from seed and increasing length of shoot growth.

(5) *Chimeras and bud variation.*—Studies of tree and fruit characters have been made on forms that seem to be chimeral, in the general variety collection of citrus.

Florida

The citrus hybridization work by Camp and Jefferies at the Florida State Citrus Experiment Station, Lake Alfred, with acid citrus fruits was begun in 1924. Numerous crosses have been made, including 18 different combinations, with the following as parents: Calamondin; Rangpur lime; Meyer, Genoa, and Villa Franca lemons; Jamaica and Key limes; and the limequat. The F_1 progency have reached the fruiting stage and are under test.

The work carried on in cooperation with the Department is concerned with bud selection and with the testing of the citrus varieties originated by the Department.

The citrus progeny testing collection, begun in 1921, contains 52 strains of oranges, tangelos, grapefruit, and tangerines selected from record trees, and these have been intensively studied. From the superior strains budwood has been distributed in quantity to nurserymen. Selections from Thompson and Marsh grapefruit and Valencia, Hamlin, Parson Brown, Temple, and Pineapple oranges are in greatest demand.

The Department hybrids have been tested out over a long period. According to the latest report, the utilization of Rusk and Morton citranges as rootstocks for the satsuma orange is promising.

Alabama

The citrus work of the Alabama Agricultural Experiment Station, begun in 1933 in cooperation with the Department, is concerned with the testing out of over 50 strains of the satsuma orange, both early- and late-maturing, and with the selection in the F_2 generation of citrange, particularly for high quality fruit and cold resistance. The experiments have not been carried on for a sufficient period to yield concrete results, although several of the recently introduced satsuma orange strains appear promising for hardiness, early bearing, and fruit quality.

Texas

The citrus breeding work begun by Yarnell and Wood at the Texas Agricultural Experiment Station in 1934 comprises a study of the adaptability of citrus varieties and citrus relatives, both for fruit and rootstock purposes; mass selection of open-pollinated citrange seedlings, primarily for cold resistance; crossing and selfing in sweet orange, mandarin orange, grapefruit, and acid citrus fruits. In all cases of crossing and selfing some cytological studies of root tips, buds, and young fruits are also carried along.

The following rootstock plants introduced primarily by the Department are under test: (1) *Balsamocitrus paniculata* Swingle; (2) citradia; (3) *Citrus aurantifolia*—Key, Mexican, Rangpur, Tahiti; (4) *C. aurantium*—African, Bittersweet, Brazilian, Paraguay, Roubidoux, Rough Seville, standard Sour; (5) *C. bergamia* Risso; (6) *C. ichangensis;* (7) *C grandis*—Triumph; (8) *C. limetta* Risso—sweet lime; (9) *C. limonia*—Keller, Meyer, Perrine, Ponderosa, Rickart, Rough; (10) *C. maxima* Marr.—Chinese pummelo, Cuban and Pink shaddocks; (11) *C. medica*—Diamante, Etrog, Indian, Italian; (12) *C. mitis*—calamondin; (13) *C. nobilis*—Cleopatra; (14) *C. sinensis*—Oroville,

Weldon, Raymondville; (15) citrange; (16) citrangedin—Glen; (17) citrangequat—Thomasville; (18) citrumelo (citrange × pummelo); (19) limequat—Lakeland, Tavares; (20) Suen Kat orange; (21) tangelo—Altoona, Clement, Lake, Minneola, Sampson, Seminole, Thornton, Umatilla, Wekiwa, Yalaha.

The following crosses have been made: (1) Sweet orange—Ruby × Hamlin, Valencia × Hamlin, Ruby × Meyer lemon and reciprocal, Parson Brown × Meyer lemon and reciprocal, Parson Brown × Ponderosa lemon, Pineapple × Pink Marsh grapefruit, Valencia × citron; (2) mandarin orange and hybrids—Meyer lemon × Clementine tangerine, Meyer lemon × Owari satsuma, Owari × Hamlin orange, Owari × Pink Marsh grapefruit, Thornton × Clementine, Thornton × Pink Marsh; (3) grapefruit—Meyer lemon × Pink Marsh, Pineapple orange × Pink Marsh, satsuma orange × Pink Marsh, Thornton tangelo × Pink Marsh; (4) acid citrus fruits—Meyer lemon × Pink Marsh grapefruit, Meyer lemon × Mexican lime, Meyer lemon × Clementine tangerine, Meyer lemon × Eureka lemon, Meyer lemon × citron, Meyer lemon × Ruby orange, Meyer lemon × satsuma orange, Meyer lemon selfed, Parson Brown orange × Meyer lemon, Parson Brown orange × Ponderosa lemon.

The citrus varieties originated by the Department, and also introductions from abroad, have been tested out on a cooperative basis since 1930. The most promising variety in the testing collection at the Texas substation at Weslaco up to the present time is the Texas Navel, to which reference has already been made. In cooperation with the Department more than 50 strains of the satsuma orange, both early and late maturing, are under test at Texas substations at Angleton and Winter Haven, and attempts to select desirable individuals of high quality and resistant to low temperatures in second generation citrange progeny are under way at College Station.

Hawaii

The Hawaii Agricultural Experiment Station (*28*) reports that rootstock and variety tests are in progress to determine the suitability of various combinations of scion and rootstock to different sites and soils. Many recent introductions of promise are being tested in comparison with the older standard varieties.

APPENDIX

UNITED STATES SUBTROPICAL AND TROPICAL FRUIT-BREEDING STATIONS AND EARLY AND PRESENT WORKERS

[An asterisk (*) designates workers all or part of whose salaries were or are paid from Federal funds]

(1) United States Department of Agriculture, Washington, D. C.:
Early workers—*H. J. Webber, *W. T. Swingle, *Eugene May, *Frank W. Savage, *R. E. Caryl, *L. B. Scott.
Present workers—*Hamilton P. Traub, senior horticulturist; *T. Ralph Robinson, senior physiologist; *Edward M. Savage, assistant plant breeder; *A. D. Shamel, principal physiologist; *C. S. Pomeroy, associate pomologist; *A. E. Longley, associate botanist.

(2) Alabama Agricultural Experiment Station of the Alabama Polytechnic Institute, Gulf Coast Substation, Fairhope:
Present workers—*Harold F. Yates, acting superintendent.

(3) Arizona College of Agriculture and the Agricultural Experiment Station, Tucson:
Present workers—W. E. Bryan, head of Department of Plant Breeding (date breeding).

(4) California College of Agriculture and the Agricultural Experiment Station of the University of California:
Early workers—C. S. Milliken, C. L. Dyer, F. N. Harmon.
Present workers—H. J. Webber, emeritus professor of subtropical horticulture, Riverside; Ira J. Condit, associate professor of subtropical horticulture, Riverside; L. D. Batchelor, director of Citrus Experiment Station, Riverside; Robert W. Hodgson, head of Division of Subtropical Horticulture, Los Angeles; R. E. Caryl, associate in orchard management, Riverside; H. B. Frost, associate plant breeder, Riverside.

(5) College of Agriculture and Agricultural Experiment Station of the University of Florida:
Early workers—H. H. Hume, John Belling.
Present workers—H. S. Wolfe, horticulturist in charge, Subtropical Experiment Station, Homestead; A. F. Camp, horticulturist in charge, Citrus Experiment Station, Lake Alfred; J. H. Jefferies, superintendent, Citrus Experiment Station, Lake Alfred.

(6) Glen St. Mary Nurseries Co., Glen St. Mary, Fla.:
Early workers—G. L. Taber (trifoliate rootstock investigations), H. Harold Hume (persimmon investigations).

(7) University of Hawaii and the Hawaii Agricultural Experiment Station:
Early workers—*J. E. Higgins, *V. S. Holt, *J. M. Westgate.
Present workers—*J. H. Beaumont, principal horticulturist; *W. T. Pope, senior horticulturist; *R. H. Moltzan, principal scientific aide; *J. C. Thompson, principal scientific aide; *W. B. Storey, junior biological aide.

(8) Louisiana State University and Agricultural and Mechanical College and the Agricultural Experiment Station:
Present worker—J. C. Miller, horticulturist in charge of research.
(9) Puerto Rico Agricultural Experiment Station, Rio Piedras, Puerto Rico:
Early worker—O. W. Barrett.
Present worker—Julio S. Simons, agronomist for plant introduction and propagation.
(10) Federal Experiment Station, Mayaguez, Puerto Rico:
Early workers—*O. W. Barrett, *Holger Johansen, *T. B. McClelland.
Present worker—*C. L. Horne, associate horticulturist.
(11) Panama Canal Zone Experiment Gardens, Summit:
Present workers—*J. E. Higgins, consultant in plant introduction and utilization; *Walter R. Lindsay, acting director.
(12) Commonwealth of the Philippines, Department of Agriculture and Commerce (citrus, avocado, pineapple, and papaya breeding):
(a) Bureau of Plant Industry, Manila:
Early workers—C. F. Baker, T. P. Reyes, P. J. Wester.
Present workers—J. P. Torres, J. de Leon, F. Galang, F. K. Morada.
(b) College of Agriculture, University of the Philippines, Department of Agronomy, Laguna:
Present workers—N. B. Mendiola, plant breeder and geneticist; J. M. Capinpin, plant breeder and cytologist; T. Mercado, assistant plant breeder.
(13) Texas Agricultural Experiment Station:
Present workers—S. H. Yarnell, chief, Division of Horticulture, College Station; J. F. Wood, horticulturist, Weslaco; H. M. Reed, horticulturist, Angleton.

Subtropical and Tropical Fruit-Breeding Stations in Foreign Countries and Workers and Present Work

Europe and North Africa

Spain:
(1) Estacion Naranjera de Levante, Burjasot, Valencia (citrus breeding):
Present worker—Manuel Herrero.
Italy:
(2) Regia Stazione Sperimentale de Olivicoltura ed Oleificio, Pescara (olive breeding):
Present worker—Julio Savastano.
(3) Regia Stazione Sperimentale di Frutticoltura e de Agrumicoltura, Arcieale Catania, Sicily (breeding for resistance to mal secco in lemons).
French Morocco:
(4) Experimentation Fruitière et Maraichère, Rabat (citrus breeding):
Present workers—F. Lacarello, Director; Ch. Miedzyrzecki, geneticist.
Greece:
(5) Hellenic Kingdom Superior School of Agriculture, Laboratory of Horticulture, Athens (olive and fig variety studies):
Present worker—P. Th. Anagnostopolous.

Asia and Malaya

Palestine:
(6) Jewish Agency, Agricultural Experiment Station, Rehoboth (citrus breeding):
Early worker—J. D. Oppenheim.
Present worker—Ch. Oppenheimer.
(7) Agricultural School, Mikweh-Israel (collection of Jaffa orange bud mutations):
Present worker—S. Yedidja.
India:
(8) Poona, Bombay Presidency; Horticultural Section (1) Ganeshkhind Fruit Experiment Station, Kirkee; (2) Modibag (Garden), College of Agriculture, Poona. (Improvement of citrus, mango, papaya, pineapple, guava, pomegranate, fig, banana, jujube, annona.)
Early workers—W. Burns, S. H. Prayag, L. B. Kulkarni, H. P. Paranjpe.
Present workers—G. S. Cheema, horticulturist and professor of horticulture; P. G. Dani, assistant; S. R. Gandhi, assistant; S. S. Bhat, assistant; B. Nazareth, assistant.

(9) Department of Agriculture, Bihar (mango and papaya breeding):
Present workers—R. Zarbakht-Kahn, horticulturist; R. Shah, assistant; S. Prashad, assistant.
(10) Royal Agricultural and Horticultural Society of India, Alipur, Calcutta (variety studies of tropical fruits):
Present worker—Sydney Percy Lancaster.
(11) Government Gardens, Saharanpur, United Provinces (lime, mango, and loquat improvement):
R. D. Fordham, deputy director.
Straits Settlements and Federated Malay States:
(12) Department of Agriculture, Kuala Lampur (pineapple breeding):
Present worker—W. D. P. Olds, director of agriculture.
Siam:
(13) Department of Agriculture and Fisheries, Bangkok (variety studies of tropical fruits):
Present worker—Luang Suwan, director general.
China:
(14) College of Agriculture, Lingnan University, Canton; Department of Horticulture (variety studies of citrus, avocado, mango, papaya, pineapple, banana, lychee, diospyros, annona, artocarpus, Chinese olive (*Canaria*), etc.):
Present workers—G. Weidman Groff, professor of horticulture; Pui-man Lei, Iu-nin Shiu, A. N Benemerito.
Japan:
(15) Imperial Horticultural Experiment Station, Okitsu (fig, loquat, and citrus breeding):
Present worker—T. Tanikawa, acting director.
(16) Chiba Horticultural College, near Tokyo (loquat variety studies):
Present worker—Taiji Miki, professor of pomology.
(17) Shizuoka Agricultural Experiment Station (bud mutations of satsuma orange):
Present worker—Kimijiro Noro, pomologist.
(18) Taihoku Imperial University, Formosa (citrus breeding):
Present worker—Tyozaburo Tanaka, professor of citriculture.
(19) Agricultural Experiment Station, Shirin, Taihoku, Taiwau (subtropical fruit crops breeding):
Present worker—Y. Sakurai, pomologist.
Netherland East Indies:
(20) Buitenzorg Botanical Gardens (improvement of citrus and other tropical fruits):
Present workers—G. J. A. Lirra, horticultural adviser; H. J. Toxopeus, geneticist.

South and Central Africa

Union of South Africa:
(21) Division of Plant Industry, Union of South Africa; Subtropical Horticultural Research Station, Nelspruit, Eastern Transvaal (papaya and pineapple breeding):
Present worker—J. D. J. Hofmeyr, research horticulturist.
(22) Department of Pomology, University of Stellenbosch (fig and olive variety trials):
Present worker—O. S. H. Reinecke, head of department of pomology.
Southern Rhodesia:
(23) Citrus Experimental Station, Mazoe (citrus variety trials):
Present worker—L. A. Lee, horticulturist.
Zanzibar, East Africa:
(24) Department of Agriculture (variety trials—citrus, banana, pineapple, mango, papaya, lychee, and rambutan):
Present worker—A. J. Findley, director.
Nigeria:
(25) Agricultural Department, Ibadan (breeding of pineapple, and variety trials with citrus, mango, avocado, and papaya):
Present worker—E. H. G. Smith, agricultural botanist.

Australia and New Zealand

Victoria:
(26) Department of Agriculture, Division of Horticulture, Melbourne (bud selection in citrus):
Present worker—J. M. Ward, superintendent of horticulture.
New South Wales:
(27) Grafton Experiment Farm and the Hawkesbury Agricultural College (citrus breeding).
Queensland:
(28) Department of Agriculture and Stock, Brisbane (improvement of citrus, avocado, mango, papaya, pineapple, date, olive, granadilla, persimmon, fig, loquat, and guava):
Present worker—(Appointment of research staff in fruit crops now under consideration).
(29) Queensland Acclimatisation Society, Brisbane (introduction of tropical and subtropical fruits):
Present worker—R. Allsopp, overseer.
New Zealand:
(30) Department of Agriculture, Horticulture Division, Wellington (citrus, avocado, and olive variety trials):
Present worker—J. A. Campbell, director, Horticulture Division.
(31) Department of Scientific and Industrial Research, Plant Research Bureau, Mount Albert, Auckland (subtropical fruit variety trials):
Present worker—Dr. Allen.

Mexico, Central America, and the Antilles

Mexico:
(32) Estacion Experimental:
(a) Acapulco, Guerrero (mango, lime, pineapple, and avocado).
(b) Oaxaca, Oaxaca (mango, lime, avocado).
(c) Jalapa, Veracruz (papaya, mango, pineapple).
(d) Colima, Colima (lime).
(e) Leon, Guanajuato (avocado).
(f) Queretaro, Queretaro (avocado).
(g) Coalan del Rio, Morelos (papaya).
(h) Hecelchakan, Campeche (avocado).
Honduras:
(33) Lancetilla Experiment Station (United Fruit Co.), Tela (Extensive tropical fruit variety trials):
Present worker—Wilson Popenoe, agricultural director.
British Honduras:
(34) The Agricultural Office, Belize (introduction and testing of citrus varieties):
Present worker—H. P. Smart, agricultural officer.
Costa Rica:
(35) Alan Kelso, Aparto. 246, Punta Arenas. (Private work; tropical fruit crop introduction and improvement.)
Cuba:
(36) Agricultural Experiment Station, Santiago de las Vegas (variety tests and selections of citrus, avocado, mango, banana, and pineapple):
Early workers—M. Fortun, J. Ajete.
(37) Atkins Institution of the Arnold Arboretum (Harvard University), Cienfuegos (breeding of citrus and other tropical fruits):
Present worker—H. C. Gray, director.
Jamaica:
(38) Department of Agriculture, Hope, Kingston (papaya and banana breeding):
Present worker—L. N. H. Larter, Government botanist.
Trinidad, British West Indies:
(39) The Imperial College of Tropical Agriculture (banana and other tropical fruits breeding):
Present worker—E. E. Cheeseman, professor of botany.

South America

Chile:
(40) Salvador Izquierdo, Monedo 778, Santiago.
(Private work confined mostly to introduction of new varieties of subtropical fruits.)

Brazil:

(41) Instituto Agronomico do Estada de São Paulo, Genetics Department (citrus and banana breeding):

Present worker—C. A. Krug, head of department.

Argentina:

(42) Estacion Experimental de Concordia, Ministerio de Agricultura de la Nacion Argentina (citrus breeding):

Present worker—Ruben Bence Pieres, ing. agr. and director of the station.

TABLE 4.—*Chromosome numbers of Citrus species and varieties and related species (family Rutaceae) as far as determined up to 1936*

[See literature citations *18, 19, 23, 24, 33, 44, 45, 47, 49, 72*]

Species or variety	Chromosome number (*n*)	Authority and year determined	Remarks
Aeglopsis chevalieri	9	Longley, 1925	
Triphasia trifolia	9	do	
Triphasia trifolia var. *bivalens*	18	Longley, 1937	Determined in 1928.
Severinia buxifolia	9	Longley, 1925	Do.
Microcitrus australis	9	Longley, 1937	
Citropsis schweinfurthii	9	Longley, 1925	
Poncirus trifoliata	9	do	
Fortunella crassifolia	9	do	
F. margarita	9	do	
F. japonica	9	do	
F. hindsii	18	do	
Citrus medica	9	do	
C. limonia	9	Frost, 1925 Longley, 1925	
C. limonia var. *bivalens*	18	Frost, 1925	
C. aurantifolia	9	Longley, 1925	
C. grandis	9	do. Frost, 1925	
C. aurantium			Undetermined.
C. sinensis	9	Frost, 1925; Longley, 1925; Oppenheimer and Fraenkel, 1929.	
C. sinensis var. *bivalens*	18	Frost, 1925	
C. nobilis	9	Longley, 1925	
C. nobilis var. *deliciosa*	9		Quoted by Oppenheimer (*49*) without citation of author.
C. nobilis var. *unshiu*	9	Nakamura, 1929	
C. mitis	9	Longley, 1925	
C. ichangensis			Undetermined.

TABLE 5.—*Citrus species and varieties introduced by the United States Department of Agriculture*

Species	Common or varietal name	Native habitat	Source of introduction	Where now available	Remarks
Citrus grandis	Shaddock	Southeastern Asia	Original habitat; also Australia, West Indies, South Africa.	Orlando, Eustis, Coconut Grove, and Lake Alfred, Fla., Riverside, Calif., Weslaco, Tex.	Cuban shaddock is being tested for possible use as rootstock; Arajan (pink,) Alamoen
Do	Pummelo	Southeastern Asia, Malaysia.	Siam, China, India, Philippines, Hawaii.	Eustis, Fla	The following varieties are being tested for utilization of fruit and resistance to saline soil solution: Kao Pan, Kao Phuang, Thong Dee, Nakorn, Victoria, Siam, Pandan Wangi, Better Pummelo, Wong Yau, Banda, Indian Red.
Do	Grapefruit	do	South Africa	do	Cecily grapefruit, reputed to be a seedless mutation, being tested for difference, if any, from standard seedless varieties.
C. aurantium	Sour, Bigarade, or Seville orange.	China, southeastern Asia.	Original habitat; also Spain, North Africa, West Indies, Australia.	Orlando, Eustis, Coconut Grove, and Lake Alfred, Fla., Riverside, Calif.	For testing as semihardy and disease-resistant stocks for use in hybridization, for utilization as marmalade fruits.
	Chinotti		Southern France	do	A preserving fruit; also useful as a potted dwarf plant.
	Bergametto (bergamot orange).		Sicily	do	Used in preparing flavoring extracts and perfumes.
C. sinensis (sweet orange).	Washington Navel or Bahia Navel.	China, southeastern Asia.	Brazil	do	The original introduction which served as a basis for developing the orange industry of California. Other varieties, as the Thomson Navel, have sprung from this variety. Not adapted to Florida culture.
	Texas Navel	do	do	Weslaco, Tex., Riverside, Calif.	Several navel types (seedless) introduced by Dorsett, Shamel, and Popenoe; one of which is being propagated in southern Texas as the Texas Navel for testing and breeding.
	Algerian	do	Algeria	Orlando and Eustis, Fla	Reputed to be productive and of good quality; being tested, not yet fruiting.
	Matidja	do	do	do	Do.
	Zatina	do	do	do	Do.
	Chamoudi (Shamooti)	do	Palestine	Orlando, Eustis, and Coconut Grove, Fla., Riverside, Calif., Weslaco, Tex.	A large seedless orange, famous as the "Jaffa" orange in European markets; for testing its adaptability and for use in hybridization.
	Capuchin	do	Chile	Orlando, Eustis, and Oneco, Fla.	Small, hardy orange; useful as potted ornamental and in breeding.
	Telde	do	Canary Islands	Orlando and Eustis, Fla	Small-fruited sweet orange; reputed of high quality; for testing and breeding.
	Lau Chang, Hang Chang.	do	China	do	Sweet orange reputed to be of high quality; for testing and breeding; not yet fruiting.
	Harvard	do	Cuba	Orlando, Coconut Grove, and Eustis, Fla.	An early-maturing orange, reputed to be of hybrid origin; for testing.

	Tankan	do	Formosa	do	A small disease-resistant, late-maturing orange of high color Used for testing and breeding
	Rico	do	Puerto Rico	Orlando and Eustis Fla Riverside Calif, Weslaco Tex	Rico, nos 1 to 6 Six selections made from seedling oranges for seedlessness and quality not yet fruiting
	Selecta	do	Brazil	do	Parent variety of the Washington Navel
	Byfield seedless	do	Australia	Orlando Fla	Reputed to be a midseason orange, seedless, of good quality Not yet fruiting
C nobilis var *deliciosa* (mandarin group)	Ponkan	China	China and Taiwan	Orlando Eustis Coconut Grove and Oneco Fla Riverside Calif	A large free peeling orange, early to midseason disease-resistant, highly esteemed in the Orient, for testing and breeding
	Clementine		Algeria	do	Reputed to be a natural hybrid of tangerine and sour orange but resembles tangerine, use in crosses with grapefruit gave rise to Clement tangelo
	Suen Kat (sour mandarin)	China	China	do	Serves as budding stock for best mandarin varieties of China and Formosa, being tested as stock for hardiness and disease resistance
	Changsha	do	do	Orlando Fla Fairhope Ala	Very hardy free-peeling orange promising for use in breeding
	Chin Kom	do	do	Orlando Fla	Not yet fruiting
	Sun Chu Sha	do	do	do	Do
	Hung Kat	do	do	do	Do
	Beauty (Ellendale) tangerine		Australia	do	To be tested for fruit quality, size, disease resistance and hardiness
	Vermilion tangerine	China	China	do	Do
C nobilis var *unshiu* (satsuma orange)	Kawano (early) also about 40 similar early maturing satsuma mutations	Japan	Japan	Fairhope and Silverhill, Ala Eustis, Fla (in part), Winter Haven, Tex (in part)	These large-fruited, early maturing satsuma varieties make possible earlier shipment of the commercial crop—avoiding frost risk and competition with tangerines Being tested for stock affinity, hardiness, stability of type, fruit quality also used in cross pollinations
	Ikiriki, Suzuki, Hiri Kashima Mizomoto, Miyasaki	do	do	do	Satsuma varieties of local fame in Japan, being tested for possible superiority to standard variety (Owari) in United States for hardiness, fruit quality, size of fruit, etc
C medica (citron)	Corsican, Spatafora Peretto, Java, Diamante, Chinese, Etrog	India	Italy, Sicily, Corsica Greece	Orlando Eustis Coconut Grove and Oneco, Fla Weslaco Tex Riverside, Calif	Varieties of citron adapted to the preserving industry are being tested for productiveness, disease resistance, and quality hybrids being made to improve existing forms Commercial citron growing has made a start in Florida, Puerto Rico, and California, but information is needed on stocks, varieties, disease resistance, etc There is a limited demand for the Etrog variety, used in certain Jewish ceremonials its form must accord with a fixed standard

TABLE 5.—*Citrus species and varieties introduced by the United States Department of Agriculture*—Continued

Species	Common or varietal name	Native habitat	Source of introduction	Where now available	Remarks
C. limonia (lemon)	India, Simla, Mazoe (wild types).	India, southeastern Asia.	India, South Africa	Orlando, Coconut Grove, and Eustis, Fla.	Testing importations in comparison with the "Florida rough lemon" for stock use and disease resistance.
	Algiers (seedless)	do	Algeria	Coconut Grove, Fla	Testing for adaptation to a humid climate, stock adaptability, and disease resistance.
	Meyer	China	China	Orlando and Eustis, Fla., Weslaco, Tex., Fairhope, Ala.	Testing for hardiness, stock adaptability, fruit quality, and disease resistance; also in hybridization work. This variety has been in commercial production for several years in Florida and the Gulf coast region; has proved quite hardy.
	Sumatra	Sumatra	Sumatra	Orlando, Fla., Weslaco, Tex	Not yet fruiting.
C. aurantifolia (lime)	Woglum	India, Malaysia, southeastern Asia.	India	Orlando and Coconut Grove, Fla.	Testing for seed content, fruit quality, productiveness, disease resistance; used in hybridizing.
	Giant, Cameron, Debe, Dominica.	do	West Indies	Orlando and Eustis, Fla	Tests of these introduced varieties indicate the names are local names for the common Mexican (or West Indian) lime, similar to the Florida Key lime.
	Sweet	do	Palestine	Orlando, Fla., Weslaco, Tex	Used to a limited extent as a stock; fruit insipid.
	Java	do	Java	do	Not yet fruiting.
C. mitis	Calamondin	Philippine Islands	China, Philippine Islands	Orlando, Eustis, and Coconut Grove, Fla., Weslaco, Tex., Fairhope, Ala.	A semihardy, limelike fruit, of possible use as a stock and serving as an excellent lime substitute. Crossed with the citrange it has given rise to an extra-hardy hybrid, the Glen citrangedin, an excellent "ade" fruit for the home fruit garden.
C. ichangensis		China	China	Orlando, Eustis, and Coconut Grove, Fla.	A very hardy form of citrus, of possible use as stock and for breeding purposes. "Ichang lemon", apparently a hybrid or large-fruited form.
C. junos Sieb	Yuzu	do	Japan	Orlando and Eustis, Fla	A hardy lemonlike form of citrus of possible use as a stock, as a lemon substitute in cool regions, and for breeding purposes.
C. hystrix		Philippine Islands, Malaysia.	Philippine Islands	Orlando, Coconut Grove, and Eustis, Fla., Summit, Canal Zone.	Fruits lemonlike but usually too aromatic to be edible; of possible use as stocks; not hardy.
	Kalpi	do	do	do	Fruits large, oblate, with edible lemonlike pulp; of vigorous growth; promising as a stock.

TABLE 6.—*Citrus relatives (Rutaceae) introduced by the United States Department of Agriculture*

Species	Common name	Native habitat	Source of introduction	Where now available	Remarks
Aegle marmelos (L.) Correa	Bael fruit	India	India	Orlando, Coconut Grove, Eustis, and Lake Alfred, Fla., Riverside, Calif., Mayaguez, P. R., Summit, Canal Zone	Deciduous, semihardy, producing an edible fruit, chiefly used in sherbet
Aeglopsis chevalieri Swingle		Tropical West Africa	West Africa	do	Fruit not edible, but for testing as stock
Atalantia citroides Pierre		Cochinchine	Cochinchine	Orlando, Lake Alfred, and Coconut Grove, Fla., Summit, Canal Zone, Mayaguez, P. R.	Fruit not edible, for testing as stock, decidedly ornamental—columnar habit, dark green foliage
A. disticha (Blanco) Merr., ***A. missionis*** (Wight) Oliv.	---	Cochinchine, Java	Java	Orlando, Fla.	Very resistant to salt and alkali, serves well as a stock for citrus species, decidedly promising for alkali or salty soils
Afraegle paniculata (Schum. and Thonn.) Engl., ***Balsamocitrus dawei*** Stapf, ***Afraegle gabonensis*** (Swingle) Engl.	"Powder pear	West Africa, central Africa, French Equatorial Africa	Original habitats	Orlando, Lake Alfred, and Coconut Grove, Fla., Summit, Canal Zone, Mayaguez, P. R.	Fruits not edible, of possible use as citrus stocks ornamental, not hardy
Swinglea glutinosa (Blanco) Merr.	Tabog	Philippine Islands	Philippine Islands	do	A large forest tree serves well as a citrus stock in warm soils, resistant to disease and vigorous
Chalcas koenigii (L.) Kurz		India	India	Orlando and Coconut Grove, Fla.	Foliage used extensively in the Orient for flavoring curries, readily propagated from root cuttings, useful as an ornamental, not hardy
Clausena lansium (Lour.) Skeels	Wampi	South China	South China	do	Fruit subacid, small, of good quality, of possible use as a stock, lemon buds readily on this stock but on other citrus species with difficulty
Citropsis schweinfurthii (Engl.) Swing. and M. Kell.	Cherry orange	Central Africa	Central Africa	Orlando, Lake Alfred, Coconut Grove, and Eustis, Fla., Riverside, Calif., Summit, Canal Zone	This species appears to be closely related to citrus, serves fairly well as a citrus stock in warm locations, resistant to common citrus diseases. The large compound leaves and numerous flowers make the tree decidedly ornamental
C. gabonensis (Engl.) Swingle and M. Kell.		French Equatorial Africa	Africa	do	Do
Eremocitrus glauca (Lindl.) Swingle	Desert kumquat	Australia	Australia	Orlando, and Eustis, Fla., Indio and Riverside, Calif., Sacaton, Ariz.	A xerophytic plant of possible use as a citrus stock in dry regions, a hybrid has been secured between this species and a citrange, which is of greatly increased vigor and may serve as a citrus stock

TABLE 6.—*Citrus relatives* (*Rutaceae*) *introduced by the United States Department of Agriculture*—Continued

Species	Common name	Native habitat	Source of introduction	Where now available	Remarks
Feronia limonia (L.) Swingle	Wood apple	India, Ceylon, Indo-China.	India	Orlando and Lake Alfred, Fla., Riverside, Calif., Summit, Canal Zone, Mayaguez, P. R.	Fruit used in preserves; tree useful as an ornamental in warm locations; also being tested as a stock.
Feroniella oblata Swingle	Krassang	Cambodia	Cambodia	do	Fruit used as a condiment.
F. lucida (Scheff.) Swingle	Kavista Batu	Java	Java	do	Fruits edible; both species of *Feroniella* ornamental and of possible use as a stock.
Fortunella hindsii (Champ.) Swingle.	Hong Kong kumquat	China	China	Orlando and Lake Alfred, Fla.	Fruits used as a condiment, but are very small and bitter; chiefly of interest as the plant has proved to be a tetraploid; crosses are being made with this species to secure seedlessness; one such cross, a triploid, has been secured.
Glycosmis pentaphylla (Retz.) Correa.		India, Indo-China	India	Orlando, Lake Alfred, and Coconut Grove, Fla., Summit, Canal Zone, Mayaguez, P. R.	Fruits small. Chiefly of use as an ornamental; not hardy.
Hesperethusa crenulata (Roxb.) M. Roem.	Naibel	Ceylon	Ceylon	Orlando and Lake Alfred, Fla., Summit, Canal Zone, Mayaguez, P. R., Eustis, Fla.	Fruits sometimes used as a condiment. Chiefly used as an ornamental. Stock tests gave unions with citrus, but not vigorous.
Laranga scandens (Roxb.) Buch. Ham.	Lavanga	India	India	Orlando and Lake Alfred, Fla., Summit, Canal Zone, Mayaguez, P. R.	Climbing shrubs.
Merrillia caloxylon (Ridley) Swingle.		do	do	Orlando and Coconut Grove, Fla.	Chiefly of value as an ornamental; not hardy.
Microcitrus australasica (F. Muell.) Swingle.	Finger lime	Australia	Australia	Orlando, Eustis, and Lake Alfred, Fla., Riverside, and Indio, Calif., Summit, Canal Zone, Mayaguez, P. R.	These Australian species are drought-resistant and are being tested as stocks. They are semihardy and useful as ornamentals. The fruits are scarcely edible, except possibly the last named, which has not yet fruited.
M. australis (Planch.) Swingle.	Dooja				
M. garrowayi (Bailey) Swingle.	Garroway's Finger lime.				
M. inodora (Bailey) Swingle	Russell River lime				
Paramignya monophylla Wight, *P. longipedunculata* Merr.		India	India	Orlando and Lake Alfred, Fla., Summit, Canal Zone, Mayaguez, P. R.	Climbing shrubs.
Poncirus trifoliata (L.) Raf.	Trifoliate orange	China	China	Orlando and Eustis, Fla., and Fairhope, Ala., Winter Haven, Tex.	This deciduous citrus relative is extremely hardy and useful as a stock in the northern limit of citrus culture, especially for the satsuma orange. Two forms have been noted, the normal small-flowered form and a large-flowered form of seemingly greater vigor. The trifoliate orange has been used in numerous hybrids, as the citranges and citrangequats.

Severinia buxifolia (Lam.) Ten.	"Box-leaved orange"	South China	South China	Orlando, and Eustis, Fla., Fairhope, Ala., Summit, Canal Zone, Mayaguez, P. R.	This shrubby tree is resistant to salt and may serve as a citrus stock. It is chiefly of use in ornamental hedge plantings. Several strains have been selected from imported seed of varying vigor and thorniness. Its immunity to citrus canker recommends it as a substitute in hedge plantings for the susceptible *Poncirus trifoliata*. Used as a dwarfing stock, it causes early flowering, hence is useful in hybridizing.
Triphasia trifolia (Burm. f.) P. Wils.	Lime berry	Unknown. (Widely distributed in tropical regions.)	Java	Orlando, Eustis, and Lake Alfred, Fla., Riverside, Calif., Summit, Canal Zone, Mayaguez, P. R.	A shrub or dwarf tree, chiefly of use as an ornamental; resistant to salt; fruits used sometimes in preserves.

Table 7.—*Summary of citrus breeding by the United States Department of Agriculture*

[Hybrids or selections introduced by the Department, 1892–1934]

Breeding procedure	Year introduced	Name of hybrid or variety	Parentage	Remarks
1. Hybridization through controlled cross-pollination:				
(a) Interspecific: F1 hybrids	1904	Sampson and Thornton tangelos.	Dancy tangerine × Bowen grapefruit.	These early introductions proved susceptible to scab and were poor shippers, with a short season of maturity.
	1931	Orlando (Lake), Seminole, Minneola, Yalaha tangelos.	do	This series of tangelos introduced in 1931 gave varieties high in quality, maturing from October to May, scab-resistant, and of good shipping quality.
	1931	Clement tangelo	Clementine tangerine × Bowen grapefruit.	A soft-fleshed hybrid for the home fruit garden; not recommended for commercial planting.
	1931	Umatilla tangelo	Satsuma orange × Ruby orange	Classed with the tangelo group which it resembles; very late maturing; scab-resistant.
	1931	Perrine lemon	Genoa lemon × Mexican lime	Fruit of size, shape, and quality of commercial lemon: highly resistant to scab and withertip; vigorous and productive.
F2 hybrids	1931	San Jacinto tangelo	Seedling segregate of an unnamed tangelo of little promise.	Adapted to conditions in the hot interior valleys of the Southwest, where most tangelos have been disappointing.
Backcrossing hybrids on parent variety.	1931	Wekiwa tangelo	Sampson tangelo × grapefruit.	Tree resembles pollen parent (Sampson) though less vigorous; fruit small, sweet, pink-fleshed, unlike either parent.
(b) Intergeneric. Bigeneric hybrids, F1 generation.	1904	Sanford, Rusk, Willitts, and Phelps citranges.	Trifoliate orange (*Poncirus trifoliata*) × sweet orange (*Citrus sinensis*).	The citranges with one exception (Rusk) had the trifoliate orange as the female parent. They failed in producing a hardy edible orange, owing to an excess of acrid oil in rind and pulp, but are proving useful as stocks and for further work in hybridization.
	1905	Morton citrange		
	1906	Colman, Rustic, and Savage citranges.		
	1911	Saunders and Cunningham citranges.		
	1923	Eustis and Lakeland limequats.	Mexican lime (*Citrus aurantifolia*) × round kumquat (*Fortunella japonica*).	The limequats have proved similar to the lime in fruit quality, but much hardier and resistant to lime withertip.
	1923	Tavares limequat	Lime × oval kumquat (*F. margarita*).	
	1932	Nippon kumquat, "orangequat".	Satsuma orange (*Citrus nobilis* var. *unshiu*) × Meiwa kumquat (*Fortunella crassifolia*).	This hybrid may be utilized in preserving like the kumquats, but is a much larger fruit borne on a more vigorous hardy tree. It also furnishes an excellent ade, owing to its acid, deep orange pulp.
Trigeneric hybrids, F1 generation.	1933	Thomasville and Telfair citrangequats.	Willitts citrange × oval kumquat (*Fortunella margarita*).	In these crosses the objectionable oil of the citrange is reduced so that the fruits may serve as hardy lime substitutes in making ade. The Thomasville also proved immune to citrus canker, a character derived from the kumquat parent.
	1933	Sinton citrangequat	Rusk citrange × oval kumquat.	

Table 7.—*Summary of citrus breeding by the United States Department of Agriculture*—Continued

[Hybrids or selections introduced by the Department, 1892–1934]

Breeding procedure	Year introduced	Name of hybrid or variety	Parentage	Remarks
Trigeneric hybrids, F_1 generationr	1931	Glen citrangedin	Willitts citrange × calamondin (*Citrus mitis*).	In this cross the objectionable oil content of the citrange is eliminated, giving rise to an ade fruit similar to the calamondin but much more hardy.
2. Selection: (a) Seedlings (apogamic or nonhybrid).	1904	Weshart and Trimble tangerines.	Derived from Dancy cross-pollinated seed, but not hybrids.	Seedlings exhibiting apparently extra vigor and producing fruits of larger size than the parent variety.
	1905 1906	Everglade lime Palmetto lime	Grown from lime seed from cross-pollinated fruits, but not hybrids.	Apparently extra vigorous strains of the Mexican lime with some indications of withertip resistance.
	1912	Davis (Little River) grapefruit.	Original seedling from cross-pollinated fruit of a seedy grapefruit (with Dancy tangerine pollen); not a hybrid.	This seedling produced a new type of seedless grapefruit (4-6 seeds) with the fruit quality of the seedy grapefruit; indications are that it is a superior canning variety.
	1931	Silverhill satsuma orange.	Original seedling from cross-pollinated Owari satsuma (sweet orange pollen), but not a hybrid.	This variety exhibits extra vigor and hardiness, with large-sized fruit of good quality.
	1932	Oklawaha sour orange	Derived from cross-pollinated sour orange (sour pummelo pollen used), but not a hybrid.	Tree of vigorous productive character with large thick rind fruits adapted to use in marmalade preparation. This character has been transmitted in budded progeny.
Bud selection [1]	1921-36	Valencia, Lue (Lue Gim Gong), Pineapple, Parson Brown, and Homosassa oranges; King mandarin; Dancy and Oneco tangerines; Marsh, Duncan, Hall, Davis, Foster, and Thompson grapefruit	Budwood secured from performance record trees; several progeny rows of each variety budded and grown under uniform conditions with record of yield, and special attention to the production of any off-type fruit. (1 progeny of Lue was discarded and replaced, owing to tendency to produce ridged fruits. A bud sport of the Parson Brown has been studied over a period of years and seems to be a chimeral mutation).	Under the terms of the cooperative agreement the disposition of budwood from the progeny grove is in the hands of the Florida Agricultural Experiment Station, and considerable demand has developed in recent years among growers and nurserymen for this true-to-type budwood of standard varieties. The experiment station, also under the cooperative agreement, is testing the new citrus hybrids introduced by the Department and maintains a collection of the citrus relatives furnished by the Department.

[1] Standard orange varieties as listed by the standardization committee of the Florida Citrus Seminar 1916; other citrus varieties selected and propagated in cooperation with the Florida Agricultural Experiment Station at the Citrus Experimental Station, Lake Alfred, Fla. For bud selection work in California, see table 8.

TABLE 8.—*Bud mutations in citrus discovered by Shamel and coworkers, of the United States Department of Agriculture, in cooperation with the California Citrus Experiment Station, Riverside, Calif., 1909–36*

SWEET ORANGE (WASHINGTON NAVEL STRAINS)

Strains	Characteristics	Date discovered	Remarks
Superior strains:			
Improved Washington.	Uniformly heavy production of uniformly desirable oranges.	1909	1,402,950 selected buds sold by Fruit Growers Supply Co. and estimated 2,000,000 otherwise distributed.
Robertson	Early maturity, resistant to "June drop."	1925	Plant patent 126.
Inferior strains:			
Thomson	Fruits generally lacking juice and flavor.	1909	Propagated sparingly in few districts.
Unproductive	Very low production	1913	Trees top-worked to Improved Washington.
Australian	Low production, poor fruit, rank growth.	1909	Do.
Willow-Leaf	Narrow leaves, small fruit	1915	Do.
Dry	Very little or no juice	1914	Do.
Yellow	Pale yellowish color of peel	1909	Do.
Brown-Spotted	Sunken brown spots on peel	1915	Do.
Golden Buckeye	Lacking in juice	1909	Do.
Golden Nugget	Lacking in juice; pale color of peel	1909	Do.
Dual	Uneven texture of rind	1914	Do.
Corrugated	Deeply and uniformly ridged fruit	1909	Do.
Ribbed	Shallow and uniformly ridged peel	1909	Do.
Seamed	Very shallow, narrowly seamed peel	1914	Do.
Fluted	Broadly and evenly ridged peel	1910	Do.
Flattened	Flattened shape of fruit	1909	Do.
Pear-Shape	Pyriform shape of fruit	1909	Do.
Elliptical	Oval shape of fruit	1909	Do.
Sheepnose	Small, pear-shaped fruit, enclosed navels.	1915	Do.
Rolled-Leaf	Rolled leaves, unproductive	1921	Do.
Minor importance	Many strains of minor economic importance but originating from bud mutations.	1909–36	Do.

SWEET ORANGE (VALENCIA STRAINS)

Strains	Characteristics	Date discovered	Remarks
Superior strain:			
Improved Valencia	Uniformly heavy production, uniformly good quality of fruit.	1912	2,337,000 selected buds sold by Fruit Growers Supply Co., and estimated 2,250,000 buds otherwise distributed.
Inferior strains:			
Unproductive	Very low yields	1912	Trees top-worked to Improved Valencia.
Willow-Leaf	Narrow leaves, small fruits	1912	Do.
Dwarf	Small tree, low yields	1912	Do.
Persistent-Style	Style tends to remain with fruit	1915	Do.
Flattened	Flattened shape of fruit	1912	Do.
Long	Long or oblong shape of fruit	1912	Do.
Fluted	Broadly, evenly, and smoothly ribbed fruit.	1912	Do.
Corrugated	Deeply ridged, rough texture of rinds	1912	Do.
Ridged	Sharply and unevenly ridged rinds	1912	Do.
Coarse	Coarse, rough texture of rinds	1912	Do.
Yellow	Pale color of peel	1912	Do.
Misshapen-Leaf	Irregularly shaped leaves, low yields	1914	Do.
Small Smooth	Very small fruit, smooth, very thin rinds.	1912	Do.
Variegated	Leaves light and dark green	1915	Do.
Minor strains	Many economically unimportant strains differing in tree and fruit characteristics from all others.	1912–36	Do.

LEMON (EUREKA STRAINS)

Strains	Characteristics	Date discovered	Remarks
Superior strain:			
Improved Eureka	Heavy yields of uniformly good lemons.	1911	767,000 selected buds sold by Fruit Growers Supply Co., and estimated 1,250,000 buds otherwise distributed.

TABLE 8.—*Bud mutations in citrus discovered by Shamel and coworkers, of the United States Department of Agriculture, in cooperation with the California Citrus Experiment Station, Riverside, Calif., 1909–36*—Continued

LEMON (EUREKA STRAINS)—Continued

Strains	Characteristics	Date discovered	Remarks
Inferior strains:			
Small-open	Small-sized fruits	1911	Trees top-worked to Improved Eureka.
Pear-shape	Pyriform-shaped fruits	1911	Do.
Shade-tree	Vigorous tree growth; coarse, thick rinds.	1911	Do.
Unproductive	Very low yields.	1911	Do.
Corrugated	Strongly ridged and coarse-textured rinds.	1911	Do.
Ribbed	Evenly ribbed texture of rinds	1911	Do.
Variegated	Leaves light and dark green, fruits ridged.	1912	Do.
Striped	Light stripes on fruits	1912	Do.
Crumpled leaf	Crumpled appearing leaves, low yields.	1911	Do.
Minor strains	Many strains originating from bud mutations of minor economic importance.	1911-36	Do.

LEMON (LISBON STRAINS)

Strains	Characteristics	Date discovered	Remarks
Superior strains:			
Improved Lisbon	Heavy production of uniformly desirable fruits.	1913	86,215 selected buds sold by Fruit Growers Supply Co., and estimated 125,000 buds otherwise distributed.
Dense-productive	Vigorous growth, resistant to wind damage.	1913	Do.
Inferior strains:			
Open	Spreading tree growth, susceptible to sunburn.	1913	Trees top-worked to Improved Lisbon.
Unproductive	Very low yields	1913	Do.
Ribbed	Ridged texture of rind	1913	Do.
Corrugated	Heavily ridged and very coarse-textured rinds.	1913	Do.
Collared	Bottle-shaped with necked stem ends.	1913	Do.
Striped	Light-colored stripes on rinds	1913	Do.
Thornless	No thorns	1920	Do.
Minor strains	Many strains of minor commercial importance but of scientific interest.	1913-36	Do.

GRAPEFRUIT (MARSH STRAINS)

Strains	Characteristics	Date discovered	Remarks
Superior strains:			
Improved marsh	Heavy production of uniformly desirable fruits.	1910	1,262,757 buds sold by Fruit Growers Supply Co. and estimated 750,000 buds otherwise distributed.
Dawn	Early maturity of fruits	1927	
Inferior strains:			
Corrugated	Ridged texture of rinds	1910	Trees topworked to Improved Marsh.
Seedy	Excessive number of seeds	1910	Do.
Pear shape	Pyriform-shaped fruits	1910	Do.
Minor strains	Several strains of minor commercial importance but of scientific interest.	1910-37	Do.

TANGERINE (DANCY STRAIN)

Strains	Characteristics	Date discovered	Remarks
Superior strain:			
Improved Dancy	More regularly productive	1915	56,973 selected buds sold by Fruit Growers Supply Co.

TABLE 8.—*Bud mutations in citrus discovered by Shamel and coworkers, of the United States Department of Agriculture, in cooperation with the California Citrus Experiment Station, Riverside, Calif., 1909–36*—Continued

LIME STRAINS

Strains	Characteristics	Date discovered	Remarks
Superior strains:			
Improved Mexican	Selected for size of fruits	1924	5,163 selected buds sold by Fruit Growers Supply Co.
Improved Bearss	Selected for heavier production	1928	

NOTE.—*The article entitled Improvement of Subtropical Fruits other than Citrus, by Hamilton P. Traub and T. Ralph Robinson, appears in the 1937 Yearbook Separate on Improvement of Subtropical Fruits.*

NUT BREEDING

H. L. CRANE, Principal Horticulturist, C. A. REED, Associate Pomologist, and M. N. WOOD, Pomologist, Division of Fruit and Vegetable Crops and Diseases, Bureau of Plant Industry

IMPROVEMENT in nuts by some sort of selection was probably brought about originally by cave men, wild animals, and birds. The more toothsome nuts were the ones chiefly sought after and carried from place to place or hidden in caches. Weaker creatures, forced by stronger rivals from warmer and more comfortable localities, were obliged to steal their food and carry it to places safer for themselves although often less favorable for the nuts, which they might lose, to take root and thrive. It was by such means that the productive areas were gradually expanded and greater hardiness and ability to grow at higher or lower altitudes were developed. Ocean currents, which have much to do with the distribution of many kinds of seeds, appear to have had little part in the carrying of Temperate Zone nuts from place to place.

Planters have as yet made little systematic effort to breed superior varieties of any kind of nuts by hybridization. This is doubtless because of the great abundance of wild nuts that in the past could be had for the gathering, and more recently because of the practical difficulties standing in the way of tree breeding, especially the time required to complete the cycle of a generation. The countless centuries of crude selection through which such cultivated forms as filberts, almonds, Persian (English) walnuts, and European chestnuts have passed have tended so to fix the types that to a large extent they now come fairly true to type from seed, although in this country none but grafted trees of selected varieties are planted, except when only seedlings are to be had. Most of the nuts now on the world market are from seedling trees. The extensive multiplication of superior varieties resulting from selective or controlled breeding is still greatly handicapped by practical difficulties in propagation, especially in the case of the more difficult species of walnut and hickory.

CHESTNUT

CHESTNUT improvement in this country has developed along four distinct lines—by selection from native seedlings, by the introduction of Old World species and the continuance of selection with them, by natural hybridization among various species and varieties when grown together, and by controlled hybridization, the newest and most promising method.

Breeding by selection from native species has contributed little, as few varieties developed by this method have become prominent.

The majority so originated are now obsolete, and it would probably be impossible to establish the purity of the supposed American parentage of the very few still grown by nurserymen. Numbers of hybrids exist that are plainly the result of natural crossing between native species, but none has commercial value.

Because the American chestnut is very susceptible to what is known as blight, a fatal fungus disease from the Orient, which was first discovered in this country in 1904 and has since spread over practically the entire East, the chief interest in chestnut planting now lies in the use of species from the Old World.

Altogether eight species of chestnuts, including the closely related chinquapins, have been used in the chestnut developments of this country. Formerly the most important and abundant of these species was the American chestnut, *Castanea dentata* (Marsh.) Borkh. This had a natural range extending from lower New England westward to southeastern Michigan and southward to northern Georgia and eastern Arkansas. As a tree it was one of the largest growing species of the Eastern States; a trunk diameter of 6 to 7 feet and a limb spread of 50 or more feet from the center of the tree were not uncommon with trees standing in the open. As a forest tree it was once a dominant species over large mountain areas of the Appalachian Range from Pennsylvania south to the Carolinas and eastern Tennessee. In these regions a height of more than 100 feet with a diameter at the base of

WHEN *the chestnut blight wiped out this magnificent eastern forest tree in the early part of the present century, chestnut breeding became a pressing need. The most promising of all material at present is the Chinese chestnut. It is much more blight-resistant than any others, and the nuts combine the large size of the European chestnut with the sweetness of the American. The Japanese chestnut, which has considerable blight resistance, unfortunately produces nuts that are usually negative in flavor, but it may be useful in breeding. Selection and hybridization are being actively carried on by the Department of Agriculture with the object of developing varieties for both commercial and home growing that will be resistant to blight and if possible to weevils, and hardy enough to grow throughout the chestnut range; bear heavy annual crops, beginning at a fairly young age; bear not more than three rather large nuts to the bur, which must separate automatically; have fine texture, good flavor, and good keeping quality; be attractive in appearance and not subject to shell splitting; and have an inner skin or pellicle that will not adhere to the kernel.*

not more than 2 to 3 feet was common. The trees were much sought after as material for telephone poles, fence rails, mine props, and other similar purposes where important factors were abundance, uniformity of size, freedom from knots, ease of splitting, and durability both above and below ground.

The burs of the American chestnut are relatively large and the spines long and compound. The nuts are coated at the apex, or nearly to the middle, with thick, pale down. The kernels are very sweet and palatable. Selected nuts of this species are among the most delicious of any known. They were thought to be the choicest of all chestnuts until the arrival of certain oriental strains, which proved to be their equal.

Two other species of *Castanea* are indigenous to this country. Both are chinquapins and therefore not true chestnuts, although closely related. These are much alike and are restricted to more limited ranges than the American chestnut. The trees are dwarfish or shrubby in habit, and the nuts are borne singly in small burs, which form in racemes or long, stringlike clusters. The nuts are small but very sweet. The better known of the two species is the tree or common chinquapin, *C. pumila* (L.) Mill. This occurs chiefly in the Southeast, from central Pennsylvania to Florida and west to Texas. The species occasionally forms hybrids with the American chestnut. One such hybrid tree was found, probably about 1895, by the late J. G. Rush, of West Willow, Pa. This was propagated and disseminated to some extent by Rush, after whom it had been named, but after a few years of experimentation he cut down the trees as he came to regard the variety as merely a novelty of little practical value. However, trees are still grown by some who find it an interesting form of considerable value for home use. The other species of chinquapin is the so-called alder-leaved or trailing chinquapin, *C. alnifolia* Nutt., a low-growing shrub confined to certain localities in the South Atlantic States and occurring rarely as far west as central Louisiana. This species has the peculiarity of reproducing itself by means of underground stems and forming dense thickets.

Developments From Early Introductions

The first foreign chestnut introduced into this country was the European or Spanish chestnut, *Castanea sativa* Mill. The earliest record that has so far come to light appears in the notes of Thomas Jefferson, according to Bailey (*5*),[1] and shows that scions of a "French chestnut" were grafted by him in 1773 at his home, Monticello, near Charlottesville, Va. This species also is a large tree, growing in Europe to 100 feet in height and 30 feet in circumference, though in this country it seldom grows larger than a medium-sized apple tree. The trees are precocious and under American conditions very fruitful. The nuts are large and usually very good but rarely equal in quality to the average American chestnut. The tree is scarcely less fatally subject to blight than the American chestnut and therefore is not longer being planted in blight-affected zones.

The second foreign species to become important in this country was the Japanese chestnut, *Castanea crenata* Sieb. and Zucc. This is a

[1] Italic numbers in parentheses refer to Literature Cited, p. 881.

relatively small tree or shrub growing to 30 feet in height. The species is characterized by small stiff leaves, great fruitfulness, and large size of nuts, which are sometimes enormous. Occasionally the nuts are very good but as a rule the flavor is mild or neutral and the texture somewhat coarse. Quite commonly the pellicle or skin covering the kernel is thick or even woody. It may adhere tightly and be removable only by paring with a knife. The species is quite resistant to blight, although in the experience of the Division of Forest Pathology, Bureau of Plant Industry, United States Department of Agriculture, it is exceeded somewhat in this respect by the Chinese or hairy chestnut (*C. mollissima* Bl.)

The Chinese chestnut tree is intermediate in size between the European species as grown in this country and the American species. It was known in the United States to a slight extent as early as 1853, but it may be said to have been introduced by the Department of Agriculture in 1907. While very young it tends to develop many lateral branches with little tendency toward a central leader. Later on it assumes more definite shape and becomes a standard tree. It begins bearing relatively early and is sometimes highly prolific. The outstanding feature of this species, in addition to the fact that it is apparently more resistant to blight than any other, is the excellence of the nuts, many of which are as large as the European and as sweet as the best American nuts They are attractive in appearance, often being of a rich mahogany brown and frequently glossy. There is little down on the surface and that only at the apex. When in the proper stage of maturity the pellicle of the kernels tends to adhere to the shells rather than the kernels

In 1799 Irenée du Pont came to New Jersey from France and "after a residence at Bergen Point, where he took much pleasure in propagating a number of European seeds and plants received from France, removed to Delaware in 1802 and settled on the Brandywine, where he established the famous Du Pont Powder Mills" (*26*). At both places Du Pont paid special attention to bringing European chestnuts into this country, chiefly from his native home, and to disseminating both these and their offspring among his friends and acquaintances. Records show that many varieties of European chestnuts, which during the eighties and nineties became prominent in this country, were derived from Du Pont introductions

Powell (*26*) records that scions taken from one of the Du Pont trees and grafted in 1850 on stocks of the native species gave rise to a variety named Darlington, after Thomas Darlington, of West Chester, Pa., who was intrumental in disseminating the variety. This may have been the first chestnut grafting in this country after that of Jefferson.

Beginning in the early eighties and continuing for about two decades, a large number of seedlings of European species were named and propagated. Some of these were popularly supposed to have been hybrids with the American species, but this was not proved. A few were extensively used in top-working coppice growth in cut-over chestnut forest lands of eastern Pennsylvania, New Jersey, northern Maryland, and northern Virginia. All proved to be fatally susceptible to blight. The best-known varieties were Paragon, Numbo,

Ridgeley, Cooper, and Scott. These are now rarely grown and are found only in districts outside of blight-affected zones. Even there they are being replaced by better varieties.

A more recent group of varieties, thought by some to be partially or entirely European in origin, although regarded by the originator as pure American, was developed by the late E. A. Riehl, of Godfrey, Ill., from seedlings of unknown origin obtained from the nursery of Charles A. Green, Rochester, N. Y., and planted about 1890. To hasten the trees into early bearing Riehl grafted scions from them into the top of an old seedling American chestnut. The resulting nuts so impressed him that he named the variety Rochester. From Rochester seedlings he selected and named a number of still better varieties such as Progress, Fuller, Champion, and Van Fleet. Gibbens, from the same source, has been added since Riehl's death in 1924. However, these varieties, like all others having either European or American parentage, are very susceptible to blight, and when once affected the trees perish quickly.

The Japanese chestnut, *Castanea crenata*, has also been a source of numerous varieties having desirable characteristics. According to Fuller (*14*), the earliest recorded introduction of this species took place in 1876, when a number of trees were received by S. B. Parsons & Co., nurserymen at Flushing, N. Y., from Thomas Hogg, a skilled horticulturist of this country who spent several years in Japan collecting rare kinds of trees and shrubs. These trees fruited in 1878 and soon attracted attention on account of the large size and excellent quality of the nuts and their precocious bearing habits. According to Powell (*26*), "Parson's Japan" was well known for a few years, but presently disappeared.

In 1882 the late William Parry, of Parry, N. J., imported 1,000 grafted trees from Japan, and from them a single tree, the Parry, was finally selected and became the progenitor of many varieties. In 1886 Luther Burbank, of Santa Rosa, Calif., planted large Japanese chestnuts collected for him in Japan, and from over 10,000 bearing seedlings he selected 3 as worthy of perpetuation—Hale, Coe, and McFarland. In 1915 he introduced another variety, Miracle, also of Japanese origin. Groups of Japanese varieties were developed by J. W. Kerr, Denton, Md., and J. W. Killen, Felton, Del., probably from seed procured from Parry or other importers. Each of these men introduced a considerable number of carefully chosen varieties, of which Black, Felton, Kent, Kerr, Killen, and Martin are still being grown occasionally on the Chesapeake Peninsula.

Developments and extensive plantings of Japanese and European chestnut varieties made from 30 to 40 years ago included those of the Albion Chestnut Co. at Clementon, N. J.; the Mammoth Chestnut Co. and Joseph Williams at Riverton, N. J.; Joseph T. Lovett at Emilie, Pa.; the Paragon Nut & Fruit Co., Lancaster, Pa.; and C. K. Sober, Lewisburg, Pa.

Breeding by Hybridization

Chestnut breeding by controlled cross-pollination appears to have been the first work of the kind undertaken in this country, if not in the world, with any species of nut, and a number of apparently good

varieties were so developed. Unfortunately, chestnut blight entered from the Orient at about the time the hybrids were ready to be introduced, and none proved to have sufficient resistance to this disease to justify extensive planting. This early work was undertaken almost simultaneously by two men wholly unknown to each other and living in remote sections of the country. Both died about the time that material was becoming available with which the next steps in breeding and the development of blight-resistant varieties might have been taken.

The first work appears to have been that begun in 1888 by George W. Endicott, of Villa Ridge, Ill., a veteran of the Civil War, farmer, and practical fruit grower. In that year he began a search for an American chestnut tree blossoming early enough to furnish pollen for use on the pistillate flowers of the Giant (Japan Giant) variety (*39*), which was prolific but not of high grade. It was as a result of such a cross made by him in 1895 that he developed the Boone variety.

The next hybridizing work with chestnuts began in 1894 when Van Fleet (*43*) well known in this country as a breeder of roses and small fruits, who was then an associate editor of the Rural New Yorker, dusted pollen of a native chestnut on the pistillate flowers of Paragon, a popular variety of European parentage. The resulting seedlings were grown on the private grounds of Van Fleet in Little Silver, N. J. Coming into bearing in 1906, they showed unmistakable signs of hybridity and might have become valuable had they not been seriously attacked by chestnut blight a year or so after beginning to fruit.

The period of Van Fleet's most important work in chestnut breeding began in 1900. Between then and the time of his death in 1921 he made thousands of crosses, using many species and growing hybrids through several successive generations. His earlier work largely consisted of crossing the native chinquapin, *Castanea pumila*, with such leading European varieties as Numbo and Paragon and such Japanese sorts as Parry (Parry's Giant), Killen, and Hale. To some extent he also used pollen from native wild trees of the American chestnut. In his later work he included the Chinese chestnut, *C. mollissima*.

The final results of Van Fleet's work were practically nil, so far as production of commercial varieties was concerned, for the reason that all hybrids having any degree of either American or European parentage proved susceptible to blight and soon succumbed. However, one hybrid, designated as S–8 from its position in the orchard, and believed to have been the result of a cross of chinquapin with Japanese chestnut, is being tested under controlled infection conditions for possible resistance. Recent reports indicate that this hybrid is not sufficiently resistant to blight to justify general planting.

The work of both Endicott and Van Fleet is important because it gave information as to the possibility of using different species in breeding and it developed a useful technique.

The chestnut breeding of Van Fleet has been continued and expanded by the Division of Forest Pathology of the Bureau of Plant Industry with G. F. Gravatt and R. B. Clapper in charge. Thousands of crosses have been made involving the eight species, and the work has been carried through several successive generations. Selections are now being made of the most promising individuals for varietal use.

Defects and Merits of Present Varieties

Present varieties of the chestnut have many serious defects, of which susceptibility to certain natural enemies is most prominent. One of these enemies is chestnut blight, the fungus disease already referred to as attacking all species in varying degrees. It has spread rapidly over the native range of the chestnut since it was first discovered on Long Island early in the present century. It is most serious with the American and next with the European chestnut. Japanese varieties and seedlings are resistant. Varieties of the Chinese chestnut, *Castanea mollissima,* appear to be even more resistant, and as the nuts are generally superior to those of the Japanese chestnut, the species appears to offer greater promise for orchard planting.

Chestnut weevils are native pests attacking all choice varieties with about equal severity. If any chestnuts are less subject to this menace than others they are the largest and least palatable of those from Japan. The adult weevil deposits its eggs deep in the immature kernel when the nut is partially grown. One egg or many may be placed in each nut. They hatch at about the time the nuts ripen, and the larvae feed and fatten inside the nut, then bore their way out and enter the ground for the winter stage. In early-ripening varieties these insects often do not appear until after the nuts have arrived in the market. A few days later, especially if the weather is warm, and about the time the nuts reach the consumer, the white larvae or grub-like insects emerge. In severe infestations these pests will be seen crawling in all directions, or if a nut is cut open they will be found in various parts of the kernel, to the disgust of the would-be consumer.

Whether blight, which may completely kill the tree and end the story, or weevils, which do not affect the tree but ruin the nuts after they are grown, is the more seriously limiting factor in chestnut growing is an open question. No method of spraying has been found sufficiently effective with either to be worth while. However, as already stated, the blight-resistant Chinese and Japanese species appear to offer a practical solution to the former evil, and to some extent planting chestnut trees only in thickly populated poultry yards is being found successful in controlling the latter. One way of avoiding weevil damage would be to plant only in parts of the country where this pest is not known to be present. As time goes on, more satisfactory means of controlling or obviating both of these natural enemies may be developed.

Other defects of chestnuts are tardy bearing; shy bearing or over-productiveness; lateness in time of maturity; failure of the burs to open and discharge the nuts automatically; variability in size of nuts; a tendency for the shells to split badly and thus expose the kernel to weather; thickness of pellicle; tight adherence of pellicle to the kernel; and coarseness, lack of sweetness, and poor keeping qualities. No known varieties are free from all of these objectionable features. With some exceptions, the American chestnut bears nuts that are small and unattractive in appearance, and the pellicle of the kernel adheres tightly, although it is so thin as not to be objectionable. The trees grow to immense size but are tardy in beginning to bear and seldom bear

heavily. Besides being fatally subject to blight, the European chestnut is usually of medium flavor, the pellicle adheres tightly to the kernel, and the texture is seldom as fine as that of the American and Chinese species. The chief defects of the Japanese chestnut are poor flavor and coarseness of kernel, thickness and even woodiness of pellicle, and usually tight adherence of pellicle to kernel. As a rule Japanese chestnuts are good to eat only when cooked. The Chinese chestnut also has its defects, but owing to its newness in this country it has not yet been fully appraised. As already noted, it is subject to weevils and somewhat so to blight. Young trees are slow in assuming distinct tree form. While of nursery age the little trees are very subject to winter injury. Nothing is known as to the self-sterility or inter-sterility of Chinese varieties. Very few have yet been named and none has been thoroughly tested. The real merits and defects of this species can be determined only by wide observation over a period of years.

The good characteristics of chestnuts are fairly well distributed among the various species and varieties. The American chestnut makes the largest and most upright tree, is by far the best for timber purposes, and the kernels are the most uniformly sweet. The European chestnut bears well and annually, beginning at a moderately early age. The tree does not ordinarily assume such great size as to be objectionable to the orchardist. The nuts are of good commercial size, and those of some varieties are sweet and highly palatable. Nuts of this species often bring top prices. The Japanese chestnut is outstanding in its normal precocity, prolificacy, habit of annual bearing, and large size and attractive appearance of the nuts. The species is highly resistant to blight and would need only the sweetness, fineness of texture, and palatability of the best American and Chinese chestnuts, and the automatic separation of pellicle from kernel, characteristic of some of the latter, to rank among the favorites with both growers and consumers. There are a few Japanese varieties of such merit as to give promise of orchard usefulness.

As a rule, all chestnuts are more or less self-sterile and bear better when interplanted with other varieties or seedlings.

The Chinese chestnut appears at this time to offer the greatest opportunity for improvement by breeding. The trees do not attain the large size of the American species, which is undesirable, but they do become somewhat larger than the Japanese, which in this country seldom exceed the apple tree in size. The Chinese chestnut is highly resistant to blight, and so far as observed the best seedlings and varieties bear freely without being overproductive. Some of the heaviest-bearing trees of this species in a seedling orchard located at the United Station Pecan Field Station, Albany, Ga., now 10 or 12 years of age, are annually producing from 50 to 70 pounds of nuts each. The finest nuts of the Chinese species are about all that could be desired. The largest are equal in size to the average chestnuts imported from Italy as commonly seen in eastern cities from midfall until after the holidays. Typically the Chinese chestnuts are of dark, chocolate-brown color, overlain with thick to thin gray or whitish down that may cover the greater part of the exposed surface or be confined to a small area immediately surrounding the apex. They are commonly glossy and attractive. Some are only mildly sweet, but others are excellent.

With regard to automatic separation of nuts from the burs, as well as time of maturity of crop, marked variability exists among seedlings and varieties of all species. As a rule the Chinese and Japanese chestnuts ripen earlier and separate themselves from the burs better than either European or American chestnuts.

Present Breeding Work

Breeding work is largely confined to the Chinese chestnuts, though the Japanese may be useful to some extent. The present work in improving the Chinese chestnut necessarily involves the selection of seedlings promising as new varieties and the use of such varieties in actual breeding by hybridization. During the past several years the United States Department of Agriculture, Bureau of Plant Industry, through its Divisions of Fruit and Vegetable Crops and Diseases and of Forest Pathology, has examined nuts from several hundred trees in various parts of the country. Probably 100 seedlings are now under observation. Scions of many of the best have been grafted upon nursery stocks and are now on their way to early bearing. Three of the trees tentatively selected in 1930 have been propagated by individuals outside the Department and to some extent are being commercialized, although they are by no means fully tested or approved by the Bureau. One of these is known as Carr, after R. D. Carr, Magnolia, N. C., to whom the original tree was sent by the Bureau in 1919. Another is Hobson, so called after James Hobson, Jasper, Ga., to whom, with a number of others, it was sent in 1919. The third variety is Zimmerman. This was selected by the Bureau from a lot of seedlings grown by G. A. Zimmerman from nuts imported by him in 1924 through Nanking University, Nanking, China.

The trees under observation also include a number of Japanese seedlings that now appear to be of considerable promise. The majority of these are of recent origin, as they were brought to light in 1929 as a result of cash prizes financed that year by John Harvey Kellogg, Battle Creek, Mich., through the Northern Nut Growers' Association.

The aims in breeding are to produce varieties that will be of value for the general market or the home or both. The desired characteristics at present are resistance to blight and weevils, heavy annual bearing, moderate precocity, early and quick maturity of nuts ahead of frosts, automatic separation of the nut from the burs, not more than three nuts to the bur, large but not of too great size, attractive appearance, freedom from shell splitting, thinness of pellicle, automatic separation of kernel from pellicle, fine texture, good flavor, and good keeping quality. Hardiness in all parts of the native or adapted range of the chestnut is also important.

In the appendix will be found a list of persons now engaged in the improvement of the chestnut through breeding.

FILBERT

The term "filbert" is used in this article in accordance with the popular American usage and is understood to imply a superior type of nut of the botanical genus *Corylus*. The term "hazel" is used for the inferior and smaller nuts. In Europe the distinction is drawn upon the basis

of length of husk in proportion to that of the nuts. Those that have husks no longer than the nuts are called hazels, while those with husks longer than the nuts are called filberts. This distinction is difficult to follow, once the husks have been removed.

At least four species of *Corylus* are under cultivation for nut production. Two of these are tree forms attaining a height of 80 to 125 feet. Both are commonly called hazels, as the nuts they bear are rather small, thick-shelled, and inferior in edibility. One is the Turkish or Constantinople hazel, *C. colurna* L., of southeastern Europe and western Asia. According to Rehder (*28*), this species was introduced in 1853. It is extremely hardy, doing well in western New York, where three fine trees 50 feet tall are to be seen in Highland Park, Rochester. It is used in this country for ornamental planting and as a stock on which to graft superior varieties of the European filbert. The latter use is still in the experimental stage and is not recommended for commercial purposes. The other tree species is the Chinese hazel, *C. chinensis* Franch., which Rehder states was introduced into this country in 1895. Its usefulness for stock or other purposes has not yet been determined.

Two native species of *Corylus* that are being used to some slight extent in the development of varieties are the eastern hazel, *C. americana* Marsh., and the beaked hazel, *C. cornuta* Marsh. Both are shrubby species producing nuts ordinarily of little value. The former has much the greater range in this country, as it is common from the Lakes to the Gulf, whereas the latter occurs only in the northernmost States. Nuts of the eastern hazel have husks longer than the nuts, and they develop as overlapping valves opening at one or both sides to the base. The beaked hazel has long, tubular, and thickly spiny husks, which remain tightly closed. A form found on the Pacific coast, greatly resembling the latter and known by some authorities as *C. californica* Rose, but by others as a form of *C. cornuta*, is common as a wild shrub from California north to Washington. This has been used little or not at all in breeding work. A number of varieties of *C. americana* have been introduced into garden culture in the East and are being grown by nurserymen. The three best known are Rush from Pennsylvania, Littlepage from Indiana, and Winkler from Iowa. Rush has been used extensively in breeding new hybrid varieties. Littlepage and Winkler have been used to some extent in this way.

The commercial production of filberts is now an important industry in the Pacific Northwest, especially in the Willamette Valley of Oregon and in nearby parts of western Washington. Most of the varieties are of the species *Corylus avellana* L., although some are of *C. maxima* Mill. and others are apparently hybrids between these two species. Trees of the former often attain heights of 25 to 30 feet, and many of those first planted in this country now have trunks fully 18 inches in diameter a foot or so above ground. Those of the latter are said to attain a height of 30 to 35 feet in Europe and Asia, but no trees of such size are known in this country. The husks may be shorter or longer than the nuts, or of the same length. All cultivated varieties except those of *C. maxima* parentage have husks that are open or overlapping at the sides. The husks of *C. maxima* varieties

remain tightly closed. The nuts may or may not be naturally discharged free from the husks; varieties of *C. avellana* vary greatly in this respect. Typical varieties of *C. avellana* are Barcelona, Bolwyller, Du Chilly, Daviana, and Italian Red. White Aveline is the best known variety of *C. maxima* parentage.

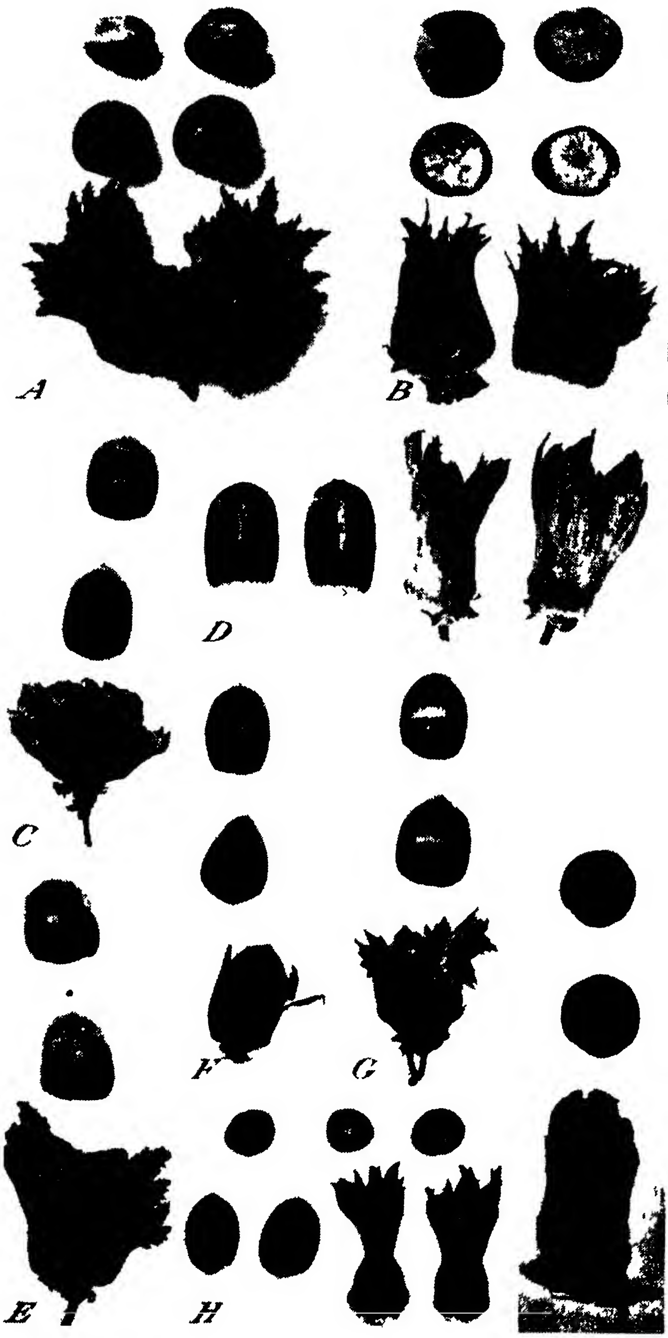
Need for Cross-Pollination

As far as known all varieties of *Corylus* are self-sterile and must be interplanted in order to assure effective pollination, a fact that is of rather recent discovery, although it became known more than a century ago that varieties are often made more fruitful by the application of additional pollen from other trees to the pistillate flowers of those having a scarcity of staminate flowers. This appears to have been the discovery of George Swayne of England about 1821. He discussed it at some length in a paper On the Fertilization of the Female Blossoms of Filberts, which he read February 18, 1823. The paper was published the following year in the Transactions of the Horticultural Society of London.

Figure 1.—John Franklin Jones (1871–1928), Lancaster, Pa., introducer of many valuable varieties of nuts. He is believed to have been first to breed filberts by hybridization of species. Beginning in 1917, he sought to cross European varieties of *Corylus avellana* with the Rush hazel, *C. americana*. Being entirely unsuccessful for 2 years, he reversed the order in 1919 with immediately favorable results. By this method he developed the Bixby and Buchanan varieties, which have been named and introduced since his death.

In that paper Swayne told of a series of experiments begun by him in 1820 and continued for 3 years. During the first year he suspended catkins of the wild hazel (*Corylus avellana*) in the tops of two filbert trees having profuse pistillate blooms but a scarcity of staminate flowers. The trees had been owned by him for 14 years, during which time there had been practically no crops. That year, however, following the application of abundant pollen, the yield was "exactly 2 pounds." With this encouragement he checked the experiment the following year by first noting as before that the pistillate flowers were abundant but that there were practically no staminate flowers. He refrained from adding pollen and the crop that year was again a practical failure. The next year, when for the third time there were many pistillate flowers and few staminates, he made applications of pollen from the wild hazels to the stigmas of the garden trees. The crop was again very good, and soon after the harvest he reported the results of his 3 years' work.

So far as known, the next investigation of this nature occurred almost a century later when, in 1917, the late J. F. Jones (fig. 1), of Lancaster, Pa., sought to hybridize the European varieties of filbert with the Rush variety of American hazel, *Corylus americana* (fig. 2, *A*). He and many others had found the former not commercially



Corylus varieties that have been successfully used in eastern filbert breeding: *A*, Rush (*C. americana*), the pistillate parent mainly used; *B*, Barcelona (*C. avellana*); *C*, Rush × Barcelona, Buchanan variety; *D*, Du Chilly (*C. avellana*); *E*, Rush × Du Chilly; *F*, Italian Red (*C. avellana*); *G*, Rush × Italian Red, Bixby variety; *H*, White Aveline (*C. maxima*); *I*, Rush × White Aveline.

Figure 2.

hardy in the East, and the Rush was the best of the native hazels that came to his attention. For 2 years he applied Rush pollen to the pistillate flowers of several European varieties, with negative results. In 1919 Jones reversed the order and there was a good crop of nuts. These were planted during the following spring, and from that time until his death in January 1928, Jones was an active and enthusiastic filbert breeder. His hybrids came into bearing early, and by 1924 about 100 were in fruit. By the end of the next 3 years he had selected 12 to 15 for further observation and eliminated a considerable number. One that had been numbered 200 proved so promising that he was seriously considering its propagation and introduction to the public. This plant was the result of a cross between Rush and Italian Red. It has since been named Bixby (fig. 2, *G*) after the late Willard G. Bixby, of Baldwin, N. Y., a friend and coworker of Jones. Another plant, no. 92, greatly resembling Bixby, but shown by Jones' record to be a Rush × Barcelona cross, has been named Buchanan (fig. 2, *C*) and is being propagated for the nursery trade. Both Bixby and Buchanan are apparently of considerable promise for home planting in the East

Figure 3.—Felix Gillet (1835–1908), proprietor of Barren Hill Nurseries, which he established at Nevada City, Calif., in 1871. He was one of the most outstanding figures of his time in introducing carefully selected varieties of filbert. Persian walnut, and chestnut from Europe.

European Filberts in the Eastern United States

In the aggregate there has been a large amount of selection work with the filbert in this country during the past century or more. Plantings of European varieties and seedlings have been made frequently in various sections. Most of the better varieties and seedlings were introductions made during the eighties and nineties by the late Felix Gillet (fig. 3), a Frenchman who established a nursery at Nevada City, Calif., in 1871. A good many introductions have been made by others, so that altogether several hundred varieties and seedlings from Europe have been tried out in this country. The best of these have proved commercially profitable only in the Pacific Northwest. They have been successful in the East to a limited degree and as a rule only when grown in situations well protected from extremes of temperature, as by a large body of water, a building, a hill, or a group of trees.

Three known factors stand in the way of success with the European varieties of filbert in the East. The most important is a serious blight, *Cryptosporella anomala* (Pk.) Sacc., which causes little injury to the native species but spreads quickly and with fatal results to

European varieties planted in the vicinity. The likelihood of serious losses by this disease has decreased greatly during the last half century with the more or less general eradication of the native hazel plants on roadsides and fence rows, incident to clearing the land. However, the disease is still a grave menace whenever either European varieties or the new hybrids (*Corylus americana* × *avellana*) are planted near native species growing wild.

The second factor is lack of hardiness. Most European varieties of filberts are subject to winter injury, which may kill only the staminate flowers, or the pistillate ones, or both, or it may kill the tree tops, or even the tree trunks to the ground. As a rule, however, only the flowering parts are injured.

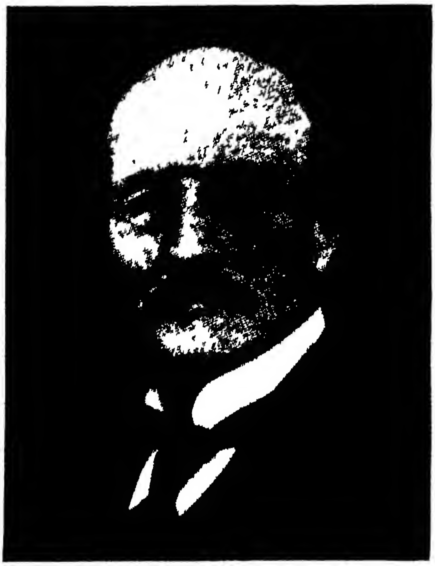


Figure 4.—A. A. Quarnberg (1849–1933), Vancouver, Wash., one of the leading figures in laying the foundation of both the filbert and Persian walnut industries in the Pacific Northwest. He was one of the first to plant and test most of the varieties now of leading importance in that part of the country.

The third factor is self-sterility. So far as known all varieties are largely, if not entirely, dependent upon other varieties for effective pollination. Until recent years most plantings in the East were made without regard to pollination requirements.

Some of the men who were most active in the introduction and early testing of varieties of filberts in the Pacific Northwest were A. A. Quarnberg (fig. 4), Vancouver, Wash.; Thomas Prince, Dundee, Oreg.; and George A. Dorris, Springfield, Oreg. Among those most recently active in the field of selecting and testing new varieties are Pearcy Bros., Salem, Oreg.; H. A. Henneman, Portland, Oreg.; A. M. Gray, Milwaukie, Oreg.; W. A. Schmidt, Corvallis, Oreg.; A. B. Scherf, Newberg, Oreg.; and D. Fitzgerald, Washougal, Wash. These men procured their trees mainly from Gillet, but to some extent they made direct importations. Among those in the East who have contributed most to filbert culture since the early eighties may be mentioned the United States Department of Agriculture; the New York State Agricultural Experiment Station at Geneva; A. S. Fuller, Ridgewood, N. J.; J. W. Kerr, Denton, Md.; Conrad Vollertsen, Rochester, N. Y.; Robert T. Morris, Stamford, Conn.; W. G. Bixby, Baldwin, N. Y.; and J. F. Jones, Lancaster, Pa. Vollertsen brought a number of varieties from Germany in 1912. Of these, Italian Red (fig. 2, *F*) is the only one now in special favor among eastern planters. Dr. Morris introduced a valuable seedling from Bohemia, which he later named Bonybush. The other men named in this group made their contributions by testing varieties in their respective localities.

Raw Material for Filbert Breeding

Most filbert varieties of either American or European production are without conspicuous merit. As previously noted, few are both hardy and fruitful except in specially favorable environment. Most filberts are of medium palatability and the nuts of many varieties are often imperfectly developed and the kernels thickly coated with coarse fiber. Some varieties are poor bearers, or the nuts may be too small or too thick-shelled to be acceptable on the market. Many are difficult to extract from the husks, and some produce only small quantities of pollen.

Some varieties are very good in quality and flavor. The nuts of some are of good size and thin-shelled. The kernels are often plump and bright-colored. The best nuts are entirely free from coarse covering over the kernel. However, some of the finest are too small for commercial use. White Aveline (fig. 2, *H*) is typical of the mixture of good and bad characteristics found in filberts. In quality of kernel it is one of the finest varieties known. It also has a remarkably thin shell; but, since it belongs to the species *Corylus maxima*, it has a long, tubular, tightly closed husk, which fails to open at maturity, and husking is difficult.

The variety with the greatest number of good points now grown in this country is Barcelona (fig. 2, *B*), which was introduced from Europe by Gillet probably during the seventies or early eighties. The tree is a vigorous grower and a good bearer; the nuts ripen early and within a short period and readily fall free of the husk. They are attractive in appearance and of large size. The shells are of medium thickness, and the kernels are usually plump, clean, quite sweet, of fine texture, and fairly rich. The nuts are roundish in form, although variably so. The kernels are not so clean or free from covering over the pellicle as some others, nor are they the best in flavor. Nevertheless, everything considered, commercial growers of the Willamette Valley, Oreg., have thus far found this to be their most profitable sort.

The second leading variety in the Pacific Northwest is Du Chilly (fig. 2, *D*), also an early European introduction made by Gillet. As compared with Barcelona it is moderately vigorous, not as productive, and less hardy. The nuts do not mature quite so early, and only a small proportion are naturally separated from the husks, although they are not difficult to husk. The nuts are oblong and flattened instead of being roundish. The shell is about as thick as that of Barcelona. The kernel is similar in plumpness and about equally free from fibrous covering. It is slightly sweeter and more palatable than Barcelona. Du Chilly nuts bring a somewhat higher price in the market, which largely, if not entirely, offsets the lighter fruiting of the variety. Both Du Chilly and Barcelona are less inclined to throw up suckers persistently about the base of the tree than are some others.

Daviana is the best known of the large varieties from Europe, which are notably thin-shelled. It is an excellent pollinizer for other varieties, but is itself a shy bearer, is very subject to injury by a bud mite, and frequently the kernels are not plump. From the standpoint of the breeder, its chief advantages are believed to be thinness of shell and its value as a pollinizer.

Nature of the Problems Involved

The problems involved in filbert breeding are relatively simple as compared with those of the chestnut, since there is already ample material. The area in the Pacific Northwest within which commercial filbert growing is centered is relatively small and has many full collections of varieties. In the East species and varieties now thought essential are represented in collections of the Bureau of Plant Industry, United States Department of Agriculture, near Washington, D. C., and of the New York State Agricultural Experiment Station at Geneva. Breeding by hybridization has made much headway at each place. Also a valuable collection of first-generation hybrids between Rush, one of the best-known native varieties of *Corylus americana*, and certain leading European sorts, mainly of *C. avellana*, is under observation at the J. F. Jones Nurseries, Lancaster, Pa.

Present Breeding Work and Future Possibilities

The most promising line of attack for the breeder in the East seems to be a continuation and expansion of breeding by hybridization, such as is already under way, rather than by making further selections from European varieties or the native species, both of which generally fall below the standards of American growers or consumers. Until superior hardy varieties can be developed, the best of the American varieties are likely to be used to a limited extent for home planting in zones beyond the climatic limits of safety for hybrids or European varieties.

In the Pacific Northwest the problem of the breeder is to develop more perfect varieties, chiefly from seedlings of *Corylus avellana*. The problem of hardiness is less acute than in the East. A desirable variety in the Northwest would be one that is resistant to fungus diseases and insect pests, a strong grower, either self-fertile, or a good pollinizer for other varieties, and a heavy annual bearer of choice nuts. The nuts should mature early and all at one time; they should separate naturally from the husks; they should be bright-colored, uniform in size, and probably oblong rather than rounded for greater appeal to the consumer. The shells should be thin enough to be broken easily, and the kernels should be plump, clean, bright, sweet, and of fine texture. In the appendix will be found a list of breeders engaged in work with the filbert, and of varieties considered promising for breeding work.

On the western coast filbert breeding is still largely carried on by mass selection. Out of the thousands of seedlings that are being grown and tested by private growers, the best finally come under critical observation when all but an extremely small percentage are rejected. Few varieties have yet come to light that meet the dual requirement of commercial crop production and pollination of other varieties. When breeding reaches the point of seeking greater hardiness in order to widen the western range of successful production, it is not improbable that the wild species, *Corylus californica*, of that region will be given a trial as one of the parents, in the same way that *C. americana* has been used successfully in the East. Thus far, pollen of neither of these native species has been found to function on the

pistillate flowers of European varieties, but as the eastern species has been useful as a pistillate parent, the same may prove true with the western one.

Filbert breeding, both by selection and by hybridization, is in progress at a number of points in the East. The United States Bureau of Plant Industry has made important contributions in its studies of varietal values not only in that part of the country but also in the Pacific Northwest. It has also made a number of important introductions of varieties from Europe. It is continuing its studies of the merit of European varieties both at the Arlington Experiment Farm, Arlington, Va., and at the United States Horticultural Station, Beltsville, Md. The work at the latter place is now largely confined to testing first-generation hybrids resulting from crosses made by its staff on the grounds of the late W. G. Bixby, Baldwin, N. Y. The pistillate parents used in making these crosses were Rush, Littlepage, and Winkler varieties of *Corylus americana* as well as a number of varieties of *C. avellana* and *C. maxima*. Among others used as pollen parents were *C. colurna*, the Turkish tree hazel, and *C. heterophylla* Fisch., from eastern Asia, sometimes called the "various-leaved hazel." Altogether, there are now at the Beltsville station about 2,000 hybrid plants of bearing age, transplanted from the nursery from 1932 to 1936. Several of those that have fruited appear highly promising for home use. Nuts of the first generation are a little small for sale in the unshelled condition.

Hybridization of filberts at the New York (State) Agricultural Experiment Station was begun in 1930. In 1933, 535 hybrid plants resulting from crosses made by Federal workers were transferred to Geneva from the Bixby grounds at Baldwin, N. Y. Some of these now in bearing are exceedingly promising. In addition to these plants there are 352 other plants at Geneva resulting from more recent crosses made by station workers. Climatic conditions at Geneva seem to be more favorable for varieties of *Corylus avellana* than at either of the Federal stations, but partial or complete crop failures are not infrequent even there.

The Virginia Agricultural Experiment Station at Blacksburg began selective breeding from Kentish Cob seedlings in 1921. The purpose has been to develop hardy varieties of merit for use in that State. One seedling has been selected as worthy of further observation.

The Minnesota Agricultural Experiment Station at University Farm, St. Paul, is breeding by selection from native plants of *Corylus americana* for the purpose of developing hardy varieties of value in that State for home planting. About 200 plants have been brought to fruiting and discarded. Nine hundred more are now under observation, of which some appear to have considerable promise.

Working privately, S. H. Graham, Ithaca, N. Y., is doing considerable filbert breeding, mainly by selection. However, he has brought into fruit a number of second-generation hybrids of the crosses made by the late J. F. Jones, Lancaster, Pa. From these he has made one or two selections of considerable promise.

E. M. Ten Eyck, South Plainfield, N. J., has had for many years a number of *Corylus avellana* seedlings grown from nuts bought on the market. These have been injured very little by winter temperatures,

have borne well, and the nuts have been quite satisfactory for home use. C. P. Close and J. J. T. Graham, of the United States Department of Agriculture, have both grown for many years a considerable number of seedlings of *C. avellana* from which it now seems possible to make selections of value for home planting. The trees of Close are at his home in College Park, Md., and those of Graham at Glenn Dale, Md.

The J. F. Jones Nursery, Lancaster, Pa., is now fruiting and continuing under test about 50 first-generation hybrids from crosses made by Jones. As already noted, two of these have been given variety names and are being propagated commercially. While it is improbable that further selections will be made for production varieties, it is possible that some of this collection will be found useful as pollinizers.

There is a large 24-year-old Barcelona tree on the premises of C. A. Reed, Takoma Park, Md., which bore a full crop for the first time in 1936, although it has bloomed freely with great regularity. Apparently it was effectively pollinated in the spring of 1936 by pollen from first-generation Rush × Barcelona hybrids nearby. If further investigation should prove that a Rush × Barcelona hybrid will effectively pollinate Barcelona, which is both self-sterile and sterile to Rush and to all other varieties of *Corylus americana*, the result will be extremely interesting as well as significant. If such hybrids can be used as pollinizers for Barcelona and other European varieties whose staminate flowers are easily killed by winter temperatures, the successful cultural range of such varieties might be considerably widened.

Progress already made in the improvement of filbert varieties by hybridization indicates great future possibilities for this kind of work. It should be possible within a reasonable period to develop superior varieties for commercial growing in the Pacific Northwest with which to meet the requirements of American markets now largely supplied by imports. Eastern varieties of high merit should be developed for home planting over much of the region from lower New England and the Great Lakes on the north to perhaps the Potomac and Arkansas Rivers on the south. No doubt much of Wisconsin, southern Minnesota, South Dakota, and Nebraska might also be included.

THE HICKORY GROUP

THE hickories form an important group of trees valuable for the production of both nuts and timber. With the exception of a single species, *Hicoria cathayensis* Sarg., from southeastern China, the entire genus is strictly American. The hickory range extends from the Provinces of Quebec and Ontario in Canada across the eastern and central United States into northern Mexico. Fifteen species are described by Sargent in the Manual of the Trees of North America. Of these only three or four produce nuts of particular value, although the nuts of certain others are edible in varying degrees.

From the standpoint of value of nuts the pecan, *Hicoria pecan* (Marsh.) Britton, is the most important member of the group. In crop value it rivals the Persian (English) walnut of the western coast. The tree is one of the largest east of the Rocky Mountains. Broadly

speaking, the natural and cultivated range of the pecan covers the Cotton Belt and lower elevations northward in the Mississippi Valley into Indiana, Illinois, Iowa, and southeastern Kansas.

The pecan tree is valuable in ornamental planting wherever climatic and soil conditions are favorable. It sometimes succeeds as far north as Connecticut, but nut production is unimportant north of the District of Columbia or the latitude of Terre Haute, Ind.

Other hickories offering inducement to breeders include the shagbark, *Hicoria ovata* (Mill.) Britton, the shellbark, *H. laciniosa* (Michx. f.) Sarg., and a number of other species of less importance, as well as various hybrid forms that occur with considerable frequency in nature. The shagbark is much the most valuable nut producer. Nuts of the shellbark, while large and alluring, are often poorly filled.

Breeding to improve hickories of any species has thus far largely been confined to selective methods. By such means a very considerable number of varieties of both pecan and others have been brought to light. Breeding by hybridization has been under way with the pecan for many years, but so far without the introduction of many varieties. This form of breeding has not yet been undertaken in earnest with other hickories.

Pecan

According to dates given by Taylor (*38*), pecan selection is known to have begun as early as 1846 or 1847, when scions of a variety later named Centennial were successfully grafted by a Louisiana slave named Antoine. The next variety known to have been grafted was Van Deman, in 1877, although it was not permanently named until 15 years later. The Rome variety was first propagated in 1882, Hollis in 1884, Frotscher in 1885, Stuart in 1886, and Pabst in 1890. The first pecan nursery was that of William Nelson, New Orleans, La., who began selling seedlings in 1874 and grafted trees in 1879. The period of greatest activity in the introduction of new varieties was probably between 1905 and 1925. During that time practically every important pecan center of the entire South introduced its favorite varieties of local origin.

The first carlot shipment of pecan nuts of named varieties, carefully graded according to definite standards of size and quality, is believed to have been made in 1917 by J. M. Patterson, president of the Georgia Papershell Pecan Growers' Association, Putney, Ga. By 1920 there was a great multitude of varieties in bearing, and nuts of the same size and general character, whether from seedling trees or named varieties, brought about the same price. This caused the selling agencies to begin marketing a large portion of the crop by brand instead of by variety as had been done until that time. Now, with the exception of a few varieties, such as Schley and Stuart, most of the pecan crop, no matter whether from cultivated or wild trees, is graded according to size, form, appearance, and to some extent thinness of shell and general merit. High uniformity, possible only when varieties are sold separately, has largely disappeared, at least for the time being.

The loss of varietal status, insofar as selling pecans is concerned, has been partially due to the failure of a good many varieties to meet the requirements of successful production and marketing, and of any

varieties to become outstanding. Light bearing, uncertain filling, variability in size of nuts from year to year, even from the same trees, together with susceptibility to insect pests and fungus diseases, have had much to do with a situation that has practically compelled the blending of the nuts of the different varieties together instead of selling them separately. A process of readjustment is now taking place throughout the entire field of production and will probably continue until a majority of present varieties have been superseded by new kinds better suited to the requirements of the orchard and the market. Future plantings will doubtless be established with superior varieties now unknown, and with greater consideration of environmental and cultural requirements.

Figure 5.—E. E. Risien, San Saba, Tex., a pioneer in propagation and varietal improvement of the pecan by selection and hybridization. A majority of the most popular varieties of Texas are among his productions.

Past Breeding Work With Pecans

Apparently the first breeder of pecans by hybridization was Forkert (*13*), of Ocean Springs, Miss., who began this work in 1903. He was followed 1 year later by Risien (*29*), of San Saba, Tex. Both men were of foreign birth, Forkert having been born in Germany and Risien in England. They spent much time in searching for the best varieties obtainable by selection from seedlings before undertaking the work of hybridization. Forkert found no chance seedlings that he thought worthy of introduction, but Risien introduced several varieties selected from wild seedlings.

Forkert's first introduction, Dependable, was the result of a Jewett×Success cross. This proved disappointing and has since been practically abandoned. Admirable, a Russell×Success hybrid, also was a disappointment insofar as being an improvement over existing varieties was concerned. His one apparently meritorious introduction is Desirable, a variety of unknown parentage. It was not widely disseminated previous to his death in 1928, and would doubtless have been lost had it not been for scions that he sent to the United States Pecan Field Station near Albany, Ga., in 1925. From this stock the variety has been widely disseminated for test planting.

The work of Risien (fig. 5) was in a semiarid region at high altitude in western Texas. He seems to have been the first in the South to conduct a systematic survey of wild pecans for seedlings worthy of propagation as new varieties. About 1882 (*30*) he discovered the parent tree of the variety that he later named San Saba. He was probably the first to plant nuts from a selected tree in orchard form

for the purpose of growing seedlings from which to make selections. A great many persons planted seedling trees for nut production during that early period because grafted trees were unavailable, and from such trees many good selections were made later. Risien planted chiefly for the purpose of originating valuable varieties, and in this he was successful.

Risien independently mastered the art of propagating pecan trees during the early nineties, and while he was a half century behind Antoine in this work, so far as is known he was the first propagator in Texas, and so far as he knew he was the pioneer in the field. He was the first in the South to top-work large pecan trees. In addition to San Saba, he introduced Attwater, Kincaid, and Sloan as selections from wild seedlings. Among the selections from his orchard of 1,000 San Saba seedlings are Colorado, Jersey, Libertybond, Onliwon, San Saba Improved, Sovereign (Texas Prolific), Squirrels Delight, Supreme, and Western (Western Schley). Among varieties from definite crosses are Banquet (Sovereign×Attwater), Commonwealth (Longfellow×Sovereign), Kincaid Improved (Onliwon×Kincaid), Sloan Improved (San Saba×Sloan), and Venus (San Saba×Attwater). A recent introduction is Garner (John Garner), an open-pollinated seedling of San Saba Improved.

Another Texan who has contributed much to the pecan industry, not only in his native State but also in the entire South, is J. H. Burkett, of Clyde, Tex., for many years chief of the division of edible nuts in the State department of agriculture at Austin, and author of several bulletins on pecan culture. Burkett was the discoverer and introducer of the valuable Burkett variety, which has a large, round nut with very thin shell and excellent kernel characteristics. It has long been a favorite among planters from western Texas to the Pacific coast. It has several features that should make it desirable for use in breeding work.

Other planters in many States, covering practically the entire South, established seedling pecan orchards having from a few hundred up to several thousand trees. One such orchard, planted in 1897 by James (*17*), of Mound, La., later became the source of such important varieties as Carman, James, and Moneymaker. During approximately 30 years, beginning in 1880, seedling orchards and dooryard trees on the Gulf coast of Mississippi, especially in the vicinity of Ocean Springs and Pascagoula, became fruitful sources of new varieties. It was then that Alley, Delmas, Pabst, Russell, Schley, Stuart, Success, and many others less prominent were introduced from that section. Among persons most active in the introduction of these varieties were Theodore Bechtel, C. E. Pabst, and W. R. Stuart, of Ocean Springs, and A. G. Delmas, I. P. Delmas, and F. H. Lewis, of Pascagoula.

In northwestern Florida during the nineties, seedlings grown from nuts of trees owned by Arthur Brown, Bagdad, Fla., had an important part in giving rise to varieties in that region. An orchard planted with such stock in 1886 by J. B. Curtis at Orange Heights, Fla., became the source of the Curtis variety in 1896, and of Hume, Kennedy, and Randall somewhat later. Many other Florida varieties, less well known, are believed also to have originated as seedlings of the Arthur Brown stock.

Probably the first large-scale breeding of pecans by hybridization was begun by the United States Bureau of Plant Industry in 1915 in the orchard of C. E. Pabst, Ocean Springs, Miss. Hundreds of crosses were made that year and the next, and the resulting nuts were planted on the grounds of Pabst. However, with the entrance of the United States into the World War the work was discontinued and the young trees were neglected. Pabst died in 1919, and with the change in ownership of the property the entire lot was lost.

This work was resumed in 1920 in the orchard of B. W. Stone, Thomasville, Ga., and continued for several years. The first nuts were planted on the grounds of the Georgia Experiment Station, Experiment, Ga. Of these, a Schley × Moneymaker hybrid is now believed to have considerable promise. In 1922 the United States Pecan Field Station at Philema, Ga., was established, and several thousand young hybrid trees were soon developed. In 1930 the youngest trees were transferred to the United States Pecan Field Station at Robson, La. A considerable number of trees at the former station have been in bearing for several years and are now being observed closely with regard to bearing habits, disease resistance, and merits of nuts. Some of these hybrids are highly promising but require considerable further observation.

In the North, where the native pecans are mostly small and difficult to crack but otherwise much like those of the Southeast, the first recorded steps toward selecting varieties began during the early nineties, when the Department of Agriculture received nuts from Illinois, selected mainly because of their superior size. One of the first trees to attact attention in this way belonged to H. G. Hodge, York, Ill. During the next few years this variety came to be known as Hodge's Favorite or Illinois Mammoth, and many nuts from the original tree were sold for seed purposes. It was accorded varietal recognition by Taylor (*38*) in 1908, who called it Hodge.

The second northern pecan variety to be recognized appears to have been Major, discovered by W. N. Roper, Petersburg, Va., about 1907. His attention was attracted to the superiority of certain nuts in a mixed shipment that he procured for seed purposes from a merchant in southern Indiana. By persistent efforts Roper traced the nuts to the parent tree near Green River in northern Kentucky, some 15 miles southeast of Evansville, Ind.

The next step toward bringing out new northern varieties seems to have been made in 1908, when a pecan contest was held at Mount Vernon, Ind., under the direction of the Purdue University Agricultural Experiment Station. It was then that Warrick, now practically obsolete, was brought to light.

During the period of 1910 to 1915, Simpson Bros., Mason J. Niblack, and W. C. Reed, Vincennes, Ind.; J. F. Wilkinson, Rockport, Ind.; and Thomas P. Littlepage, a native of the Rockport region but then a resident of Washington, D. C., spent much time, labor, and money in searching for other worthy varieties. It was during this period that Busseron, Butterick, Greenriver, Indiana, Kentucky, and Posey were recognized and introduced. From then until quite recent years very few other northern sorts have come to notice. However, beginning

in 1933 and continuing annually since, a pecan contest has been held in New Haven, Ill., under the direction of H. C. Neville, formerly farm adviser of Gallatin County. As a result of these contests several highly promising varieties have come to light, but they have not yet been offered by nurserymen. In 1934 a nut contest conducted by the Northern Nut Growers' Association brought out several apparently desirable new varieties, which ought not to be lost. Present-day breeders of pecans are listed in the appendix.

Problems in Pecan Breeding

The known defects of present varieties of pecan are many, regardless of the reputation the species justly enjoys of being one of the finest of table nuts. In the orchard many varieties are seriously susceptible to attack by insect pests and diseases of various kinds. Other defects include shy bearing; late ripening; weak crotches, which split badly; wood that breaks under the weight of nuts, especially late in summer during storms; poor shelling characteristics; failure to fill well; lack of good flavor; and a tendency of the nuts to germinate before dropping from the trees, when dry summer weather is followed by wet periods late in the growing season.

Pecans reach the consumer in two forms, shelled and unshelled. The kernels are known in the trade as shelled nuts, and by far the greater portion of the crop is marketed in this form. Nuts of small and medium sizes from either the forests or orchards are sold as "halves" or "pieces." Pecan halves are used as salted and roasted nuts and in capping such products as cakes, breads, and candies. Pieces are used as an ingredient in pastry, ice cream, and confections. For capping, the smaller the halves the better, since this means a larger number per pound. Seven hundred per pound is usually the minimum required.

When the cultivated crop is of bumper proportions or offgrade for any reason, so that prices are inclined to drop, many of the nuts are diverted from the unshelled to the shelled market. Prices for cultivated varieties, once 10 to 50 times as great as for the medium to small nuts from the forest, are now only 2 to 5 times as great. The best prices now being received by growers for cultivated pecans is about one-fifth of what it was two decades or more ago when the great majority of the present varieties were discovered and introduced.

In the present economic status of the pecan industry the most profitable varieties are those that are the most productive largely without regard to other qualities. Fruitfulness, therefore, is the characteristic sought above all others, often to the exclusion of other important factors, particularly quality and flavor.

Some of the choicest pecan varieties, from the standpoint of the nuts alone, are no longer being planted because of extreme susceptibility to fungus diseases, failure to bear well, or deficiencies of kernel. Often these weaknesses are aggravated by unfavorable environmental conditions such as severity of climate, poverty of soil, or too close planting. For these reasons it is impossible to attribute the failure of any given variety to any single factor or to any particular combination of factors. It is equally impossible at this time to predict with certainty the commercial requirements for varieties in the future.

However, it seems to be a reasonable assumption that pecans will be marketed more and more in the shelled condition, and varieties must be developed with this requirement in view. Present varieties can, in many cases, be made to give more satisfactory results by improving cultural practices according to knowledge now available.

Desirable combinations of nut characters are to be found in a good many varieties. In the nursery and orchard such points as ease of propagation, rapid growth, precocity, productiveness, and resistance to disease are all to be found, distributed variously among the different varieties but not in perfect combination in any. For example, well-grown nuts of the Schley variety have good size, handsome appearance, suitable form for shelling by hand or machine, very thin shells, good shelling quality, and superior kernel characteristics. The variety is easy to propagate, is a rapid grower, and forms a symmetrical tree. It begins bearing at a relatively early age and normally is fairly productive. However, the susceptibility of Schley to scab makes it undesirable for commercial orchard use. Another example is Moneymaker, which is easy to propagate, a rapid grower, precocious, prolific, and early in ripening. On the other hand, the nuts are roundish in form, variable in size, not especially thin-shelled, not easy to shell by hand, and medium in quality and flavor of kernel. In appearance the nuts are only moderately attractive, and the tree is so susceptible to certain leaf diseases that it is no longer in favor with leading growers.

Three well-known eastern pecan varieties having outstanding points, which should be useful in breeding, are Curtis, Moore, and Stuart. Curtis nuts are among the best of any variety to eat out of hand. They are a little small but quite thin-shelled and easily cracked, and the kernels are very fine, being plump, rich in quality, and unusually sweet. Moore is one of the most prolific bearers and the nuts ripen with the earliest. Stuart is probably the most dependable variety in the Southeast. While it is not a heavy bearer, in most localities it performs consistently and the nuts are large, attractive in appearance, and uniform in size.

Among varieties of the western group, Burkett, Halbert, and Sovereign are well known and probably as useful for breeding purposes as any. All begin bearing at an early age and increase in productivity rapidly. The shells of Burkett and Halbert are remarkably thin. The kernels of all are plump, bright-colored, and distinctly superior to those of most other varieties.

The problem of improving pecan varieties by breeding is greatly affected by the uncertainty as to future market requirements. With few exceptions past efforts have been to develop varieties for the unshelled market. For this purpose, large size has been one of the principal assets. Two small varieties, the Candy, by Theodore Bechtel, of Ocean Springs, Miss., and the Reuss, by G. B. Reuss, of Hohen Solms, La., were introduced at about the same time many years ago for sale in the shelled trade. These nuts were unusually thin-shelled and of excellent shelling and kernel qualities. The parent trees in both cases were heavy bearers, but neither variety met with favor on the part of nurserymen or planters on account of the small size of the nuts. However, the nuts of neither were small enough to meet the present market requirement of more than 700 halves to the pound,

and it is an open question as to whether either would be of particular value in breeding to develop smallness in size. Probably the only varieties that can meet this requirement are a few recently brought to attention in some of the Northern States but not yet well tested.

Growers as a class prefer not to produce pecans of small size. In fact it is doubtful whether it would be profitable for them to do so at the present time. The question is to what extent, if any, it would pay to raise pecans exclusively for the shelled market. The demand in that direction is usually well supplied with pecans from the forests or those from the cultivated orchards that might be classed as imperfect or surplus pecans. It may be that, with the exception of the peanut, which strictly speaking is not a true nut, none of the American-grown nuts can compete on a price basis in the retail market for shelled nuts with certain foreign species that are produced at much lower labor costs. It is certain, however, that very large pecans no longer sell readily to discriminating consumers. It is also true that greater portions of the crops from orchard trees are steadily finding their way into the shelled market. It would be very desirable, if possible, to determine the probable future market requirements as to size. In the absence of a basis for an accurate prediction as to what the future may bring forth in this direction, it will probably be well to follow the present trend, which is definitely toward nuts of medium size. The largest nuts from these crops can be separated out by sizing machines and sold in the increasingly more limited market willing to pay a premium for such sizes.

The best pecan varieties lack certain characteristics necessary to make them ideal New varieties with all the features of an ideal nut are not to be expected until a planned program of breeding to accomplish certain definite ends is carried out Such a program would involve the growing of a large number of second-generation hybrids from the best breeding stock. In this way alone will it be possible to develop material from which to select varieties resistant to disease and superior in other characteristics. Cytological analyses of varieties may be expected to yield information as to their value as breeding stock and to throw light on problems of pollen viability and sterility.

Present Breeding Work and its Aims

Pecan breeding as it has long been carried on by the Bureau of Plant Industry has for its objectives improvement along seven distinct lines. These are (1) hardiness, (2) disease resistance, (3) fruitfulness, (4) size of nut, (5) shell thinness, (6) shelling quality, and (7) kernel quality. The purpose is to develop good varieties that can be grown with profit in each of the three distinct natural pecan districts, southeastern, southwestern, and northern. The southeastern district extends from the South Atlantic seacoast west to central Texas. The southwestern district includes localities wherever the pecan succeeds from Fort Worth, Tex., west to Arizona and southern California. The northern district includes all localities suitable for pecan growing in the Mississippi Valley north of the latitude of Memphis, Tenn., and in the Coastal Plain or lower Piedmont regions in Virginia and northward.

No great amount of pecan breeding has yet been undertaken by State experiment stations. In cooperation with the Bureau of Plant Industry, the Georgia Experiment Station grew to fruiting several hundred seedling trees resulting from crosses made by Bureau workers at Thomasville, Ga. From these the station workers selected for further observation one designated as A–93, a Schley × Moneymaker hybrid. This is a strong-growing, fruitful tree producing nuts of considerable excellence.

The North Carolina Agricultural Experiment Station began breeding pecans at Willard, N. C., in 1912. From a large number of seedlings of named varieties station workers have selected a Schley seedling, RT–6–4, as being of much promise. The New Mexico Agricultural Experiment Station at State College, N. Mex., has made one selection from seedlings of named varieties. This is designated as College No. 1. It grew from a Sovereign nut that had been open-pollinated.

A certain amount of pecan breeding has been started in two foreign countries. The Department of Agriculture of New South Wales is doing preliminary breeding at the Breeding Station, Grafton Experimental Farms, Sydney, Australia. Selective breeding is under way in Mexico under the direction of the Secretariat of Agriculture, Department of Stations and Experimental Fields, Mexico, D. F.

Three different sets of pecan varieties are required to meet environmental conditions in the respective American regions. Greater hardiness is being sought in order that varieties may be used for planting north of the present limits and to safeguard more southern plantings against extremes of cold. Resistance to disease is one of the most vital points for the success of any variety. Many otherwise good varieties have had to be abandoned because of their susceptibility to fungus diseases. No factor is more important than that of productiveness. It makes little difference how worthy a variety may be in other respects—if it does not bear well it must be replaced sooner or later. By good nut size is meant medium rather than large. Overlarge nuts are objectionable because of the tendency to develop imperfect kernels. Pecans that will average 60 to 70 to the pound are most desired in the unshelled market. Thinness of shell and ease of shelling are also being sought after, as without these characters pecans in the shell are unlikely to compete successfully with nuts of other kinds that can easily be shelled in the hands or that are sold only in the shelled condition. Varieties of pecan of probable value for breeding are listed in the appendix.

Hickories Other Than Pecans

Selections from species of hickory other than pecan have resulted in the naming of a large number of varieties. Relatively few have been propagated by nurserymen and none has been planted in commercial orchards. A considerable number have been top-worked on trees of bearing age, and a few, grown as nursery trees, have been established in small test orchards.

Improvement of the hickories by selection was strongly urged as early as 1855 in an article by S. Hale, Keene, N. H., in The Magazine of Horticulture, in March of that year. The earliest record of hickory

selection appears even before that, as the "Perkiomen Shellbark" was brought to light in October 1853, when Abraham Wismer, of Perkiomen Township, Montgomery County, Pa., exhibited nuts of this seedling as "a large variety with thin shell and kernel of best quality." There is no record that this "variety" was ever propagated by budding or grafting, and it may be assumed that it is now lost.

The next northern hickory to receive varietal recognition seems to have been the so-called Hales Papershell, a thin-shelled variety of shagbark discovered by Henry Hales, of Ridgewood, N. J., first recorded by A. S. Fuller in 1870 and first propagated by J. R. Trumpy, of Parsons & Son, nurserymen of Flushing, N. Y., about 1880. This variety was propagated to a limited extent and widely disseminated throughout the East over a period of many years. It is now practically obsolete.

Figure 6.—Robert Tuttle Morris, Stamford, Conn., who has contributed much to the published knowledge of species and varieties of native nuts in the Northeastern States. In 1905, 1906, and 1907 he conducted annual contests for the best walnuts and hickories. He became charter president of the Northern Nut Growers' Association, founded in 1910. He has written many articles and one book pertaining to various phases of nut culture, especially propagation.

The next varieties to receive recognition grew from nuts planted in 1885 by J. W. Kerr, Denton, Md. Kerr sent away for "shellbark" seed nuts, which he planted along the roadways of his farm. From the resulting trees he selected a number of seedlings to which he gave varietal names. He grafted some of these on his home grounds, but so far as known none was established elsewhere and none is now believed to be in existence.

Varietal names were used for hickories in the annual report for 1891 of H. E. Van Deman, pomologist of the United States Department of Agriculture. He described Leaming, from Rush G. Leaming, Sedalia, Mo.; Milford, from O. C. Cook, Milford, Mass.; and Shimar, from Samuel C. Moon, Morrisville, Pa. In 1892 A. J. Coe, Meriden, Conn., offered a prize for the best hickory that might be submitted to the Connecticut Agricultural Society. The prize went to Whitney Elliot, of North Haven, Conn., for a variety named Elliot in his honor.

To Robert T. Morris (fig. 6), formerly a leading surgeon of New York, N. Y., but now retired and living at Stamford, Conn., belongs credit for beginning a movement in 1905 by which the majority of the varieties of hickory now known have been brought to notice. In that year he inaugurated a series of northern nut contests in which

cash prizes were given for the best nuts from seedling trees. These contests were continued for 3 years, then dropped. They were resumed in 1911 by the Northern Nut Growers' Association, a society founded in 1910 by W. C. Deming, then a physician of New York but now living at Litchfield, Conn. Dr. Morris was its charter president. The association has held many nut contests, the last in 1934.

During recent years other similar contests have been held. In 1926, under the guidance of J. Russell Smith, professor of economic geography, Columbia University, New York, N. Y., a contest for hickory varieties was held by the Philadelphia Society for Agriculture. A contest for northern nuts, including hickories and other species, was held in Michigan in 1929, under the guidance of the experiment station at East Lansing, and two excellent varieties of shagbark were brought out, Mann and Miller. These appear to be as promising as any yet discovered. The ownership of the parent trees has since changed hands one or more times, but both varieties have been successfully established by various persons, including G. A. Zimmerman, Harrisburg, Pa.

A similar contest for hickories was held in Ohio in 1933, and one for walnuts in the following year. New York held a general contest for nuts in 1934. The Ohio contests were sponsored jointly by the experiment station at Wooster and two members of the Northern Nut Growers' Association, C. F. Walker, of Cleveland Heights, and Homer L. Jacobs, of Kent, Ohio. The New York contest was directed by the State Experiment Station at Geneva, Cornell University at Ithaca, and S. H. Graham, Ithaca, a prominent member of the Northern Nut Growers' Association.

Following the discovery of the Perkiomen shellbark, previously mentioned, the shellbark seems to have received little attention until about 1915, when J. F. Jones, Lancaster, Pa., selected, named, and began propagating the Stanley shellbark from near Carthage, Ind. Other shellbarks, probably more desirable, have come to light during recent years. Along with the shagbark and the shellbark, a number of other hickories, such as mockernut, *Hicoria alba* (L.) Britton, and sweet pignut, *H. ovalis* (Wang.) Ashe, have been included in the search for varieties of merit. The mockernut is a handsome tree with dense, dark green, fragrant foliage, trunk bark without scales, and nuts having thick hulls, very hard shells, and small but sweet kernels. The sweet pignut also has handsome foliage and smooth bark. The hulls are thin, the shells moderately so, and the kernels often nearly as rich and sweet as shagbark. Neither species is as commonly associated with rich bottom lands as are the shagbark and the shellbark.

Few varieties of sweet pignut have been recognized or propagated. Probably the first and one of the very few introduced was Brackett, discovered in 1890 by G. B. Brackett, then of Denmark, Iowa. On the basis of nut characteristics alone a number of varieties of mockernut and other hickory species and types have been named, but very few of these are especially promising and in a majority of cases considerable uncertainty exists as to the identity of the reputed species.

Many natural hybrids between *Hicoria* species have been given varietal names and propagated to some extent. In many cases the

parentage on both sides is reasonably certain, but in others it is a matter of conjecture. Some of the earliest hybrids to become known were apparently pecan × shellbark crosses, including McCallister from Indiana, Nussbaumer from Illinois, and Rockville from Missouri. The Burton variety from near Owensboro, Ky., is supposed to be a pecan × shagbark cross. All of these were first grafted during the early nineties, or possibly earlier.

The natural type of hybrid of special value occurring most frequently among the hickories is probably shagbark × shellbark, one of the best varieties of which is Weiker, discovered in Lancaster County, Pa., by J. G. Rush, of West Willow, and first propagated in 1903 by J. F. Jones, then of Monticello, Fla. Other supposed hybrids are apparently crosses between pecan and bitternut, shagbark and bitternut, and pecan and mockernut.

Problems and Possibilities in Hickory Breeding

Hickory nuts have never met with the popular favor accorded pecans and black walnuts. In the shell they bring too low prices to justify shipment over long distances or extensive handling. Sale in the shelled condition is largely limited to small lots in local markets. Before nuts of the slow-growing hickory species can be expected to become popular enough with consumers to justify the planting of extensive orchards, irrespective of time or cost involved in bringing the trees into full bearing, varieties must be found or developed that can be shelled easily. Until this is done hickory nuts in the shell will probably continue to compete poorly with pecans, almonds, chestnuts, peanuts, and many of the Persian walnuts, most of which can be shelled easily without mechanical aid. All known varieties of pure species, and with few exceptions all of the hybrids, have shells either too thick or too hard to be cracked readily in the hands, though the shells of many may be readily broken open with a light tap of a hammer or by the use of some of the hand-power devices now on the market. The shells of many varieties split open when the nuts are hit on an edge with a hammer in such way as to release one half kernel perfectly while the middle partition holds the other half practically as securely as before the nut was broken open. A few varieties of shagbark have been found with shells of such thinness that breaking in the hands is not difficult, but in all such nuts that have been examined by the writers the cleavage has not been good. Instead of cracking along definite lines, the shells have merely mashed at the points where pressure was applied with another nut. With the exception of the pecan × hickory hybrids and pure pecans, which are usually oblong, all nuts of hickory varieties have been generally roundish in form and therefore quite unsuited for shelling in automatically fed machines.

The parent trees of some of the varieties are known to be heavy bearers during favorable years, and top-worked trees have come into bearing relatively soon, that is, in about the same time as is required for apples. The kernels of some are plump, bright-colored, sweet, and palatable. To many persons, especially to those who knew good shagbarks and shellbarks in childhood, no other nuts taste so good.

However, it is too early in the growing of these hickories to know how well any of them will be received by consumers, even when prepared in convenient and attractive form.

The problem of breeding other hickories, as in the case of the pecan, is difficult because of uncertainty as to what characteristics are likely to meet market requirements best. However, it may be assumed safely that the requirements for these hickories will not be very unlike those of the pecan and other nuts that are popular in the shell. In at least one respect other hickories should have an important advantage over the pecan. With the latter, seedling nuts of good size, good form for shelling, thin shells, and general excellence are not uncommon in the wild product. If such nuts exist among other hickories they have not yet been brought to light, in spite of many searches that have been made. When superior varieties of hickory are developed by breeding, as seems well within the realm of probability, they will have no competition with nuts of the same types, either wild or imported.

A small amount of breeding of other hickories by hybridization has been undertaken by the Bureau of Plant Industry. The objectives are much the same as for pecans. However, hardiness is more important than with the pecan because there is greater demand for varieties that can be grown successfully beyond the northern limits to which the various species are naturally adapted. This demand is from home owners who at present are unable to grow nuts of any kind for family use.

Nature has already laid much of the foundation for the hybridization program with hickories. It has produced many interesting hybrid forms, of which some may have considerable horticultural value. The majority of the first-generation hybrids are of little or no value except for novelty planting or further breeding. Very few second-generation hybrid populations have been grown, and until facilities are available for growing and studying large numbers of such progenies, progress will be slow in the selection of new and valuable types.

The natural hybrids are suggestive of what may be expected from crosses between certain species. For example, thinness of shell, and to a varying degree astringency, seem to be dominant in all bitternut (*Hicoria cordiformis* (Wang.) Britton) hybrids, and elongation of nut seems dominant in pecan × shellbark hybrids. Also, large size and uncertain or poor filling appear to be characteristic of hybrids between the pecan and either the shagbark or the shellbark.

By systematic breeding it should be possible to extend the range of the shagbark and other good hickories both north and south of present limits. A new form having the thinness of shell, the easy shelling character, and the rich quality of the pecan, the whiteness of shell of the shagbark, and the flavor of either pecan or shagbark, would be a great benefit to the nut industry. Such a nut is needed by orchardists, small home owners, and consumers.

In the appendix are given the names of breeders interested in improvement of the hickory and a list of varieties of probable value for breeding.

WALNUTS

Black Walnut

Five species of black walnut occur naturally in this country. Four of these are from the far West and Southwest and one from Texas. Of the former, two are from California, one from Arizona and New Mexico and one from New Mexico, Texas, and Oklahoma. The two California species are known as the Hinds or northern California walnut, *Juglans hindsii* Jepson, and the southern California walnut, *J. californica* S. Wats. The former grows to be a fairly large tree, now more commonly seen along roadsides and about residence grounds, where it has been planted for shade and ornamental effect, than in forests and fields. Nursery seedlings of this species are the stocks chiefly used on which to graft varieties of the Persian walnut.

The southern California walnut is a smaller growing and less valuable tree. It varies greatly in habit, depending upon its environment. Being drought-resistant, it often occurs in dry, gravelly, or unfriendly soils where other species of walnut would certainly fail entirely. Under such conditions it develops as a true shrub only 5 to 10 feet in height instead of as a standard tree. When conditions are more favorable it grows rapidly and becomes a fairly good-sized tree. It differs from the Hinds walnut in lacking a central leader, as its branches spread out in more or less vase shape. It is not planted to any great extent.

The two walnut species native in the Southwest are much alike and nowhere of great value. One is *Juglans major* (Torr.) Heller, from Arizona and southern New Mexico. This sometimes attains a height of 50 feet and a trunk diameter of from 3 to 4 feet, although ordinarily it is a small tree. The other species is *J. rupestris* Engelm., from parts of New Mexico, Texas, and Oklahoma. This is a shrubby tree rarely attaining a height of 30 feet. The nuts are the smallest of any American walnut. Generally speaking, all of these western and southwestern walnuts are of little value for either timber or nut production. They should be useful, however, in breeding hybrid strains for that part of the country.

The eastern black walnut, *Juglans nigra* L., is the most important native walnut of this country in both timber and nut values as well as in extent of native and adapted range. No other American timber tree equals it in value for such special uses as cabinetmaking, interior finishing, and the manufacture of many articles, particularly gunstocks. Few other tree species are so widely distributed over the entire United States. It is grown to some extent in practically every State in the Union. Under the most favorable conditions it sometimes attains a height of 100 to 150 feet and a trunk diameter of more than 6 feet. The nuts are variable in size, form, thickness of shell, and shelling quality and also in character and flavor of kernel. The kernels of this species are favorites with manufacturers of confections and baked goods on account of the extent to which the pleasing flavor is retained in the cooking processes. So far as known, the eastern species is the only black walnut thus far used in breeding.

The history of breeding the eastern black walnut closely parallels that of the northern hickories. It has been limited chiefly to the selection of varieties from wild trees, the propagation and testing of

many of these by amateurs, and the commercial planting of a few. The Thomas variety from Montgomery County, Pa., discovered, named, and first propagated about 1880 by J. W. Thomas & Sons, nurserymen, of King of Prussia, Pa., appears to have been the first to attain varietal status. It has since been widely disseminated and is still the general favorite with most planters. Its seedlings are notable because of their vigor and rapid rate of growth. Six varieties, including Thomas, were described by the Department of Agriculture in a special report (*16*) issued in 1896. One of these was named Peanut because of the more or less cylindrical and peanutlike shape of the single-lobed kernels. So far as is known, with the exception of Thomas, no other of these varieties is now being grown.

The introduction and testing of black walnut varieties received little further attention until early in the present century. It was largely as a result of nut contests begun in 1905 by Morris, and later expanded by the Northern Nut Growers' Association and other organizations and individuals, that this interest became somewhat general. The industry received its next major impetus about 1915 when the prize varieties were first propagated by nurserymen and made available to the public A large number of promising varieties are now on record. Many of these have been propagated to some extent.

Following the lead of Morris in bringing out new varieties, and cooperating closely with him, mainly through the Northern Nut Growers' Association, W. C. Deming, J. Russell Smith, Swarthmore, Pa., the late W. G. Bixby, and the late J. F. Jones conducted many surveys in the East to discover black walnut seedlings suitable for varietal recognition. The Bureau of Plant Industry has participated actively in all of these efforts.

During recent years other black walnut contests have been conducted by the State experiment stations of Michigan, Ohio, and New York, and also by a number of individuals, especially N. F. Drake, Fayetteville, Ark., and H. F. Stoke, Roanoke, Va. In most of the association contests Deming did much of the detail work and participated actively in all judging. In this he was closely followed by Bixby during a period of about 15 years beginning in 1918. Smith took entire charge of advertising the 1926 contest, which was one of the most important ever held by the association. He has been one of the principal judges in several of the contests.

Of the eastern black walnut varieties that have been brought to light in various ways, several are now grown by nurserymen. The best known of these are Creitz from Indiana, Cresco from Iowa, Ohio from Ohio, Rohwer from Iowa, Sifford from Virginia, Stabler from Maryland, Stambaugh from Illinois, Tasterite from New York, Ten Eyck from New Jersey, and Thomas from Pennsylvania. Many other varieties from New York to Arkansas and from Minnesota to Virginia are also being tested, primarily by individuals, although to some extent by public institutions. Many of these merit much greater attention than they are receiving. Unless they are propagated soon, they are likely to be lost.

The Bureau of Plant Industry has made many crosses for the purpose of developing better varieties, but so far all have suffered from adverse circumstances and few nuts have been produced. A small

number of hybrid trees are now growing on the grounds of the United States Horticultural Station at Beltsville, Md. The Minnesota Agricultural Experiment Station is growing many seedlings of certain northern varieties for the purpose of selecting individuals hardy and otherwise of merit in that latitude.

As with the hickories, practically no varieties of black walnut have yet been fully tested in orchard plantings. The shells of all black walnut varieties yet recognized are much too thick to be cracked except by mechanical means, although some shells are less thick than others.

Butternut

What has been said concerning the varietal status of the eastern black walnut is largely applicable to the butternut, *Juglans cinerea* L., although considerably less progress has been made in the development of choice varieties. This species has a rather restricted range within the Eastern States, but it occurs naturally as far west as eastern Nebraska. At present it is nowhere abundant over large areas. As a tree it does not equal the black walnut in size, although in a favorable environment it sometimes reaches 100 feet in height and nearly 4 feet in trunk diameter. The nuts are oblong, cylindrical, sharp-pointed at the apex, bluntly rounded at the base, rough and jagged over the surface, and usually thick-shelled. Nevertheless some varieties have very good shelling quality and the majority have kernels with a rich, agreeable flavor. In cooking and in the manufacture of confections the butternut shares the popular favor of the black walnut.

The first variety of butternut to be named seems to have been Aiken, discovered in 1917 by S. E. Aiken, Grasmere, N. H. It was first propagated in 1918 by J. F. Jones, Lancaster, Pa. Other varieties have since been found mainly as a result of contests held by the Northern Nut Growers' Association, but none have been commercialized.

While most varieties of butternut have thick shells and are difficult to crack, some crack so well with hand-power machines, of which several are on the market, that the kernels are released in unbroken halves.

This species has been greatly neglected by horticulturists. Besides producing nut kernels of excellent quality the species is the hardiest member of the walnut genus, its native range extending well into Canada. It is abundantly worth development wherever it succeeds, especially in the North.

Japanese Walnut

The Japanese walnut, *Juglans sieboldiana* Maxim., was first introduced into this country about 1860. It has since been widely tested in practically all parts of the country without anywhere attaining great importance. The tree has much the size and general form of a large apple tree. Its nuts are of two distinct shapes, and botanists at one time thought there were more than one species. One of these was called *J. cordiformis* Maxim., literally "heart shaped", from the shape of the nuts. However, there is but one species, as the tree characteristics are identical, and seed nuts of either type produce offspring of both fruit types as well as of many intermediate forms.

The nuts of both types are smaller, of smoother surface, and with somewhat thinner shells than eastern black walnuts. In general, both Japanese walnut types are top-shaped and sometimes sharply pointed at the apex. Those once called *Juglans cordiformis* are now known as heartnuts. These are the better of the two and are now receiving the attention of horticulturists. The late J. F. Jones propagated a number of varieties, beginning in 1918 with one that he called Lancaster. Somewhat later he introduced Bates, Faust, and Ritchie. These make quick-growing trees of much ornamental value. The nuts are excellent. Often the flavor is indistinguishable from that of the best butternuts.

The Japanese walnut, the butternut, and the Persian walnut blossom about together and 2 or 3 weeks ahead of the black walnut. Consequently they hybridize freely. The stamens and pistils of individual flowers mature at different times, usually the stamens first, and this, with wind distribution of pollen, tends to promote cross-pollination. By breeding it should be possible soon to develop valuable new forms not grown elsewhere, which would therefore have no competition with others of their own kind either imported or grown in the forests of this country. The hybrids are usually very vigorous and luxuriant in foliage, but fruit setting is sometimes very meager in spite of abundant production of both staminate and pistillate blooms. Size of tree seems to have little relation to the number of nuts produced.

Seedling Japanese walnuts grown in this country often produce nuts greatly resembling butternuts. This occurs with any generation, beginning with direct importations and continuing indefinitely. With imported seed this is undoubtedly due to reversion to a parent type common in the Orient, known as the Manchurian walnut, *Juglans mandshurica* Maxim., which is so much like the American butternut that it is considered to be the same by most travelers from this country. In other cases the resemblance is quite definitely known to be due to hybridization with either butternut or Persian walnut. It is possible that there may be occasional crosses with the eastern black walnut, *J. nigra*, but no case in which this appears probable has come to the attention of the writers.

As a rule the nuts of butternut type borne by possibly hybrid Japanese walnut trees are usually of little value owing to the thickness of the shells and poor quality of the kernels. However, two varieties of apparently hybrid origin with the butternut as a parent are being propagated to some extent. These are Helmick from Iowa and Creitz from Indiana. The former is a discovery of James K. Helmick, Columbus Junction, Iowa, and the latter was brought out by W. A. Creitz, of Cambridge City, Ind., after whom a variety of black walnut was also named.

Persian (English) Walnut

The Persian (English) walnut, *Juglans regia* L., is the best-known and most widely grown nut-bearing species of the North Temperate Zone. The tree is handsome, large, and of great value wherever it succeeds, both on account of the nuts it produces and for its timber. It is native to western and central Asia. Its nuts form an important

article of food and of general commerce. Production is important in California, Oregon, and to some extent in Washington in this country, in many European countries, in China, and to some extent in Chile.

The origin and early history of this walnut is concisely given by Heiges (*16*), who wrote:

> It was known to the Greeks, who introduced it from Persia into Europe at an early day as "Persicon" or "Persian" nut and "Basilicon" or "Royal" nut. Carried from Greece to Rome, it became *Juglans* (name derived from *Jovis* and *glans*, an acorn, literally "Jupiter's Acorn" or "Nut of the Gods"). From Rome it was distributed throughout continental Europe.

It reached England prior to 1562. There seems to be no clear record of the first introduction of this walnut into the United States, but occasional references and other evidence indicate that it came with the earliest settlers. Robbins and Ramaley (*31*) state that "In colonial days, the term English was used to distinguish this walnut from the native American black walnut and because at that time the nuts were imported via England."

At present Persian walnut trees occur quite frequently along the Atlantic seaboard from Long Island Sound west to Rochester, N. Y., and south to Virginia. Old trees, mostly in decrepit condition, are not uncommon. What is perhaps the oldest if not the largest Persian walnut in the United States stands on what is known as the Jacob Bauder farm, 7½ miles northeast of Reading, Pa. This tree was discovered in 1922 by the late J. F. Jones and was determined by him to be 210 years old. It measured 15 feet 1 inch in circumference at 4 feet from the base and had a limb spread of 90 feet. It is supposed to have been planted by the earliest German settlers.

Under the heading "A Giant English Walnut", the American Garden for September 1888 gave an account of a number of Persian walnut trees, one of which was still standing at that time and had been part of a planting by Roger Morris, an English gentleman, who in 1758 built a spacious mansion on his estate on Manhattan Island. The supposition is that the trees may have come from the Prince Nursery, Flushing, N. Y., which was established in 1713, 45 years previous to the Morris planting.

Other definite evidence of early planting is afforded by the so-called James River Hybrid, which was cut down in 1928. It stood on Rowe Farm, opposite Brandon, near the bank of the James River in southeastern Virginia. This was believed to have been a natural hybrid between the Persian and the eastern black walnut. Its apparent age was estimated by Bisset (*9*), who observed it in 1911, to have been from 150 to 200 years. As the year of Bisset's visit was 304 years after the settlement of the first successful English colony in this country at Jamestown in 1607, it would seem probable that the Persian walnut parent was brought from Europe and established there by colonists some time during the first century of English colonization in this country.

According to Lelong (*21*), the Persian walnut is supposed to have been introduced into California by the Franciscan monks in 1769. He reported that the earliest planting outside of the missions was made in San Diego probably in 1843, and that a second such planting was made near Calistoga in 1848.

The first Persian walnut planting in California to lead to commercial development was made by Joseph Sexton, of Santa Barbara, from nuts presumably of Chilean origin, bought by him in San Francisco in 1867 (*36*). Nuts from the Sexton trees were later used for growing seedlings for extensive orchard plantings in southern California. The nuts from these are known on the market as Santa Barbara soft-shells. Hard-shell walnuts were planted in northern California at about the same time as in southern California. It remained, however, for Felix Gillet, a Frenchman, who established the Barren Hill Nurseries at Nevada City, in 1871, to arouse interest in the whole State in grafted walnut trees of soft-shell varieties. He early imported many shipments of scions and nursery trees and was the first to introduce into California practically all of the best French walnut varieties now grown in this country.

Plantings of seedling Persian walnut trees are known to have been established in Oregon during the seventies or early eighties, as occasional seedling trees estimated to be from 50 to 75 years of age are to be found in the Willamette Valley of that State. The first commercial planting in Oregon consisted of seedling trees put out in 1893 by L. T. Davis, of Dundee, Oreg.[2] This orchard was later purchased by Thomas Prince, by whom it was materially expanded and made famous for many years as the Prince Orchard. Grafted trees began to appear in the Pacific Northwest during the late nineties, when A. A. Quarnberg, of Vancouver, Wash., and others first planted trees of French varieties, which they procured from Gillet.

The practice of breeding walnut varieties by selection appears to have been inaugurated by the French. L. D. Batchelor stated in an unpublished report on walnut culture in France that some of the varieties, such as Mayette and Franquette, had been grafted for over 100 years, and that the present commercial walnut industry of France is based upon grafted walnuts.

The planting of the seedling trees by Sexton was followed by marked expansion of seedling orchards in the southern part of California until about 1900, when many individual trees began to be selected and used as new varieties. Since about 1905 practically all plantings have been of named varieties and many seedling orchards have been top-worked.

In the Eastern States for approximately 10 years, beginning about 1915, efforts were made by J. F. Jones, and others to develop Persian walnut varieties that would be hardy in that section of the country. It was assumed that hardiness would be increased by grafting varieties on stocks of the eastern black walnut, *Juglans nigra*. However, practically all of the varieties so developed have since become obsolete, as they proved too subject to injury by winter cold or late spring freezes. Hardiness was apparently not affected appreciably by the use of black walnut stocks.

Persian walnut breeding by cross-pollination is still in the initial stages. Much preliminary work has been done in the way of conducting studies of blossoming habits and of pollen behavior. Varieties of this species are largely dependent upon other varieties or species of

[2] Personal statement made July 21, 1910, in Washington, D. C., by E. R. Lake, former professor of horticulture and forestry, Oregon Agricultural College, Corvallis.

walnut for pollen for the reason that their own pollen is often not available at the time it is needed. This is because the staminate or pollen-producing flowers do not function simultaneously with the pistillate or nut-producing flowers. Usually in such cases the staminate flowers mature and shed their pollen, dry up, and fall to the ground before the pistillate flowers become receptive. Occasionally, however, this order is reversed and the pollen is shed too late to function on earlier maturing stigmas. Young trees seldom produce staminate flowers until several years after the appearance of the first pistillate flowers. Wood (*46*) has found that varieties of this species are entirely fertile to their own pollen when it is available at the right time, and equally fertile to pollen of any other species of *Juglans*.

Persian walnut hybrids, resulting from natural crosses with the Hinds walnut (*Juglans hindsii*) of northern California, occur with great frequency in that State. In the East natural hybridization is not uncommon with the eastern black walnut (*J. nigra*) or with the butternut (*J. cinerea*) and occasionally with the Japanese walnut (*J. sieboldiana*). No hybrid of these types yet found has been of horticultural value, although often the trees are vigorous growers of much beauty and not infrequently of greatly increased hardiness. No doubt some of these hybrids would furnish timber of value; but the cost of developing hybrids, added to that of bringing walnut trees of any form to timber age, is entirely too great to justify consideration of hybrids for this purpose under present economic conditions. The few nuts produced by these hybrids are usually thick-shelled and contain very little kernel.

Breeding the Persian Walnut

The principal weak points in present varieties of Persian walnuts are susceptibility to bacterial blight, lack of hardiness sufficient for conditions in the Eastern and Northern States, lack of uniformity in bearing, and general lack of quality of nuts. Some varieties have considerable astringency in the pellicle of the kernels, owing to the presence of tannic acid.

Practically all varieties are susceptible to walnut blight, a serious bacterial disease affecting both nuts and twigs. This disease is now being controlled by proper spraying, but only at great expense. Lack of hardiness is a definitely limiting factor in the East, although there are occasional trees in many of the Eastern States. Trees that survive longest in this region usually have the protection of buildings, lakes, or other agencies that modify local temperature extremes. The Persian walnut is quickly responsive to warm periods in late winter or early spring and consequently is vulnerable to frost injury. When injured by frost or other mechanical agency the tree recovers slowly. Loss by freezing is a matter of universal concern in commercial walnut districts of Europe, Asia, and the United States.

Variation in annual yield largely results from environmental influences and would be difficult to overcome or reduce through breeding alone. Nevertheless, it is more serious in some varieties than in others, and development of greater fruitfulness should result in appreciable improvement.

Some varieties are more resistant to blight than others, and because of slow response to mild temperatures, some are less subject to injury by cold in winter or spring. Other superior qualities of some varieties include fruitfulness; uniformity in size of yearly crops; shells well-sealed at the ends and so firm that they do not crack while being handled, although they are easily cracked by machine or hand; very little or no astringency in the pellicle; and richness and palatability of kernel. Such varieties, each having certain good qualities, are the material from which the breeder hopes to develop new varieties having combinations of larger numbers of desirable characteristics.

The problems involved in breeding by cross-pollination are not unusually intricate. While it is possible that better varieties or better basic material for use in breeding, particularly in the matter of hardiness, might be obtained from some foreign country, this does not seem probable, as the principal walnut regions of the world have been fairly well searched. It is believed that an abundance of varieties and strains of types desirable for breeding is already within this country. As a rule French varieties are the hardiest among grafted kinds, although a few seedlings in the East, probably of German origin, may be somewhat more hardy. However, eastern-grown Persian walnuts seldom have the high quality and relative freedom from astringency of pellicle characteristic of the western nuts, such as the French and the Santa Barbara soft-shell varieties.

Persian walnut breeding has thus far been confined to selective methods for developing greater hardiness, greater resistance to blight, heavier bearing habits, and nuts of superior quality. Nuts are desired of large but not too large size, of good sealing quality, and with shells thin enough to crack readily without breaking during normal handling. The kernels must be plump, bright, smooth, free from prominent points that break off easily, rich in quality, sweet in flavor, and without tannic bitterness in any part of the pellicle.

The New York (State) Agricultural Experiment Station has made crosses between *Juglans regia* and *J. nigra* in the hope of developing walnuts of the Persian type hardy at that latitude. Similar crosses have been made by the Minnesota Station at University Farm, St. Paul. In both cases the first-generation offspring has shown increased hardiness as well as vigor, but the nuts have been of little value.

In Mexico a certain amount of breeding by selection and of variety testing is being conducted under the direction of G. Gandara, Secretariat of Agriculture, Department of Stations and Experimental Fields, Mexico, D. F.

Breeding by selection to develop superior or even more hardy varieties of Persian walnut appears to have about reached its practical limit, as the principal walnut-growing regions of the world have been more or less thoroughly surveyed and no new varieties of outstanding merit have been found in considerably more than a decade. However, an effort is now being made by P. C. Crath, of Toronto, Canada, with the financial aid of Carl Weschcke, St. Paul, Minn., to procure *Juglans regia* seed from certain known trees in the Carpathian Mountains of Poland, which, it is hoped, will produce seedlings hardy in northern parts of this country and Canada. Distributions of seed nuts from that source have already been made more or less generally

throughout Wisconsin, Minnesota, the Dakotas, and Ontario, Canada. Reports as to the behavior of resulting seedlings are contradictory, but there is a possibility that some of the Crath introductions will prove suitable for limited use in home plantings where other trees of the same species have not been hardy.

Breeding by hybridization in the hope of developing an entirely new form of walnut, which would be distinctly unlike any existing form and therefore would have no direct competition, is now being planned by the Bureau of Plant Industry for the early future. This is to be undertaken by crossing the Persian walnut with the butternut for hardiness and flavor, and probably with the eastern black walnut for a blend of excellent flavors and possible greater timber value. Crosses will be made so as to include the best of the Japanese walnuts, as that group is more hardy than the Persian walnut and will grow farther south than the butternut. Heartnut trees do not attain the great size of the eastern black walnut, and from that standpoint they are more desirable for orchard purposes.

Hybridization of varieties strictly within the species with possible infusion of characters from some other species on the western coast should greatly improve resistance to disease, hardiness, fruitfulness, and the general quality of nut. However, plans for breeding of this sort do not appear to have been announced by any institution or individual. Nevertheless, the possibilities are so great and the field so inviting that it is hardly to be conceived that it will long remain neglected.

In the appendix are listed varieties of black walnut, butternut, Persian walnut, and Japanese walnut, likely to be of value in breeding work, and the names of plant breeders who are actively working with *Juglans*.

ALMOND

THE almond, *Amygdalus communis* L., is a close relative of the peach and therefore a member of the botanical family Rosaceae. It resembles the peach in appearance of tree, foliage, and flower. It is one of the earliest orchard fruits to blossom. In this country the blooming period is from January to March, and on this account it succeeds only in regions where there is minimum danger of killing temperatures during that period. It requires a definite although short period of complete dormancy, without which it tends to become evergreen. For this reason it is unsuccessful in the mild regions of the South.

Two types of almonds are under cultivation, sweet and bitter. To the former belong the familiar almonds of commerce, common in the markets. Of these there are three types, depending upon the thickness of the shells—hard-shell, soft-shell, and paper-shell. The Jordan is a typical hard-shell variety, the Peerless a typical soft-shell, and the Nonpareil a typical paper-shell. Seedlings of both sweet and bitter almond are used as stocks upon which to bud edible varieties.

Like the Persian walnut, the almond is of Old World origin and has been known and prized for food since the earliest times. It is supposed to have originated in the Mediterranean Basin.

It is not improbable that improvement of the almond by crude selection began quite as early as with any orchard fruit. There is evidence that grafting was practiced long before the Christian

Era. The almond is easy to bud, and it is presumable that in very early times good almonds were worked on those less good and thus perpetuated.

Almond varieties have been recognized as such for a century or more in Spain, but varieties there are types rather than clons. Almonds were first introduced into the eastern United States by pioneer horticulturists, but without success. Later they were taken to California, where, during the last half century, their cultivation has become an important orchard industry. Introductions of varieties of European origin into California began before 1853.

Figure 7.—A. T. Hatch (1837–1910), Suisun City, Calif., greatest contributor to the development of almond varieties in this country. During the eighties he originated the so-called "Hatch varieties" IXL, Ne Plus Ultra, and Nonpareil, which have since been the leading sorts grown in California. At that time these became his final favorites out of many of the first selections made by him from seedlings of a bitter almond tree standing near a sweet almond by which it had doubtless been pollinated.

The first varieties introduced into California proved of little permanent value and have since been gradually supplanted by others of California origin. Out of 76 varieties rated by Wood (*45*) as being of commercial importance in California in 1925, 60 were of California origin, 4 of uncertain origin (probably California), and 12 only were from Europe. None of the European varieties was rated as being then in favor with experienced growers or apparently of value for future use. However, the early introductions and their ill-advised planting in various parts of the State threw much light on the possibilities of almond growing in California and on environmental and cultural requirements, and furnished material for developing better varieties.

Almond breeding by selection from seedlings grown on a large scale for the purpose appears to have long preceded similar work with any other nut grown in this country. In 1878 A. T. Hatch (fig. 7), of California, who at one time had almond plantings in 20 counties put out at Suisun City an orchard of over 2,000 seedlings grown from nuts of a supposedly seedling bitter-almond tree which stood near a tree producing sweet almonds from which its flowers were undoubtedly cross-pollinated.[3] The purpose was to use these seedlings as stocks upon which to bud good varieties. Concerning his next move, Hatch wrote:

I found a supposedly seedling almond which had been prolific in its bearing for several years. It was small but soft-shelled, sweet, but hard to hull and therefore

[3] Letter from Mr Hatch in Department file written June 20, 1892; Nut Culture in the United States (*16, p. 80*); and recent statement by Mrs. P. C. Campbell, Vacaville, Calif, a daughter of Mr. Hatch.

expensive to handle, though I thought it was better than one that did not bear good crops, so I budded the seedling trees in place in the orchard with buds from these trees (probably this tree), but not having buds sufficient for all there were, somewhere near 300 remained seedlings. The second year after planting I found upon some of these a few almonds, some of which seemed to be very fine, sweet, soft-shelled almonds, when I concluded to leave them as seedlings until they might bear fruit.

From then on he marked the trunk of each tree in such manner as to indicate the character of the nuts and size of the crop. It was from trees so marked that he made many selections, including two that he later named IXL and La Prima.

Hatch was so pleased with the general character of the nuts from these unbudded trees that he tried to induce those that he had previously budded to push out sprouts from below the buds in order that they too might bear. In this way he was able to add greatly to the total number of promising new sorts. Among those so discovered were two that he later named Ne Plus Ultra and Nonpareil. These two, together with IXL, were his final selections; and under the popular group name of "Hatch varieties" they later took rank among the most important varieties of almond grown in this country. To some extent these have been introduced into foreign countries.

The great majority of varieties now grown in California originated as chance seedlings discovered by careful observers in various parts of the State. A few were introduced from France, mostly by Gillet. Several came from Spain as the result of introductions by David Fairchild and Walter T. Swingle, of the United States Department of Agriculture. However, next to Hatch it is probable that the man who did most toward contributing valuable varieties to California was A. M. Newlands, of Colusa. Newlands planted a sack of almonds in 1883, and 3 years later chose 4 seedlings, to which he gave the names of California White, Commercial, Eureka, and Lassen (*45*). Of these, Eureka is one of the best small varieties in the State.

Breeding by hybridization was begun by M. N. Wood, of the United States Bureau of Plant Industry, in 1923, in cooperation with the University of California. Thousands of crosses have been made and the resulting seedlings brought to fruiting at the State Agricultural Experiment Station at Davis, Calif. A number of promising seedlings are now under observation. Two of these are being tested in many parts of the State. Nuts from one of these and from both parents are shown in figure 8.

Present Work in Almond Breeding

Few of the varieties producing the best nuts are good bearers. Some of the best bearers are unsymmetrical trees, difficult to prune. The nuts of many of those that bear well have hard shells or are of inferior flavor. The shells of some others are of such softness that they crumble badly in ordinary handling. A considerable portion of the kernels of certain varieties are gummy and objectionable. In many cases the foliage is seriously subject to red spider injury. Some varieties are difficult to "knock" from the trees; that is, to jar off when fully mature. In some varieties there are often a great many "sticktights" or nuts from which the husk separates poorly or not at all. A few of the varieties most extensively grown produce nuts too small to bring good

prices. A not uncommon defect is that of forming double kernels, called "philopenas."

If a variety of almond could be found combining all of the good points of present varieties and seedlings, little more could be desired in the way of a first-class almond. Such desirable characteristics as late blooming; full bearing; good qualities for harvesting, hulling, and

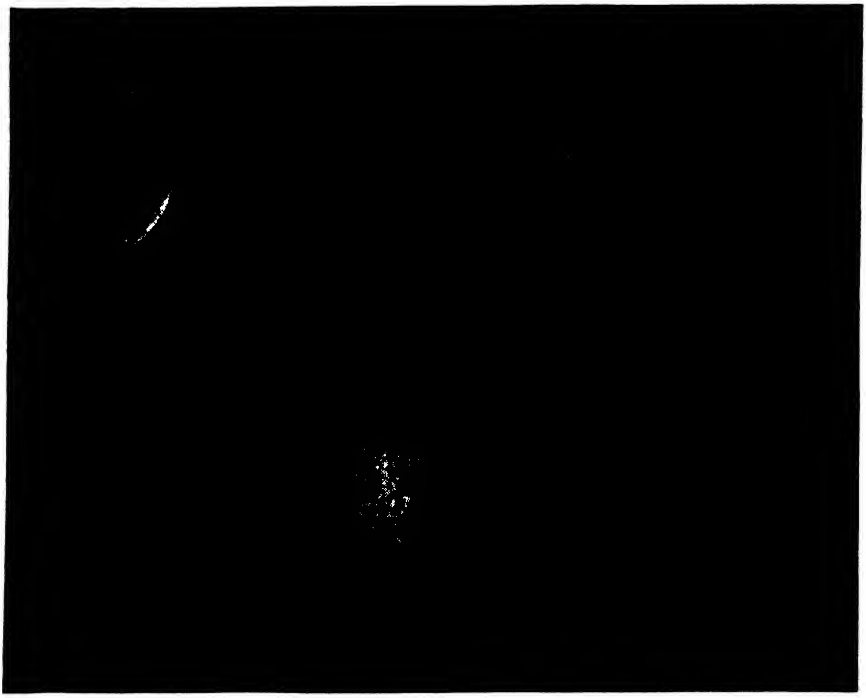

Figure 8.—Two of the almonds used in breeding and their offspring, which is believed to be promising as a new variety: *A*, Pistillate parent; *B*, staminate parent; *C*, the offspring. $\times 2/3$. The nut of the new variety is superior to that of either parent in being larger, brighter in color, and of thinner shell. The kernel is larger, brighter, smoother, and of finer flavor. The tree is more fruitful and so far has been highly resistant to the red spider.

shelling; a high degree of resistance to certain insects, particularly the red spider, and to a number of diseases; and general excellence of kernel, are all to be found distributed among present varieties and seedlings.

The problem of the almond breeder is to combine as many as possible of these good qualities in a few varieties. This should not be difficult, as the technique of almond breeding, like that of other rosaceous fruits such as apple, peach, plum, and others, is not especially difficult to perform. Almond pollen is carried only by insects and not by wind, and pollination is therefore easily controlled. This is quite different from walnuts, hickories, chestnuts, and filberts, the pollen of which is wind-carried, produced in great abundance, and difficult to control.

Present work in almond breeding by the Bureau of Plant Industry is well-organized and, as already noted, is being systematically carried on in cooperation with the University of California. Nuts from crosses made by Bureau workers are planted in nursery rows at University Farm, Davis. When the seedlings are 1 year old, scions from some of the more vigorous growers are top-worked in old trees and quickly brought into bearing. Large numbers are soon eliminated and only the most promising are preserved. In 5 to 10 years after the seed is planted further selections are made, and these are tested in various almond sections of the State by top-working on established trees. The work is making very satisfactory progress, although no varieties are yet ready for general distribution.

With the possible exception of certain of the Jordan types as grown in Spain—long, hard-shelled varieties, very popular with confectioners, chiefly because of the form of the kernel—it is generally conceded that the best almonds on the world's markets now come from California. When the good points of the California varieties are rightly combined there is abundant reason to expect that American almonds will completely dominate the markets of this country.

Breeders now engaged in work with almonds are named in the appendix, which also contains a list of almond varieties considered valuable as breeding material.

PISTACHE

THE pistache, *Pistacia vera* L., is a small-growing, wide-spreading tree up to 30 feet in height, dioecious in habit of flowering, and producing nuts of much value. The nuts are small in size and borne in clusters that often weigh several pounds. Each nut has a thin, reddish, leathery husk. The shell of the nut is very smooth, whitish, and thin, yet of bony hardness. It tends to split open slightly upon maturity, but not to such extent as to release the kernel. The flavor is mild, the texture fine, and the color of the kernel greenish throughout. When finely ground, pistache kernels are used to give color and flavor to confections. The darker they are the better they suit the purpose. The nuts are prepared for market by salting and roasting while still in the shell.

The pistache grows in hot dry regions where it withstands adversity better than either the almond or the Persian walnut. It is native in Syria and nearby regions. It was first introduced into the United States in 1853–54 by the Commissioner of Patents, by whom seeds were widely distributed throughout the Southwest. Little interest was aroused, however, until 1876, when other introductions were made by G. P. Rixford, of San Francisco, Calif., by whom trees were brought into fruit in 1881. Many more recent introductions have been made by the Division of Plant Exploration and Introduction, Bureau of Plant Industry.

There are now numerous small plantings of pistache trees in the interior valleys of central and southern California. For many years the most extensive grower in that State was Claude Tribble, of Elk Grove. He made many experiments in propagation, including the use of different species as stocks upon which to graft the better varieties. In his experience *Pistacia atlantica* Desf. proved more satisfactory than *P. chinensis* Bunge. Others have used *P. terebinthus* L. as a stock with satisfactory results.

Much work is still necessary to determine the most satisfactory pollinizers to use for the cultivated varieties. Practically no work in breeding has yet been reported and so far as known none is planned for the immediate future. However, the superior merit of this species and its ability to grow under conditions to which no other nut of this country is well adapted would seem to justify immediate attention by our breeders.

THE TUNG TREE

The tung tree, *Aleurites fordii* Hemsl., is the hardiest and most valuable member of a group of closely related tropical and subtropical trees producing inedible seeds or nuts from which a valuable drying oil is extracted. This oil has been used in the Orient for many centuries in waterproofing wood, paper, fabrics, and other products. Within the last half century it has come into important use in Europe and the United States in the manufacture of waterproof varnishes, paints, paint dryers, and linoleum. Tung oil is much like linseed oil but dries more rapidly and is more resistant to water. The tree is handsome, having a round top and dense, catalpalike leaves.

The species was introduced into the United States in 1905 by the Division of Plant Exploration and Introduction through the efforts of David Fairchild, then in charge, and United States Consul General L. S. Wilcox, Hankow, China. It has since attracted wide attention among planters in northern Florida, southern Georgia, and Gulf Coast States westward to Texas.

The earliest plantings were entirely of seedlings chosen without regard to hardiness, fruitfulness, or merit of nuts produced. In 1923 studies as to relative merits of strains and seedlings were begun by the Florida Agricultural Experiment Station at Gainesville. Later, similar work was taken up by the State stations of Georgia and Louisiana and by certain individuals, notably the late J. B. Wight, Cairo, Ga. Several selections have been made, and in a few cases these have been placed on a varietal basis by budding and grafting in the nursery. One commercial orchard of grafted trees consisting of about 4 acres has been established at Cairo, Ga.

The Florida station found that seed nuts planted in early winter or midwinter often result in trees ranging from a few inches up to 6 to 8 feet in height by the end of the first season. Such large trees may be budded during the late summer or fall. The buds will remain dormant until the following spring, when the tops should be cut back and the buds made to push out. In this way budded trees suitable for transplanting may be grown in about 24 months from the time the seed is planted.

Active hybridization was begun by the Florida station at Gainesville in 1929. Several selections from the resulting seedlings have since been made, but their value has not yet been fully determined. Selective breeding at the Georgia Coastal Plain Experiment Station, Tifton, Ga., begun in 1933, has resulted in the selection of three promising seedlings, nos. 24, 39, and 49. Breeding through pure-line selection and hybridization was begun at the Louisiana Agricultural Experiment Station, Baton Rouge, in 1935. The objectives at each of the stations are much the same; that is, to produce varieties that are hardy, vigorous, and heavy producers of good nuts rich in oil.

FUNDAMENTALS IN NUT BREEDING[4]

COMPLETE pollen control is vital to efficiency in nut hybridization work. The chief genera grown in this country are walnut, hickory (including the pecan), filbert, pistache, chestnut, almond, and tung. With the

[4] The following pages are intended primarily to give instruction to students and those professionally interested in nut breeding.

exception of almond and pistache, all are monoecious; that is, the pollen and nut-producing flowers form separately in different parts of the same tree, as shown for the pecan in figure 9. The almond bears perfect flowers; that is, stamens and pistils occur in the same flowers, as shown in figure 10. The pistache is dioecious and bears the pistillate and staminate flowers on different trees. In general appearance the tung flowers greatly resemble those of the almond, but they are imperfect, as stamens appear in some flowers and pistils in others. The pollen of almond and tung trees is carried by insects; that of the walnuts, hickories, filberts, pistaches, and chestnuts is carried by wind.

Figure 10.—Essential parts of an almond blossom: *a*, Stigma; *b*, style; *c*, ovary; *d*, anther; *e*, filament.

In most wind-pollinated nut-bearing species, dichogamy exists to a greater or less extent. This development and maturity of the staminate (male) and the pistillate (female) flowers at different times necessitates cross-pollination. The degree of dichogamy varies with the variety, the age and nutrition of the tree, and seasonal conditions. In the case of some varieties of the same or different species, dichogamy is so complete that the trees are unfruitful unless they are pollinated by another variety producing pollen at the time the pistils are receptive. Some varieties are protandrous, that is, mature their pollen in advance of the period of stigma receptivity of the pistillate blossoms; while others are protogynous, that is, the stigmas of the pistillate flowers are receptive before pollen is matured. In other varieties there is a short and inadequate overlapping period of pollen shedding and stigma receptivity. Therefore, the degree of dichogamy in the material worked is of considerable importance in nut-breeding operations and technique. In the case of the protandrous varieties pollen must be so collected and stored that it will retain its viability until it can be used for selfing or for pollinating other varieties with later pistillate blossoms. The protogynous varieties present a different problem in that the development of the staminate flowers must be forced by cutting off catkin-bearing shoots and storing them in water in a warm place, or by obtaining pollen from localities where the varieties blossom earlier in the season.

Procuring pollen is quite easy, since all that is necessary is to collect the mature catkins just prior to the liberation of their pollen and to place them on smooth, hard paper in a warm, dry room, where the locules will soon open and release the pollen.

The stage of maturity of pollen can be determined by the stiffness of the catkins and the color of the anthers. Woodroof and his coworkers (*49*) found that a pecan catkin that will not shed pollen within 48 hours is relatively stiff, while one that will do so in 12 hours is limber. The color of the anthers until within about 48 hours of the time when they will begin shedding pollen is about the same as that of the leaves and bracts. After that the green color is gradually replaced by the orange yellow of the pollen. This description of pecan catkins applies in general to those of other species of *Hicoria* as well as to *Juglans*, *Corylus*, and *Castanea*.

In order to get a controlled cross it is necessary to use unmixed pollen. This is probably best procured by collecting mature catkins shortly before any pollen has been shed, washing them repeatedly with running water, removing the excess water with a sterile towel, and then drying the catkins slowly in a desiccator or other similar container. The catkins should not be too green, as they will be likely to wilt without shedding, or the viability of the pollen may become impaired.

With some species pollen loses its vitality quickly. In making crosses it is not infrequently necessary to preserve pollen for some time while waiting for the pistillate flowers of desired varieties to mature. To do this successfully, pollen that is thoroughly dry, yet fresh, must be placed in vials or tubes plugged with cotton and held at a low but not freezing temperature.

Figure 11.—Instrument consisting of a hypodermic needle attached to a rubber bulb by means of a curved glass tube, used by pecan breeders in applying pollen to the stigmas of pistillate flowers enclosed within cellophane covers.

Numerous methods have been used for controlling pollination in the wind-pollinated nut plants. Absolute control in such cases is quite difficult and requires a special technique not needed with insect-pollinated plants. It is essential that the pistillate blossoms be covered well in advance of their receptivity with a material that will preclude pollination. These covers must not be removed, even momentarily, while there is pollen in the air. In the pecan it has been shown that pollen is not shed when the relative humidity is about 85 percent; however, that does not insure that the air is free of pollen, for the reason that it may not have had time to settle out. Woodroof (*47*) found that the usual methods of covering the pistillate flowers with cloth bags or paper sacks do not eliminate all possibility of the entrance of pollen. Their findings were later supported by investigations of Traub and Romberg (*40*). These latter workers devised a method of using closely woven cloth bags impregnated with paraffin to cover the pistillate blossoms. A hypodermic needle

attached to a rubber bulb (fig. 11) was used to introduce the desired pollen by simply pushing the needle through the cloth bag and lightly squeezing the bulb to force out the pollen. They also found that if the covers were removed and the blossoms pollinated between 5 and 7 a. m., when the relative humidity was about 85 percent, there was little danger of contamination. Later Smith and Romberg (*34*) improved the method by using transparent cellophane bags made from sausage casings. Since this method of pollination control is readily adaptable to all walnut and hickory species, it will be described in some detail. Cellophane sausage casings are made in many different sizes; usually a casing 1⅛ inches in diameter is satisfactory. These casings are seamless tubes, usually sold in lengths of approximately 32 feet. They are cut to the length desired, and one end is closed by tying, folding over, and tying again. The finished case or tube should be 4 to 5 inches long. The tubes are placed over the clusters of pistillate flowers well before the stigmas become receptive. A plug of cotton batting is wrapped around the blossoming shoot so that the lower end of the tube can be tied over it (fig. 12). The cotton plug provides ventilation for the pistillate flowers. When the stigmas become receptive they are pollinated with the desired pollen by pushing the hypodermic needle through the plugs and blowing pollen over the stigmas by pressure on the rubber bulb in which the pollen has been placed. Separate needles and bulbs must be used for each variety of pollen, or if the same outfit is used it must be sterilized with 95-percent ethyl alcohol and carefully dried when changing from one variety of pollen to another.

Figure 12.—Cellophane cover cut from a sausage casing, used in preventing unwanted pollen from reaching the stigmas of pistillate pecan flowers to be used in breeding. This is plugged with cotton at the lower end and tied tightly at the upper end. The pollen is applied by means of a hypodermic needle (fig. 11) driven through the cotton.

Pollination control in the almond is quite simple. The flowers are emasculated by the removal of the stamens and petals before any

pollen is shed. In practice the emasculated flowers are usually covered with manila bags, or the trees are enclosed in tents or cages made of muslin or wire screen of fine mesh, to prevent the introduction of foreign pollen by insects. However, these safeguards are probably unnecessary, since in rosaceous fruits, including the almond, there is practically no wind pollination and insects do not visit emasculated flowers. When the stigmas of the almond are receptive they are pollinated by being dusted with the desired pollen applied with a camel's-hair brush.

Stigma Receptivity, Pollen Shedding, and Pollen Viability

There are no available data for some of the species of nut-producing plants on the period of stigma receptivity, the time of pollen shedding and pollen viability, and the factors affecting them. In some cases investigations on these points are under way but incomplete.

The almond has a relatively long blossoming period, especially if the time is counted from the opening of the first blossoms of the earliest varieties to the last shedding of pollen by the latest varieties. Tufts and Philp (*41*) report that in practically all instances the first pollen produced was found inferior in quantity and in viability to that produced later by blossoms on the same trees. The abundance and viability of pollen was found to vary with the variety and from season to season, but generally pollen was abundant and viable. The viability of pollen was found to be greatly affected by wind, cold, and rain.

The filbert normally has a long blossoming period, often extending, within the same variety, for more than a month, although when temperatures are unseasonally high it may be short. According to Schuster (*32*), either the filbert stigmas are receptive long before they attain full size or pollen that lodges on their surfaces remains there in viable condition until the stigmas become receptive. The quantity of filbert pollen produced varies greatly according to variety, temperature, and vigor and general condition of tree, and no doubt it is influenced by other factors. The catkins begin to form in summer, and there is great danger of their being injured or killed during the following winter. For these reasons filbert pollen often shows great differences in viability. Schuster found that pollen stored in an open vessel lost less than 25 percent in viability in 2 weeks.

Normally the pecan, as well as other species of *Hicoria*, produces enormous quantities of pollen. Young trees generally produce catkins for one or more years before any pistillate blossoms are formed. Woodroof (*49*) reports that a single pecan catkin will normally shed pollen for 2 days, a single tree for 5 to 6 days, and a single variety for 10 or 12 days. Conditions that are optimum for pollen shedding tend to be destructive to its viability.

In order to gain some idea of the quantity of pollen produced by a single pecan tree, Woodroof (*48*) made detailed observations and counts on a 13-year old Mantura tree that had a total of 941 shoots on which there were 44,885 catkins. These catkins had

approximately 14,241,334 anthers that contained an average of 2,064 pollen grains each. The estimated number of pollen grains produced by the tree, therefore, was 29,394,113,376. He points out that had it been possible for each pollen grain to produce a nut, this tree would have supplied sufficient pollen for slightly more than 229,000 tons of nuts.

The viability of pecan pollen varies greatly with varieties, seasonal conditions, and other factors. Some years a high percentage of the pollen is defective, while in others it is mostly viable. Woodroof (*49*) stored pollen of 20 varieties under 10 different conditions of temperature and humidity and reported that "no temperature and humidity condition was found under which pollen could be stored for longer than 96 hours with certainty of germination." Smith and Romberg (*34*) report that Success pollen from a healthy, vigorous tree, stored at laboratory temperatures for 12 days, still gave a set of nuts, but that under similar conditions Schley pollen remained viable for only 8 days.

Under the humid conditions of Georgia the normal period of stigma receptivity of pecans was shown by Woodroof (*49*) to be about 5 days, but he pointed out that in rainy or cloudy weather the stigmas might remain receptive for 10 to 15 days. Smith and Romberg (*34, 35*) found that under the relatively dry conditions of Texas this period ranged from 12 to 28 days. All unpollinized nuts were found to drop in 5½ to 6½ weeks after the last receptive date.

Walnuts also produce enormous quantities of pollen. Wood (*46*) working with the Persian walnut found that in dry California a single catkin produced from 1 to 4 million pollen grains, and that a single tree would produce from 1½ to 40 billion pollen grains in a single season. A single stigma has a surface area of 10 to 50 square millimeters, yet he found the average number of pollen grains distributed per square millimeter per 24 hours, when pollen shedding was at its height, to be as follows:

	Number
Directly under the trees	8.0
60 feet from nearest tree	4.0
150 feet from nearest tree	2.9
500 feet from nearest tree	1.0
1,000 feet from nearest tree	.3
½ mile from nearest tree	None

Woodroof (*49*) on the other hand, found that in humid Georgia, pecan pollen was carried in appreciable quantities for a distance of 3,000 feet, which would indicate that pecan pollen is lighter than walnut pollen and may be carried considerably farther.

Individual walnut catkins were found by Wood to shed pollen during 4 to 6 days, but under conditions of hot, sunny weather, such as normally prevails in the interior valleys of California at the time walnuts are in bloom, shedding is often limited to 1 day. There is a rather wide range in the development of the different catkins on the same tree, and therefore the pollen-shedding period is much longer than the time indicated for a single catkin. Wood (*46*) found great variation in the viability of walnut pollen. Some pollen grains were devoid of protoplasmic content, and others that appeared normal failed

to germinate. The percentages of germinating pollen grains for different varieties varied from 0 to 80 percent, the average being 23 percent. Under field conditions the Persian walnut pollen loses its viability within a few days after being shed from the anther. Artificially it may be preserved best when kept in glass vials stoppered with cotton and containing a small piece of the catkin to supply moisture to the air in the vial. When kept in this manner and stored in a cool, dry place, in many instances it remained fit for artificial pollination for 3 or 4 weeks. In other cases viability was completely lost within 2 weeks.

Walnut stigmas usually remain receptive for several days, depending largely upon weather conditions. Wood (*46*) obtained the best results from the application of pollen when fluid was being secreted by the glandular portions of the stigmatic surface

Fertilization of Ovule and Development of Embryo

Among nut-producing plants, with the exception of the filbert, pecan, pignut, and Persian and Manchurian walnuts, very little is known regarding pollen-tube growth, ovule fertilization, or embryo development. Even in the case of the species studied there is not complete accord in the conclusions reached by different workers, and such information as is available is far from complete.

According to Benson (*7*), the filbert pollen grain germinates by developing a short tube, which enters the basal region of the stigma. Here the sperm nuclei enter a resting stage, remaining in this condition for 4 to 5 months. During this time the megaspore completes its development, after which the pollen tube resumes its growth and the fertilization of the egg occurs.

According to both Billings (*8*) and N. C. Woodroof (*50*), numerous pecan pollen grains germinate on the surface and send tubes into the stigmatic tissue. The tubes do not enter the stylar canal but grow downward in the tissue on each side of the micropyle and enter the ovary cavity at a point nearly opposite the chalaza. The pollen tubes enter the cavity from 6 to 12 hours after pollination, but they do not enter the embryo sac until about 2 weeks later. The actual fusion of the egg and male nuclei probably occurs about 2 to 3 weeks later, or from 8 to 9 weeks (*2, 50*) after pollination. The first division of the fertilized egg occurs about 2 or 3 weeks later, or about 2 months after pollination.

Shuhart (*33*) reported that pecan pollination generally takes place at the time of the differentiation of the eight nuclei of the embryo sac, and that fertilization takes place about 2 weeks later. However, the stage of embryo-sac development at the time of pollination varies greatly with seasonal conditions and to some extent with the variety.

Langdon (*20*) reports that in the pignut, *Hicoria glabra* (Mill.) Britton, the megasporocyte has reached the megaspore stage or one of the early stages in gametophyte development at the time of pollination. The interval between pollination and fertilization is from 16 to 18 days, while the first division of the fertilized egg occurs about 3 weeks after fertilization or 5 weeks after pollination. In the pecan N. C. Woodroof (*50*) reports the first division of the egg at 8 to 9 weeks after pollination, and Shuhart (*33*) 3 to 4 weeks.

Nast (*22*) found that the complete development from the megaspore mother cell to the one-celled embryo in the Persian walnut, *Juglans regia*, occurs within 7 to 12 days, depending on the season and climatic conditions. Fertilization of the ovule was found to take place 2 to 5 days after pollination.

In the Manchurian walnut *Juglans mandshurica*, it is reported by Langdon (*20*) that the megasporocytes pass through the different phases of meiosis within 3 to 4 days and the embryo sacs are in one of the earlier stages of nuclear division at the time of pollination. After pollination from 4 to 5 days are required for the pollen tubes to reach the embryo sacs, and fertilization of the eggs occurs 1 day later. She found that the fertilized eggs had not divided 12 days after pollination but in material collected 5 days later or 17 days after pollination four 8-celled embryos were present.

Chromosome counts have been made for a number of the nut-producing species, and these are given in table 1, in the appendix.

Incompatibility

Except in the almond and the filbert, incompatibility, or inability of male and female cells to unite and form a fertilized egg that can grow to maturity, has not been definitely shown to exist between individuals within a variety, or between different varieties, or between species of the same genus of the nut-producing plants of the United States.

Tufts and Philp (*41*) found that at least in certain years all almond varieties studied were self-sterile. Of many thousand reciprocal crosses made by them, only the IXL × Nonpareil and Languedoc × Texas seemed to show distinct evidence of incompatibility or intersterility. The parentage of almond varieties now grown in the United States is unknown, and it is therefore not possible to determine whether relationship is a factor in this incompatibility between varieties. Since these few cases of intersterility have been definitely established, it is reasonable to assume that future investigations will disclose further instances of this kind.

In some cases chestnut trees, particularly of the American sweet species, *Castanea dentata*, that grow at a distance from others have been observed to yield unsatisfactory crops or are unfruitful, although producing staminate and pistillate flowers. Such trees apparently require cross-pollination to insure fruitfulness. This is especially true on the Pacific slope, where isolated trees that are fruitful are said to be rare. Stout (*37*) reports observations made on two chestnut trees growing apart from each other at Claremont, Calif., in which the trees were heavily loaded with burs, but those of one tree contained only shriveled nuts without kernels or embryos, and in the several bushels of burs from the other tree there were only about 30 nuts that contained kernels.

Self-unfruitfulness in the chestnut, especially the American species, may be due to either self-incompatibility or to dichogamy. The former condition is indicated by the report of Powell (*26*) in which he suggests that the pistillate flowers are probably pollinated by the staminate blossoms produced on long, slender axillary catkins, which blossom first, and also by those that are produced at the distal end of the pistil-

late catkin and blossom later. He also reports having noticed that most of the stigmas of both European and Japanese varieties are receptive while the early staminate flowers are in bloom.

Schuster (*32*) found that all varieties of filbert investigated by him are practically self-incompatible. While a planting of a single variety will generally produce a few nuts, the quantity attaining maturity is negligible in proportion to the number of pistillate blossoms. Cross-incompatibility was found to exist between a number of varieties. As with the almond, the parentage of the varieties of filbert now grown is uncertain, and therefore no correlation between relationship and cross-incompatibility can be made. Schuster found Du Chilly, which is of the species *Corylus avellana*, to be cross-incompatible with *C. colurna*. He also found *C. colurna* to be nonreceptive to pollen of either Barcelona or Nottingham, both of which are of the same species as Du Chilly. Du Chilly and Barcelona were unfruitful when pollinated with *C. californica*. Reed (*1*) reported that the filbert breeding work of the late J. F. Jones showed that a large number of varieties of the European filbert, *C. avellana*, were definitely unfruitful and none were found to be fruitful when pollinated with pollen of Rush, *C. americana*, but the reciprocals of these crosses were highly fruitful. Reed (*27*) has reported successful pollination of Rush and Littlepage varieties of the American hazel with pollen of *C. colurna*, *C. maxima*, and *C. heterophylla*.

Inheritance of Characters

Most if not all varieties of the nut-producing species as they are grown in the United States are genetically in a complex heterozygous condition. This is due to the fact that all varieties of certain species are self-incompatible, requiring cross-pollination in order to set fruits; or they are dichogamous to a greater or less degree. Thus the nut-producing species do not lend themselves to a study of the inheritance of characters. In most cases several years' time must elapse from the planting of the seed until the resulting seedling produces fruit, and each plant at the time of fruiting requires a considerable area of land, which greatly limits the number of individuals that can be grown under uniform conditions. Nevertheless nut improvement through breeding by hybridization and selection has tremendous possibilities for those who have the inclination, the time, and the facilities to carry on the work.

Very little is known regarding the inheritance of characters in any of the nut-producing species. Some study of hybrids between varieties has been made in the case of the almond, and of hybrids between species in the case of the chestnut. Since 1923 the Bureau of Plant Industry and the California Agricultural Experiment Station have been cooperating in an extensive almond-breeding project. Although the total number of almond trees grown in this project has been large, the number of individuals from any one cross is too small to establish definite genetic ratios with accuracy. However, many interesting facts have been recorded. The factor for bitterness in the nut appears to be present as a recessive in all varieties of sweet almond. In most instances when two sweet varieties are crossed, about three-fourths of the progeny will produce sweet nuts and the rest bitter nuts, giving

a genetic ratio of 3:1. In some crosses, however, the ratio is apparently 1.5:1 or 1:1. Other ratios may be found as the breeding work progresses. The factor for "red spider resistance" seems to be present in some varieties and not in others. To date, red spider-resistant progenies have resulted only from crosses involving Harriott, Eureka, Golden, Nugget, Nonpareil, and Reams. In Jordan the factor for hard shell seems to be dominant. The desirable factor of heavy bearing and the undesirable one of double kernels come out strikingly in Lewelling. From a practical standpoint the results to date show that a prime prerequisite for successful improvement in the almond by hybridization includes the discriminating selection of parents that possess outstanding characters of merit.

Beginning in 1894 and continuing for many years, Van Fleet (*42*) grew many chestnut seedlings from seeds produced by hybridizing *Castanea dentata*, *C. pumila*, *C. sativa*, *C. crenata*, and varieties of these species. Detailed records were not kept, but his work showed certain things of great importance to the chestnut breeder. Hybrids between the chinquapin, *C. pumila*, and the Asiatic chestnut, *C. crenata*, often produced nuts the second year after planting the seed. Apparently the habit of *C. dentata* of coming into bearing much later appeared in hybrids between this species and *C. crenata* or *C. sativa*, since they rarely set burs until they were 5 to 12 years old. Resistance to chestnut blight, *Endothia parasitica* (Murr.) P. J. and H. W. Anderson, was found only when the Asiatic chestnut was used as a parent, and even then when either *C. dentata* or *C. sativa* was a parent the progeny was susceptible. The chinquapin is measurably resistant to blight, but when it was crossed with *C. sativa* or *C. dentata* the progeny was readily susceptible. Detlefsen and Ruth (*12*) made studies of various taxonomic characters in three generations of chestnut trees resulting from *C. dentata* × *C. crenata* crosses made and grown by George W. Endicott, of Villa Ridge, Ill. The striking variations shown by the progeny indicate that many factors are concerned in the inheritance of the characters observed.

So far as is known, the only comprehensive attempt made to improve the European filbert, *Corylus avellana*, by hybridization was by C. T. Brixey, of Gervais, Oreg., who grew about 5,000 seedling trees, mostly from seeds produced by controlled cross-pollination. Out of these, only one seemed worthy of propagation. He named this Brixnut. Only first-generation seedlings were grown, and no effort was made to determine the dominance or recessiveness of the parental characters. Of approximately 2,500 controlled crosses made in the East by Reed (*27*) in 1927 between varieties of this species, because of cold injury only about 50 seedlings have survived. No study of inheritance has been possible.

Reed (*27*) reports that hybrids between *Corylus americana* and *C. avellana* seem to be much more hardy than the pollen parents and are less inclined to sucker, more erect in habit of growth, more vigorous, and more easily trained to tree form than are the pistillate parents. The foliage of the trees is usually like that of the pollen parents, as the leaves are thicker, darker, and stiffer than those of the pistillate parents. The size, form, color, thickness of shell, and plumpness and

appearance of kernel are much like those of the pollen parent. The Rush variety, which was principally used as the pistillate parent, has the highly undesirable character of not permitting training to a single stem. The great majority of the hybrids yield satisfactorily to the single-stem method of training.

Although hybridization of pecan varieties has been carried on for several years by the Bureau of Plant Industry and by pecan growers, very little is known about the inheritance of characters. In most cases only first-generation hybrids have been grown; however, it seems that in cases where one of the parents is susceptible to pecan scab the progeny are likewise susceptible with few if any exceptions. Furthermore, the character of a speckled seed coat, which is characteristic of the variety Brooks, appears in most of the progeny in which Brooks is one of the parents.

The only study known to the writers of inheritance of characters in the genus *Juglans* is that of Babcock (*4*), who studied the inheritance of the peculiar oaklike character of *J. californica* var. *quercina* Babcock in progenies from controlled crosses. The first-hybrid generation seedlings were all typical *J. californica* trees, and of 18 second hybrid generation seedlings grown, 12 were *J. californica* and 6 were *J. californica* var. *quercina*, or a ratio of 2:1. Later backcrosses of the first generation on *quercina* gave approximately 1:1 segregation (unpublished). Because of a widespread belief that the *quercina* type was the result of natural crosses between *J. californica* and *Quercus agrifolia* Nee., many controlled crosses were attempted between these species without any fruit being produced. Thus Babcock concludes that the variety *quercina* probably originated as a mutation.

APPENDIX

Table 1.—*Number of somatic chromosomes in certain nut-producing plants*

Common name	Scientific name	Somatic chromosome number (2n)	Authority[1]
Almond	*Amygdalus communis*	16	(*10, 11, 19, 24, 25*)
Chestnut:			
American	*Castanea dentata*	24	(*18*)
Spanish	*Castanea sativa*	24	(*18*)
Filbert	*Corylus avellana*	[2] 28	(*51*)
	Corylus avellana var. *pontica*	28	(*51*)
Giant	*Corylus maxima*	[2] 28	(*51*)
Hazelnut:			
American	*Corylus americana*	[2] 28	(*51*)
Tree	*Corylus colurna*	28	(*51*)
	Corylus heterophylla	28	(*51*)
Beaked	*Corylus rostrata*	[2] 28	(*51*)
Japanese	*Corylus sieboldiana*	28	(*51*)
Tibetian	*Corylus tibetica*	28	(*51*)
Hickory:			
Bitternut	*Hicoria cordiformis*	32	(*52*)
Mockernut	*Hicoria alba*	64	(*52*)
Pecan	*Hicoria pecan*	[3] 20–24	(*50*)
Pignut	*Hicoria glabra*	64	(*52*)
Shagbark	*Hicoria ovata*	32	(*52*)
Shellbark	*Hicoria laciniosa*	32	(*52*)
Sweet pignut	*Hicoria ovalis*	64	(*52*)
Walnut:			
Black	*Juglans nigra*	[4] 32	(*51*)
Butternut	*Juglans cinerea*	32	(*51*)
California black	*Juglans californica*	34	(*3*)
Do	*Juglans californica* var. *quercina*	34	(*3*)
Japanese	*Juglans sieboldiana*	32	(*52*)
Manchurian	*Juglans mandshurica*	32	(*52*)
Persian	*Juglans regia*	[4] 32	(*52*)
Texas	*Juglans rupestris*	32	(*52*)
Heartnut	*Juglans sieboldiana* var. *cordiformis*	32	(*52*)
Tung	*Aleurites cordata*	22	(*6*)
	Aleurites fordii	22	(*6, 15*)

[1] Reference is made by number to Literature Cited, p. 957.
[2] Woodworth (*51*) reports: "Three pairs of the gemini commonly fuse completely, so that the metaphase plate appears to have eight small chromosomes and three large ones." In view of this fact Wetzel (*44*) and Jaretzky (*18*) reported only 11 chromosomes as the haploid number.
[3] Because of the small size of the chromosomes the number has not been definitely determined; most probably the base number is the same as for the family.
[4] Nebel (*23*) reports that the somatic chromosome number in *J. regia*, *J. nigra*, and one *J. nigra* × *regia* F_1 hybrid is 34.

Table 3.—*Varieties of nuts of probable value for breeding*

Genus, species, variety, and region	Origin or introducer	Comments
Amygdalus communis:		
Drake	California	Of chief value because of prolificacy and usefulness as a pollinizer.
Eureka	do	Highly prolific, with small but very sweet nuts.
IXL	do	Long one of California's most valuable varieties.
Ne Plus Ultra	do	Do.
Nonpareil	do	Do.
Texas	do	A heavy bearer, considerably like Drake.
Corylus:		
White Aveline	Long a standard; from Europe	Shell very thin; kernel of finest quality and flavor.
Barcelona	do	Leading variety of Pacific Northwest.
Brixnut	C. T. Brixey, Gervais, Oreg.	Large nut; very prolific.
Du Chilly	Long a standard; from Europe	Long a chief variety in Pacific Northwest.
Italian Red	Long well known; from Europe	Has given good results in eastern breeding.
Littlepage	Thomas P. Littlepage, Bowie, Md.	A highly prolific native from southern Indiana.
Rush	J. G. Rush,[1] Pennsylvania	A native found highly useful in breeding.
Winkler	Snyder Bros., Inc., Center Point, Iowa	Best native variety yet found in State.
Hicoria (exclusive of pecan):		
Anthony (probably *H. ovata*).	A. B. Anthony, Sterling, Ill.	An excellent nut.
Berger (probably *H. laciniosa* × *alba*).	Russell Berger, Cove Gap, Pa.	First prize miscellaneous hickories, 1934 contest, Northern Nut Growers' Association.
Chase (probably *H. ovata*).	W. R. Chase, Hartford, Conn.	An excellent nut.
Coleman (probably *H. ovata*).	Mrs. Thomas Coleman, Saltsburg, Pa.	Third prize, 1934 contest, Northern Nut Growers' Association.
Davis (probably *H. ovata*).	Dwight Davis, Dover Plains, N. Y.	First prize, 1934 contest, New York State.
Emerick (probably *H. ovata*).	Etta Emerick, West Camp, N. Y.	Superior cracking quality.
Fox (probably *H. ovata*).	Roland D. Fox, Fonda, N. Y.	First prize, 1934 contest, Northern Nut Growers' Association.
Goheen (probably *H. ovata*).	Mrs. Martha Goheen, Pennsylvania Furnace, Pa.	Second prize, 1934 contest, Northern Nut Growers' Association.
Hagen (probably *H. ovata*).	Mrs. C. E. Hagen, Guttenberg, Iowa	One of the best known in the State.

[1] Deceased.

TABLE 3.—*Varieties of nuts of probable value for breeding*—Continued

Genus, species, variety, and region	Origin or introducer	Comments
Hicoria (exclusive of pecan)—Continued.		
Heibner (probably *H. ovata*).	Harvey A. Heibner, Danville, Iowa	Very superior nut.
Jolliffe (probably *H. ovata*).	George C. Jolliffe, Uffington, W. Va	Very high percentage of kernel.
Lawson (probably *H. ovata*).	Donald Lawson, Dorloo, N. Y	Second prize, 1934 contest, New York.
Mann (probably *H. ovata*).	Mrs. Rae D. Mann, Davison, Mich	First prize, 1932 contest, Michigan.
Miller (probably *H. ovata*).	D. P. Miller, North Branch, Mich	Second prize, 1932 contest, Michigan.
Redcay (probably *H. laciniosa*).	Adam Redcay, Lititz, Pa	Second prize, miscellaneous hickories, 1934 contest, Northern Nut Growers' Association.
Romig (probably *H. ovata*).	Romig Bros., Downington, Pa	An excellent nut.
Sande (probably *H. ovata*).	Elmer T. Sande, Story City, Iowa	One of best known in Iowa.
Swaim (probably *H. ovata*).	H. H. Swaim & Son, South Bend, Ind	Highly prolific.
Vest (probably *H. ovata*).	Luther W. Vest, Blacksburg, Va	Extremely thin shell.
Whitney (probably *H. ovata*).	W. O. Whitney, Berea, Ohio	First prize, 1934 contest, Ohio.
Wilcox (probably *H. ovata*).	P. E. Wilcox, Geneva, Ohio	Second prize, 1934 contest, Ohio.
Hicoria pecan:		
Southeastern region:		
Brake	William H. Brake, Rocky Mount, N. C.	Outstanding cracking and kernel quality.
Brooks	B. W. Stone, Thomasville, Ga	Scab-resistant; prolific; superior cracking quality.
Candy	Theodore Bechtel,[1] Ocean Springs, Miss.	Superior table variety; roundish.
Curtis	J. B. Curtis,[1] Orange Heights, Fla	Scab-resistant; superior cracking and kernel quality.
Desirable	C. Forkert,[1] Ocean Springs, Miss	Large size; scab-resistant; good cracking quality.
Lewis	F. H. Lewis,[1] Pascagoula, Miss	Do.
Mobile	B. W. Stone, Thomasville, Ga.	Prolific; scab-resistant.
Moneymaker	S. H. James,[1] Mound, La	Prolific; early to mature.
Moore	Several nurserymen, Monticello, Fla	Prolific; scab-resistant; early; good cracking quality.
Nelson	William Nelson,[1] New Orleans, La	Prolific; vigorous; scab-resistant.
Russell	H. F. Russell,[1] Ocean Springs, Miss	Scab-resistant; very thin shell; sweet.
Schley	A. G. Delmas,[1] Pascagoula, Miss	Thin shell; very superior kernel quality.
Stuart	W. R. Stuart,[1] Ocean Springs, Miss	Scab-resistant; of good commercial size.
Success	Theodore Bechtel,[1] Ocean Springs, Miss.	One of the best when good; variable.
Southwestern region:		
Burkett	J. H. Burkett, Clyde, Tex	Very fine table variety.
Clark	William Millican, Bend, Tex	Very fine all-around variety.
Halbert	H. A. Halbert,[1] Coleman, Tex	Extremely precocious and prolific.
Nugget	J. A. Evans, Arlington, Tex	Superior shelling quality.
San Saba Improved.	E. E. Risien & Son, San Saba, Tex	Notably thin shell.
Sovereign	do	Notably prolific.
Squirrel	do	Notable flavor.
Supreme	do	Generally very fine variety.
Western	do	Do.
Northern region:		
Busseron	Long a standard; from near Vincennes, Ind.	Matures early; no other advantage.
Clarksville	Arthur L. Norton, Clarksville, Mo	One of the most northern in origin.
Dewitt	George F. Dewitt, Butler, Mo	Superb cracker; high percentage kernel.
Duley	John Duley, New Haven, Ill	Very good all-around nut.
Elmer	Snyder Bros., Inc., Center Point, Iowa.	Should be one of the most hardy.
Fisher	Joseph Gerardi, O'Fallon, Ill	Said to be unusually prolific.
Gallatin	C. W. Richardson, New Haven, Ill	One of the most promising new varieties.
Goforth	Bert Goforth, New Haven, Ill	First prize, 1934 contest, Northern Nut Growers' Association.
Greenriver	Standard variety; Daviess County, Ky.	Best of older northern varieties.
Harmon	Anna S. Harmon, Mount Carmel, Ill.	An excellent seedling, not yet propagated.

[1] Deceased.

TABLE 3.—*Varieties of nuts of probable value for breeding*—Continued

Genus, species, variety, and region	Origin or introducer	Comments
Hicoria pecan—Contd. Northern region—Continued.		
Hofmann	O. J. Hofmann, Henderson, Ky	An excellent seedling, not yet propagated.
Indiana	Long a standard; 300 yards from original Busseron.	Matures early; no other advantage.
Kentucky	Long a standard; northern Kentucky	Excellent midseason pollinizer.
Major	Long a standard; Daviess County, Ky	Excellent nut, but too small and round.
Meyer	Mrs. Tony Meyer, Brunswick, Mo	Should be hardy well north.
Niblack	M. J. Niblack,[1] Vincennes, Ind	Best cracking quality; very sweet.
Norton	Arthur L. Norton, Clarksville, Mo	Large nut; should be hardy north.
Posey	Long a standard; southwestern Indiana.	Handsome tree; excellent cracker.
September	J. F. Wilkinson, Rockport, Ind	Said to be earliest to mature.
Juglans cinerea:		
Aiken	J. F. Jones Nurseries, Lancaster, Pa	From New Hampshire; small but good cracker.
Alverson	M. E. Alverson, Howard City, Mich	Third prize, 1932 contest, Michigan.
Baker	G. A. Zimmerman, Harrisburg, Pa	From New York; highly promising.
Buckley	Park Buckley, Strawberry Point, Iowa	One of best known in Iowa.
DeVan	F. E. DeVan, Rock Creek, Ohio	Fifth prize, 1929 contest, Northern Nut Growers' Association.
Hostetter	C. F. Hostetter, Bird in Hand, Pa	Third prize, 1929 contest, Northern Nut Growers' Association.
Irvine	L. K. Irvine, Menomonie, Wis	First prize, 1929 contest, Northern Nut Growers' Association.
Kenworthy	John F. Kenworthy, Rockton, Wis	Fourth prize, 1929 contest, Northern Nut Growers' Association.
Lingle	E. J. Lingle, Pittsfield, Pa	Sixth prize, 1929 contest, Northern Nut Growers' Association.
Love	Charles P. Reed, Howell, Mich	One of best known in Michigan.
Luther	F. Luther, Fairgrove, Mich	Second prize, 1932 contest, Michigan.
Mitchell	Claude Mitchell, Scotland, Ontario, Canada.	First prize, 1932 contest, Michigan.
Robinson	Mrs. Ada Robinson, Waterman, Ill	One of best known in Illinois.
Sherwood	Snyder Bros., Inc., Center Point, Iowa	One of best in State.
Smith	Horace T. Smith, Chicopee, Mass	One of best known in Massachusetts.
Thede	M. F. Thede, Wayland, Mich	One of best known in Michigan.
Thill	M. J. Thill, Bloomer, Wis	Second prize, 1929 contest, Northern Nut Growers' Association.
Utterback	W. E. Utterback, Sigourney, Iowa	One of best in State.
Wright	Douglas N. Wright, Colchester, Vt	One of best known in State.
Juglans nigra:		
Adams	R. Adams, Scotts, Mich	Highly rated by U. S. Department of Agriculture and Michigan Agricultural Experiment Station.
Allen	Glenn W. Allen, Middleville, Mich	Do.
Asbury	C. D. Asbury, Augusta, Ky	Third prize, 1926 contest, Northern Nut Growers' Association.
Benton	W. A. Benton, Wassaic, N. Y	Second prize, 1934 contest, New York.
Booth	R. A. Booth, Bonsack, Va	Excellent cracking and kernel qualities.
Brown	Mrs. Willard Brown, Rock Bridge, Ohio.	First prize, 1933 contest, Ohio.
Clark	Frank Clark, Lamoille, Minn	Fourth prize, 1934 contest, Northern Nut Growers' Association.
Cowle	B. A. Cowle, Defiance, Ohio	Third prize, 1933 contest, Ohio.
Creitz	W. A. Creitz, Cambridge City, Ind	Excellent cracking and kernel qualities.
Cresco	W. A. Bents, Cresco, Iowa	Very good nut; very hardy.
Dougherty	L. D. Dougherty, Crane, Mo	Very good nut; best for southern latitudes.
Edgewood	Ben F. Walker, Siloam Springs, Ark	Do.
Edmunds	Lewis Edmunds, Glasgow, Ky	First prize, 1934 contest, Northern Nut Growers' Association.
Edras	Gerald Adams, Moorhead, Iowa	High percentage of excellent kernel.
Franklin	G. A. Zimmerman, Harrisburg, Pa	Good nut; blooms very late.
Freel	Mrs. E. W. Freel, Pleasantville, Iowa	First prize, 1929 contest, Northern Nut Growers' Association.
Grundy	John Rohwer, Grundy Center, Iowa	First prize, Iowa State Fair, 1927.
Hepler	George Y. Hepler, South Bend, Ind	Excellent cracking and kernel qualities.
Impit	J. U. Gellatly, Westbank, British Columbia, Canada.	For consideration in Pacific Northwest.
Janson	W. W. Janson, Jefferson, Ohio	Fourth prize, 1933 contest, Ohio.
Kettler	Fred Kettler, Platteville, Wis	Excellent nut; should be hardy in North.
Knapke	J. J. Knapke, New Weston, Ohio	Excellent nut; high percentage of kernel.
Learn	Dane Learn, Aylmer, Ontario, Canada	Very white kernel; very sweet; hardy.
Lee	R. E. Lee, Troutville, Va	One of best yet found in Virginia.

TABLE 3.—*Varieties of nuts of probable value for breeding*—Continued

Genus, species, variety, and region	Origin or introducer	Comments
Juglans nigra—Contd		
Lionberger	John W Lionberger, Table Rock, Nebr	Best yet found in State, very good nut
Marion	Mrs E W Freel, Pleasantville, Iowa	First prize, 1929 contest, Northern Nut Growers' Association
McMillen	Lowell McMillen, Buchanan, Mich	Excellent cracking and kernel qualities
McPherson	A McPherson, Jr, Caledonia, N Y	Third prize, 1934 contest, New York
Mintle	J R Mintle, Glenwood, Iowa	Unusually fine nut
Monterey	L K Hostetter, Lancaster, Pa	Excellent cracking and kernel qualities
Myers	E R Myers, Bellefontaine, Ohio	Unusually thin shell, very good otherwise
Ohio	J F Jones Nurseries Lancaster, Pa	Standard variety since first propagated in 1915
Patterson	Mrs William Patterson Wever Iowa	Excellent cracking and kernel qualities
Pinecrest	Herbert Miller, Richfield, Pa	Do
Rohwer	John Rohwer, Grundy Center Iowa	Second prize, 1926 contest, Northern Nut Growers' Association
Sifford	C L Sifford, Buchanan, Va	Excellent cracking and kernel qualities
Snyder	C H Snyder, Newfield, N Y	First prize 1934 contest, New York
Sparrow	Harry C Sparrow Lomax Ill	Excellent cracking and kernel qualities
Stabler	Thomas P Littlepage Bowie, Md	Many nuts have single lobes, good cracker
Ten Eyck	J F Jones Lancaster Pa	Unusually thin shell
Thomas	J W Thomas & Sons, King of Prussia, Pa	Has long been the leading standard variety
Throp	Ralph Throp, Greensburg, Ohio	Most or all have single lobes
Tritten	Sam Tritten, Lisbon Ohio	Second prize, 1933 contest, Ohio
Waldsmith	L O Waldsmith, Hartselle, Ala	Best black walnut yet found in Alabama
Wanda	Gerald Adams, Moorhead, Iowa	Excellent cracking and kernel qualities
Wetzel	Annie M Wetzel, New Berlin, Pa	Fourth prize 1929 contest, Northern Nut Growers' Association
Wiard	Everett Wiard, Ypsilanti, Mich	Third prize, 1934 contest, Northern Nut Growers' Association
Wright	Herman Wright, Wolcott, N Y	Fourth prize, 1934 contest, New York
Juglans regia		
Concord	French parentage	Leading favorite in central portions of California, blooms late
Crath Seedlings	Poland	Now being introduced by Paul C Crath, Toronto, Canada, in the hope of finding greater hardiness
Ehrhardt	South America	A heavy bearer of high grade commercial nuts
Eureka	Persia	A leading commercial sort blooms late, nuts well sealed
Franquette	France	Late bloomer leading commercial sort of Pacific Northwest
Payne	do	Very precocious and prolific
Placentia	South America	The leading commercial variety in southern California
Juglans sieboldiana [2]		
Bates (Hn)	J F Jones Nurseries Lancaster, Pa	One of best yet tested
Bourne (Hn)	Fred Bourne, Milford, Mich	Second prize 1932 contest, Michigan
Calendar (Hn)	J U Gellatly, Westbank, British Columbia, Canada	Best variety from Pacific Northwest
Cardinell (S)	Bob Cardinell, East Lansing, Mich	Third prize 1932 contest, Michigan
Caruthers (Hn)	A Caruthers, Ferrell, Va	Best variety from Virginia
English (S)	Harold English, Chatham, Ontario Canada	First prize, 1932 contest, Michigan
Evers (Hn)	A H Evers, Petoskey, Mich	Second prize 1932 contest Michigan
Faust (Hn)	J F Jones Nurseries, Lancaster, Pa	Exceptionally vigorous, good nut, large
Fodermaier (Hn)	John J Fodermaier, Dover Plains N Y	Excellent nut highly promising
King (Hn)	John W Hershey, Downingtown, Pa	Do
Lancaster (Hn)	J F Jones Nurseries, Lancaster, Pa	Standard first variety propagated
Mitchell (Hn)	Claude Mitchell, Scotland, Ontario, Canada	First prize, 1932 contest, Michigan
Stranger (Hn)	J F Jones Nurseries, Lancaster, Pa	Said not to be dichogamous
Wright (Hn)	Ross Pier Wright, Westfield, N Y	Very new, apparently one of the best
Juglans sieboldiana hybrids		
Cording × *J regia*	R Bates, Jackson, S C	Extremely rapid grower
Creitz × *J cinerea*	W A Creitz, Cambridge City, Ind	Prolific, reasonably good
Helmick × *J cinerea*	James K Helmick, Columbus Junction, Iowa	Heavy bearer, quite good

[2] Hn = heartnut, S = Siebold walnut

IMPROVEMENT OF FLOWERS BY BREEDING

S. L. EMSWELLER, Principal Horticulturist,
PHILIP BRIERLEY, Associate Pathologist,
D. V. LUMSDEN, Associate Physiologist,
F. L. MULFORD, Associate Horticulturist,
Division of Fruit and Vegetable Crops
and Diseases, Bureau of Plant Industry

AGRICULTURE is above all things practical, and probably few people would think of it as concerned with the production of sheer beauty. Yet American agriculture has $290,000,000 invested in producing beauty, and it pays to the extent of a gross return of $131,000,000

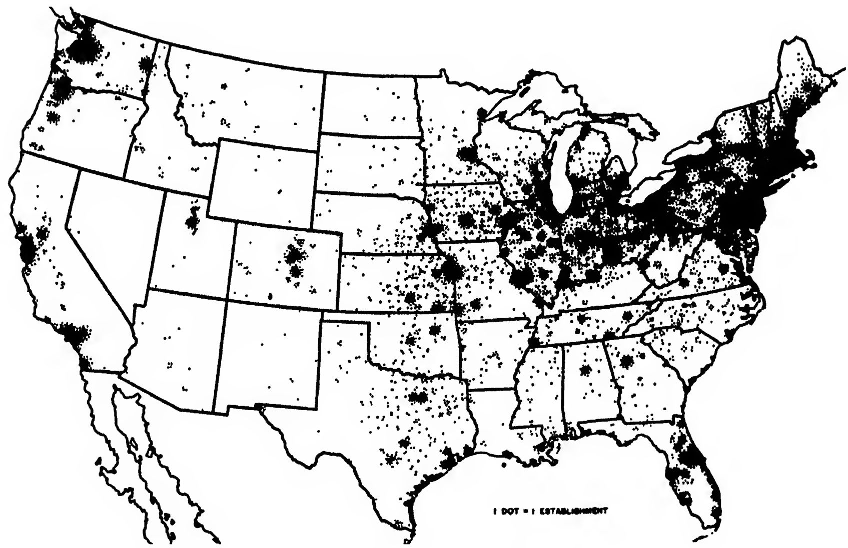

Figure 1.—Approximate location of florists' establishments producing flowers and plants grown under glass and flowers grown in the open, 1929.

a year. These figures apply to the farms and nurseries engaged in growing flowers and ornamental plants, outdoors and under glass.[1] The map (fig. 1) shows both how widespread the industry is and how heavily it is concentrated in certain regions.

This great industry supplies material for the immense number of people who grow flowering and ornamental plants for their own enjoyment. During recent years there has been a rapid increase in the

[1] In 1929, according to the census, there were 13,088 florists producing flowers and plants as a business, both under glass and in the open. The number of commercial nurseries at that time was 7,207, and probably most of these devoted at least part of their space and time to the production of ornamental plants. In addition, 1,935 farms were reported as engaged in growing bulbs commercially. The number of farms engaged in producing seed of flowering plants—a well-developed industry on the Pacific coast, expecially in California—was not included.

planting of flowers around homes and in the planned planting streets, roadways, and parks. The large number of flower shows a exhibits, ranging from the small display of a village garden club the huge annual national and international shows, is one evidence o this interest. In some of these shows the competition for prizes fo new or improved strains or seedlings has become very intense, especially among fanciers of one kind of flower, such as the chrysanthemum, dahlia, gladiolus, rose, or iris.

These demands of both florists and home growers have been the major influence in the development of new and finer types of flowers, and each year there are many new introductions. Undoubtedly changing fashions play a large part in this activity, and the florist must be constantly on the alert to meet them.

BACKGROUND OF FLOWER BREEDING

It is likely that our early ancestors were too busy securing the bare necessities of life to pay much attention to plants that had nothing but their beauty to recommend them. Conscious selection of purely decorative plants probably did not begin until some sort of stable living conditions had been achieved. When early man first began to grow flowers, he very likely transplanted entire clumps from the wild to his dooryard. It is only natural that he should have chosen the best for transplanting and thus practiced the first plant selection in ornamentals. As time went on, the use of flowers and ornamental plants played an ever-increasing part in his everyday life. We know from the remnants of early art that flowers were regarded highly, since so many of them furnished the chief motif in decoration.

The early records of selections and attempts to breed flowering plants are very meager. Considerable work had undoubtedly been done by the beginning of the eighteenth century. The first apparently authentic record of hybridizing flowers, however, appeared in 1717, vhen Thomas Fairchild's cross between a carnation and a sweet-illiam was reported. This occurred during a period when consider-le interest had been aroused by the work of Camerarius, who nonstrated the existence of sex in plants.

he species hybrid produced by Fairchild was completely sterile was commonly referred to as the plant mule. The chief interest e botanists of this period was not so much the production of better s as the accumulation of evidence on sexuality in the plant king- Fairchild's hybrid, however, received considerable attention is described in 1717 in Bradley's New Improvements in Planting rdening, as being neither sweet-william nor carnation, but as ing both equally.

Work of Amateur and Professional Breeders

he existence of sex in plants had be

flowers. The dev
ng the ninete
work

a back-yard garden. In the numerous organizations interested in some one flower, such as the American Rose Society, the American Iris Society, and others, there are many members engaged in the fascinating hobby of flower breeding. A great deal of this work is never heard of, but undoubtedly it has produced many of our present varieties of such important flowers as iris, gladiolus, dahlia, rose, and narcissus. It involves the making of many thousands of crosses each year in a very wide range of plant material. In an article such as this, it is obviously possible to mention the work of only a few amateur breeders, and this is done here and there under sections dealing with particular plants. It is likewise not possible to discuss all the numerous varieties that have been developed by flower breeders. The following résumé of the number of listed varieties of some of the groups of the commoner flowers is evidence of the extent of interest in this field.

Name	*Number of varieties*
Rose	15,000
Chrysanthemum	1,500
Narcissus	3,000
Tulip	8,000
Sweet pea	500
Snapdragon	400
Aster	600
Dahlia	7,000
Gladiolus	2,500
Iris	4,000
Peony	2,000

Since new varieties are constantly appearing and old ones going out of fashion, the data of this tabulation can be accepted only as approximations. The origin of most varieties of flowers is unknown, and it is beyond the scope of this article to attempt to indicate this for each kind of flowering or ornamental plant, but the named varieties of the plants included in this discussion far exceed in number those of our important food plants. It is safe to say that the productio of such a large number has been possible only because of the work thousands of amateur breeders, whose main compensation has be the pleasure the work has afforded them.

The contributions of the professional breeders, including nurs men, florists, and seedsmen, are likewise very large. It is to work of this group that we owe the development of nearly all modern varieties of such important flowers as the rose, zinnia, pea, carnation, calendula, aster, snapdragon, larkspur, and n tium. While it is true that profit has been a primary factor work, the professional breeder almost always has an inborn l the plants and flowers that are his stock in trade.

all the large flower-seed growers are carrying o ms. Of the many new flowers or so-call each year, some have arisen that occurred in th taneous mutant d or not

instance, to see as many as 5 acres of some one flower, with as many as 430,000 individual plants. This means that the possibility of finding rare multiple recessives is fairly great. Here it is not a question of following the inheritance of one or a few genes. The trained geneticist has an opportunity to find nearly every combination of characters that could possibly arise from the material (fig. 3).

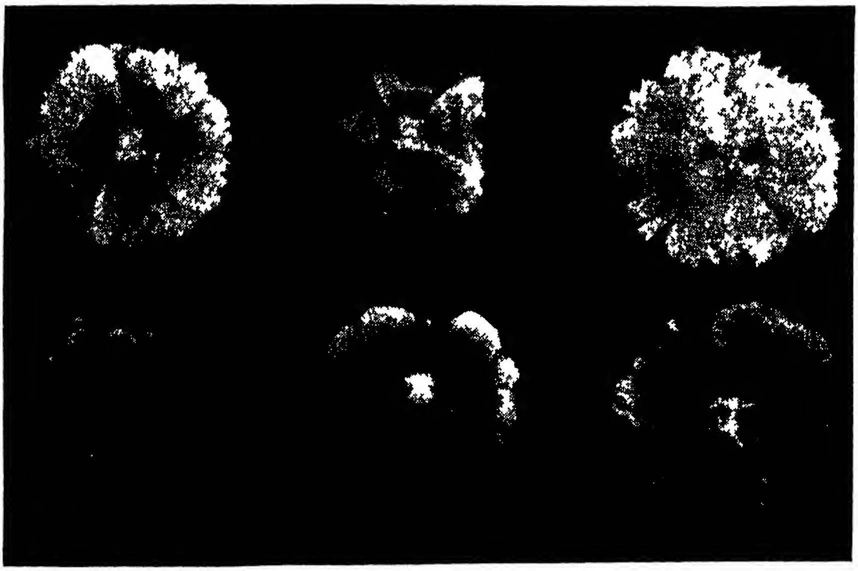

Figure 2.—Variation in hollyhock flowers collected from a group of plants growing in a garden at Davis, Calif. By selection and by controlling pollinations for several years all but the double form could probably be made to breed true. The double shown here is a rather complex form that cannot be bred to come true from seed.

When a new outstanding type appears in a field it is usually recognized. If it seems desirable, a stake is placed beside it and the seed is collected as it matures. In recent years the more careful growers take measures to protect the selected plant against cross-pollination if it is a species not normally self-fertilized (fig. 4). As many as several thousand such field selections may be made each year on a large flower-seed ranch. Only the best variants are carried on, and these are usually not introduced until they breed fairly true to type. While undergoing this period of selection and reselection they are said to be "in the shop" (fig. 5).

There is no doubt that the flower varieties of today are a vast improvement over those of 15 to 20 years ago. Undoubtedly we owe a real debt of gratitude to the amateur and professional breeders whose efforts have made this possible. When it is recalled that most of this work has been accomplished without the aid of a background of knowledge of genetics, the possibilities for the immediate future are indeed bright. In many instances the results could have been accomplished in a much shorter period, and frequently a smaller population of plants would have sufficed. Unfortunately there still

exist many erroneous ideas and beliefs among flower breeders. Some of these will be discussed later in this article.

Need for More Scientific Methods

The accumulation of data and the development of fundamental principles in genetics have gone on at a rapid pace during the last 25 years. As a result there is now available sufficient information prac-

Figure 3.—A field planting in California of annual larkspur for seed. There are several hundred thousand plants in a field of this size. To many the plants would appear uniform, but to a trained investigator there would be countless variants as to flower shape, color shades, plant habit, foliage, and many other characters. (Courtesy of Bodger Seeds, Ltd.)

tically to revolutionize the practices of the average amateur and professional flower breeder. Unfortunately this material is not readily accessible, being widely scattered in scientific journals and papers in many different languages.

Much of the unfamiliarity of flower breeders with this mass of information is probably due to the fact that it has never been called to their attention. For instance, geneticists have known for years that the common flowering stocks (*Matthiola incana* (L.) R. Br.) were limited to a maximum of about 56 percent of doubles and that no more can be obtained; yet considerable money is being spent by florists and seedsmen each year to breed strains that will produce a higher proportion.

No one would think of stepping into an airplane and attempting to fly it without some preliminary instruction, yet apparently nearly

everyone thinks the only requisite for success in flower breeding is a liking for the work. If this article seems to be somewhat more technical than the reader might expect, considering the popular appeal of the subject matter, it is because the authors believe the time has come when those interested in improving flowers must be ready to put some effort on studying the basic elements of their science. Planned breeding is unquestionably a fairly complex job. It does not sit and wait for the "breaks" but goes out and makes them. It has its rules and principles, and he who becomes familiar with them is well repaid in increased efficiency. Some of these rules and principles will be discussed in the following pages.

Figure 4.—A type of bag commonly used to protect selected flower plants from cross-pollination. A stake is driven into the ground close to the plant and a tin or galvanized-iron cylinder open at both ends is placed around the base of the plant and stake. A long cloth bag open at both ends is pulled down over the plant and stake, tied tightly about the metal cylinder, and closed at the top with a drawstring. This gives protection from insect visitors, and if mesh of cloth is fine enough also from wind-blown pollen.

Most of the early technical investigators who worked with flowers were interested mainly in establishing fundamental principles of inheritance. This explains why, until very recently, so few varieties of flowers or ornamentals have been produced by technical workers. Following the rediscovery of Mendel's work in 1900, numerous experiments were carried on to test the validity of his laws. In a goodly share of these, some species of flowering plant was used as experimental material. As a result there was built up a considerable amount of data on the inheritance of many characters in a wide range of flowering plants. This has been summarized and is presented in the appendix of this article.

Recently the possibility of producing strains of flowers resistant to diseases has been receiving more than usual attention. The achievements in this field with some plants such as wheat, sugar beets, cabbage, etc., have stimulated a desire for similar work with flowers. The control of many virus and fungus diseases of flowers is very difficult and offers a challenge to the plant breeder. The success achieved with wilt-resistant asters (fig. 6) and rust-resistant snapdragons is an

indication of the immense possibilities. In this type of work it is very probable that technical workers in public-service institutions will lead the way. A close cooperation between pathologists and geneticists will be essential and is now provided in many experiment stations and in the United States Department of Agriculture. Work in this

Figure 5.—A sweet pea "workshop" in California. Seed from controlled crosses is planted in rows, and when plants are in bloom the breeder takes notes on each lot, selecting the most desirable for further breeding Three long bamboo stakes are placed to form a tripod over each selected plant, and if seed is to be saved a little bag is numbered and tied to the bamboo support. (Courtesy of Ferry-Morse Seed Co.)

field may become involved in difficulties, such as the sudden appearance of other forms of a disease-producing organism that are able to infect hitherto resistant plants. These so-called physiological strains of fungi are discussed at some length in the section on wheat in the 1936 Yearbook of Agriculture. They will be mentioned later under the discussion of rust resistance in snapdragons.

There is also a demand for types better suited to certain unfavorable environmental conditions, such as winter cold, drought, or intense heat. At the present time practically all of the breeding work on flowers is restricted to certain sections of the United States and of Europe. It is very probable that some genetic material discarded as undesirable in one region might be extremely valuable if grown under a different set of environmental conditions. For instance, too glaring

colors would very likely be less intense in a warmer, sunnier climate and the washed-out pink of a hot region is apt to be about right in a cooler habitat. Long, slender, weak stems in a warm section are commonly shorter and sturdier when the plants are grown under cooler conditions.

The effect of length of day on blooming is another very important point that is now given scant consideration by the average flower

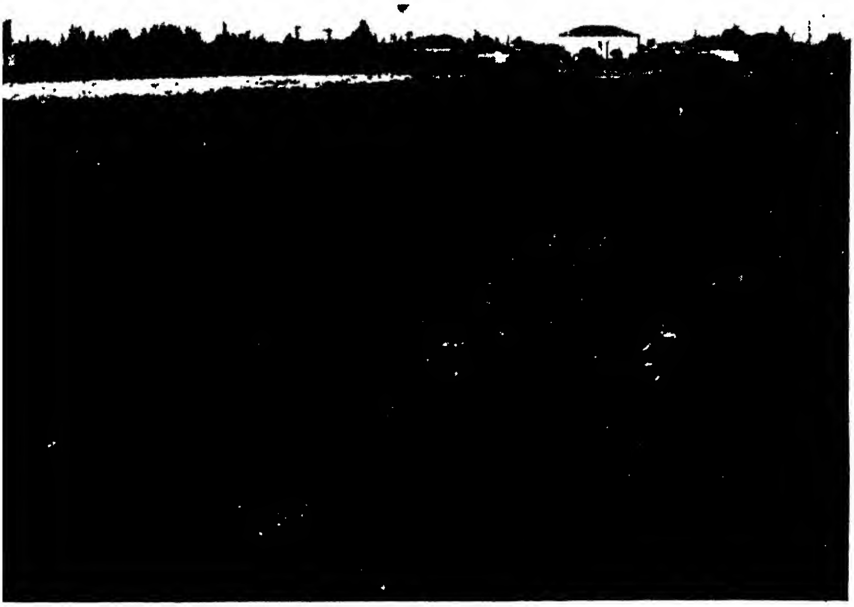

Figure 6.—Wilt-resistant and susceptible asters planted side by side on infested soil. The susceptible plants on the right have been practically wiped out by the disease. (Courtesy of Bodger Seeds, Ltd.)

breeder. When plants of a species known to be sensitive to day length are selected for blooming at some particular time of year in one latitude, it should be remembered that in another their behavior in this respect is likely to be different.

The breeding of winter-hardy perennials is just now beginning to receive some attention. Here also, results will depend to a considerable extent on the location in which the plants are to be grown. Low atmospheric temperatures are less destructive if there is a heavy blanket of snow. This explains why some flowering perennials overwinter nicely in Canada, but are frequently winter-killed in the Ohio Valley.

A very valuable aid in the breeding of flowers is the collecting of new germ plasm by introducing species and varieties native to other parts of the world. This has been done in this country chiefly by the Division of Plant Exploration and Introduction, of this Bureau. The many botanical gardens in all parts of the world also exchange

seeds and plant materials. While some of these introductions are rather unattractive as measured by American standards, yet they may carry very valuable genes. In many instances these "immigrant genes" can be introduced into some of our own standard varieties, giving new and more desirable strains.

As a result of widespread interest and to stimulate greater effort, American seedsmen have established an annual testing of new flowers in what are called the "All-American Trials." New varieties entered by seed growers are planted at a number of locations scattered over the country. A committee of qualified seedsmen in each region observes these plantings and rates each new production on its merits. Awards are then given for the most outstanding introductions. This plan has afforded an excellent stimulus to flower breeding and has probably had much to do with the recent expansion of this work by seed growers.

TECHNIQUE OF BREEDING

The first step in breeding work is the transfer of pollen from the anthers to the stigma of a flower. Two types of pollination are distinguished: self-pollination, when the pollen is produced by the same flower as the seed or by another flower on the same plant; and cross-pollination, when the pollen comes from another plant. Self-pollination is easily accomplished in most cases by enclosing the plant or its flowers in some sort of cloth cage or paper bag so as to protect them from all pollen except their own (fig. 7). Some plants may need a pollinating agent, even though they are fully self-fertile, because the pollen of the flower is shed before its own stigma is receptive, or because the stigma protrudes up above the anthers, or for some other reason. Sometimes such plants merely need to be shaken several times each day in order to scatter the pollen in the bag or cloth cage. Sometimes the best pollination can be secured by the aid of insect visitors, such as flies, bees, or some other species [2] introduced into the cage.

Frequently, however, there is difficulty in getting certain crosses to "take." Sometimes the pollen grain is unable to germinate on the stigma; sometimes it germinates but fails to grow down the style to the egg; sometimes it grows down the style, but the rate of growth is too slow to effect fertilization. Some ingenious devices have been used to overcome these difficulties. When the pollen grains refuse to start growth, they may be germinated in a very weak sugar solution, which is then daubed on the stigma. If the difficulty is due to slow rate of growth, the pollen grains may be placed on the stigma of a young, unopened flower so that they have the advantage of an early start on their journey. If the pollen tubes simply cannot grow down the style tissue, however, there seems to be no remedy, though the same pollen may function normally on the stigma of another closely related plant.

Some investigators have thought that the retardation of growth of pollen tubes was a result of some sort of inhibiting material present either in the style or the ovary of the flower. A Japanese scientist,

[2] See the article on Onion Improvement in this Yearbook for a description of this method.

Yasuda (*558*),[3] became interested in this problem and devised a unique experiment with petunias. In these flowers there occur some self-sterile races. Preliminary work indicated that sterility was due to a slow rate of growth of the pollen tubes. The same pollen applied to other races grew rapidly and effected fertilization. Yasuda conceived the idea of grafting styles from one race of petunias to another. The reader who is familiar with the parts of an average petunia will readily appreciate his difficulties. This very delicate operation was performed with a fairly high degree of success by gluing the grafted style, including its stigma, to the new ovary with a thin layer of gelatine. It was then held in place by being tied, with a thread taken from a spider's web, to a very fine wire support fastened rigidly beside the flower. Since Yasuda wished to determine the source of the material that inhibited the growth of the pollen tubes, he made reciprocal grafts.

Figure 7.—Controlled pollinations of snapdragons. Flowers are enclosed in a glassine bag, and each operation is recorded on attached tag. (From Hilgardia, University of California.)

After the grafts had "taken", pollen was applied to each stigma. On some stigmas the plant's own pollen was applied; on others, pollen from another race. In each instance ungrafted styles were used as checks, some self-pollinated and some crossed. The rate of growth of pollen tubes from the plant's own pollen was more rapid in its own styles when they were grafted on ovaries of another race. Yasuda thought this indicated that an inhibiting substance might originate in the ovary of the flower. Unfortunately, though the rate of pollen-tube growth was given, no statement was made as to whether seed was actually set in ovaries with grafted styles. In this work Yasuda was interested only in the possible presence of the inhibiting material that caused a slow rate of pollen-tube growth.

[3] Italic numbers in parentheses refer to Literature Cited See notice, p 977

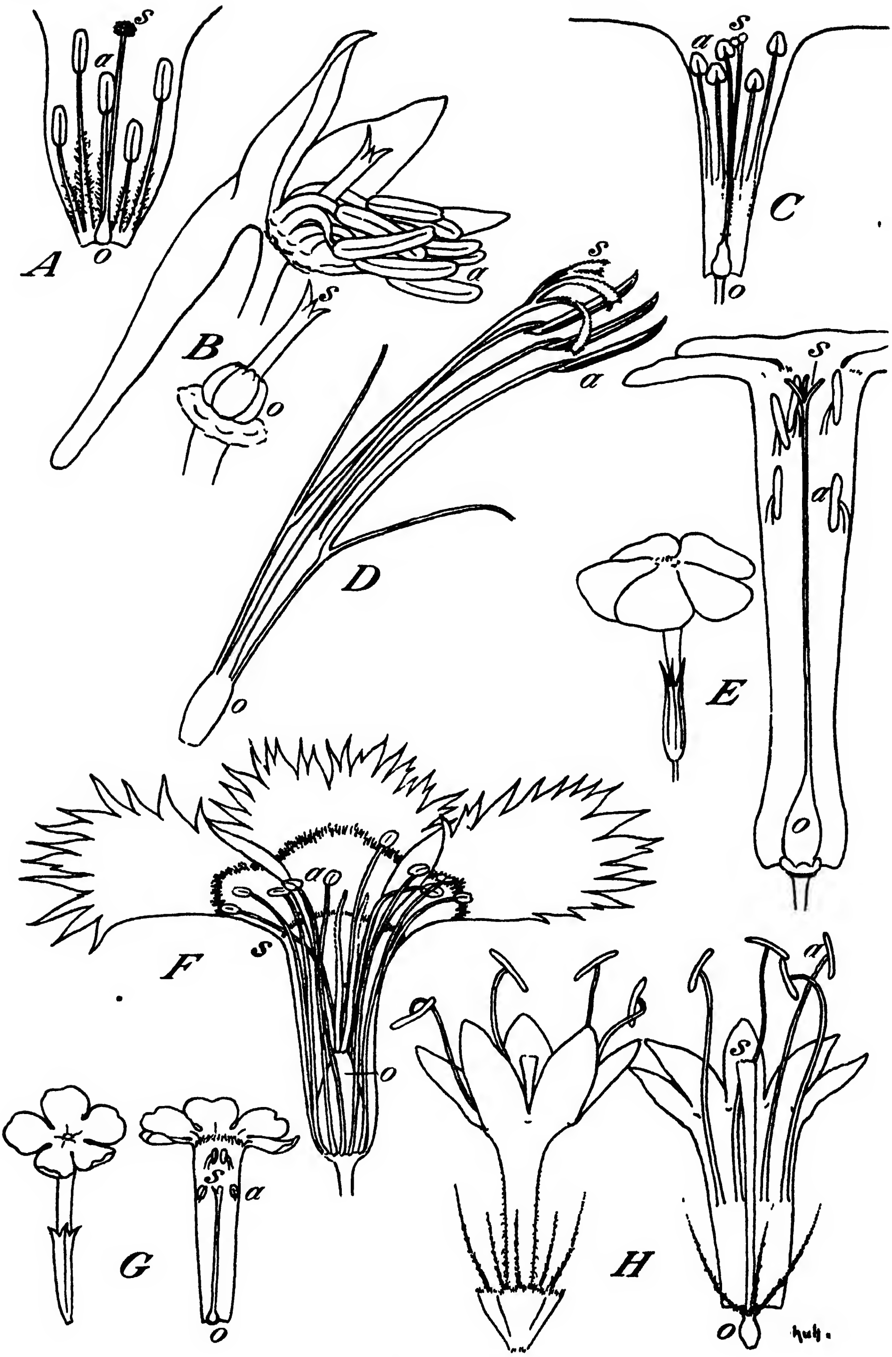

Figure 8.
(Legend on opposite page.)

This same condition of retarded growth rate of pollen tubes is also known in other plants. It has been shown in tobacco and a few others that a series of genes actually control pollen-tube growth, and it is assumed that such genes cause the formation of these inhibiting materials.

The unique method of Yasuda may lead to something valuable in flower breeding. In some cases of cross-pollination where the pollen will not grow in the maternal style it may be possible to secure hybrids by grafting a style from the pollen parent to the seed parent. This, of course, would not work if the inhibiting cause is a substance in the maternal ovary.

Successful cross-pollination depends to a great extent on having a thorough knowledge of the structure of the flower to be pollinated. In some instances it may be so constructed that considerable skill in manipulation is necessary to secure even a low percentage of successful crosses.

When a cross-pollination is to be made it is essential that every precaution be taken to safeguard the stigma from all other pollen. In general this requires the removal of the anthers before pollen is shed. In the case of many members of the composite family, such as marigolds, this is so difficult that another less certain but fairly efficient method is sometimes used. It is based on the structure of the composite floret, in which the style is surrounded by the anthers, which form a closed circle about it. As the style grows it pushes up through the column of anthers, collecting pollen as it goes. The rate of this growth is so rapid in some composite flowers that the stigma emerges from the anthers before the pollen has had time to germinate. If a fine stream of water of moderate force is used promptly, the pollen grains can frequently be washed from the stigma before they germinate.

The structure of some of the commoner flowers is shown in figures 8, 9, and 10. In each instance a longitudinal section is shown in order to bring out clearly the floral parts most important in pollination—the anther, the stigma, and the ovary.

Figure 8 shows some of the flowers in which controlled pollination is most easily effected.

The morning-glory (fig. 8, *A*) is an easy type of flower to emasculate. As shown in the drawing, the style is slightly longer than the stamens. Such a style is said to be exserted beyond the anthers. When a cross-pollination of morning-glories is to be performed, the anthers are removed at any time before they shed their pollen.

The petunia flower shown in figure 8, *C*, is very similar to the morning-glory. There are, however, other flower types in petunia that are more complex. In some of the extreme double types the stamens are greatly reduced or eliminated entirely. Such a flower can be used only as a maternal parent, and crosses are easily made since anthers are not present.

Figure 8.—**Structure of (*A*) morning-glory, (*B*) nasturtium, (*C*) petunia, (*D*) gladiolus, (*E*) phlox, (*F*) carnation, (*G*) verbena, and (*H*) scabiosa to show arrangement of the parts concerned in pollination. The anthers, stigma, and ovary are labeled *a*, *s*, and *o*, and in all instances each flower has been split open and drawn to show the relative position of these three parts. The technique for pollination of each is discussed in the text.**

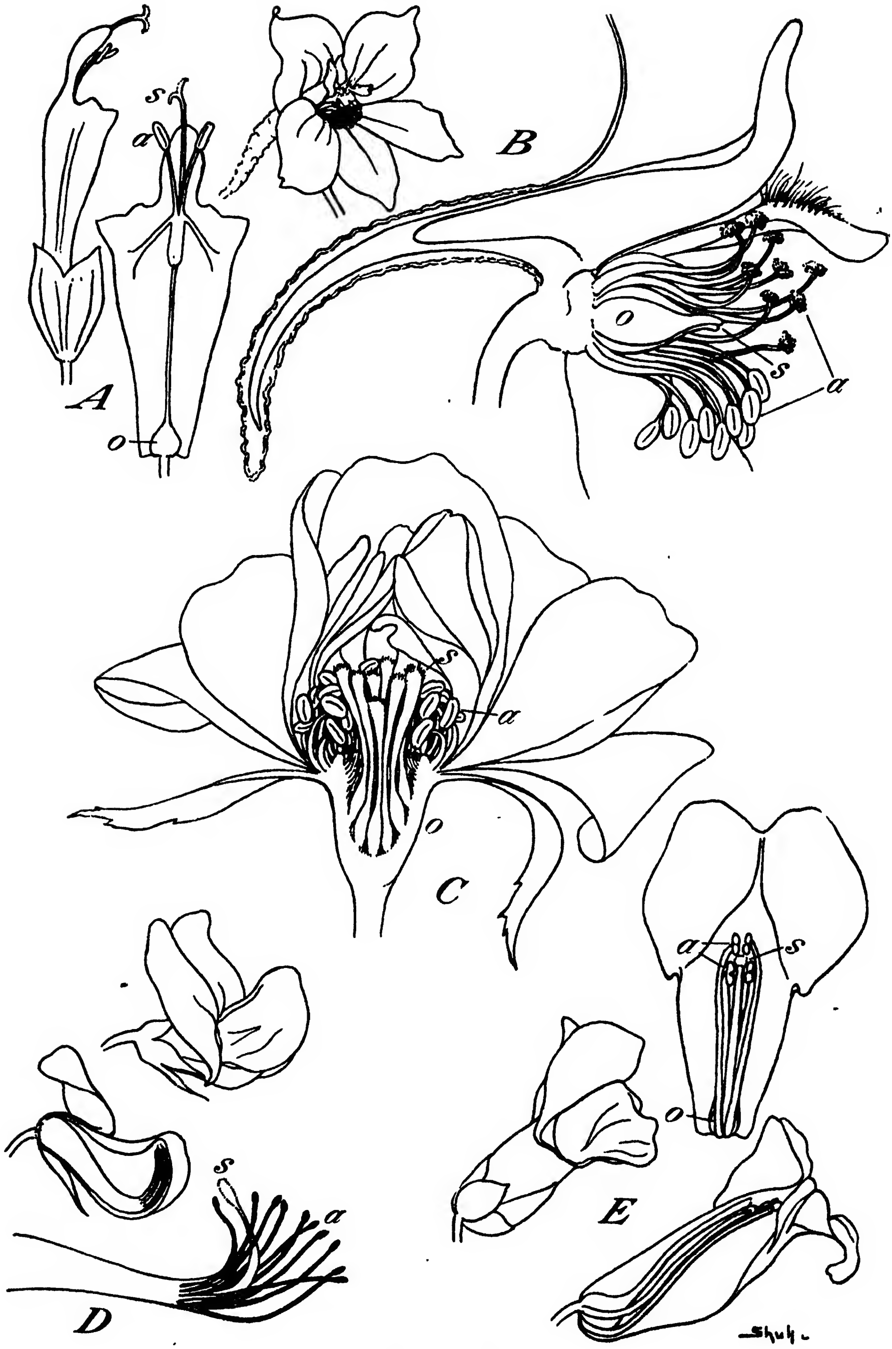

Figure 9.

(Legend on opposite page.)

In the nasturtium (fig. 8, *B*) the anthers form a tight cluster about the pistil. They are large and may be easily removed before they shed any pollen.

The gladiolus (fig. 8, *D*) has large anthers and a branching, plumelike stigma. Emasculation is very easily accomplished.

Phlox and verbena (fig. 8, *E* and *G*) are very similar in structure, and emasculation is practically identical for both. As can be seen from the illustration, the anthers are fastened to the inside of the tube formed by the petals and may be removed with the corolla, to which they are attached. This should be done just before the small bud opens, shortly after color has appeared in the folded petals. A slight pull at this time brings off the corolla tube with the anthers and leaves the stigma, which may be pollinated when it is receptive.

The carnations or pinks (fig. 8, *F*) also have a wide range of flower types. Only the single form is mentioned here. As can be seen from the figure, removal of the anthers is comparatively simple.

The scabiosa (fig. 8, *H*) is very similar to a composite flower. Here the so-called flower is actually a head of many small florets. In the figure a normal floret and one split open are shown. The anthers protrude so far beyond the stigma that their removal is easily accomplished.

The scarlet sage (fig. 9, *A*) has a rather unusual arrangement of its anthers. As shown in the illustration, they are held out from the flower wall by a bracelike arrangement. The stigma protrudes beyond them.

The larkspur (fig. 9, *B*) has a large number of anthers, which fit very closely about the stigmas of the compound ovary. The anthers may be removed with little injury to the flower, but caution must be exercised to get them all.

Roses vary from the single to the double form. The one shown (fig. 9, *C*) is a double hybrid tea. In emasculating, it is always advisable to clip away as much of the petals as possible. This gives ready access to the anthers, which can then be easily removed.

The sweet pea and the perennial pea are identical as far as emasculation technique is concerned. The sweet pea flower is one of the most difficult to emasculate without causing injury. The anthers, as shown in the perennial pea (fig. 9, *D*) form a closed column around the greater part of the ovary. They then branch out and closely surround the stigma. The removal of this column of anthers frequently injures the ovary, which is tender and brittle. It takes considerable practice to become skillful in the operation.

The snapdragon (fig. 9, *E*) is very easy to emasculate. The anthers do not shed pollen until the flower is fairly large. They may be removed readily without injury to the flower.

In figure 10 several members of the composite family are shown. While all have certain structures in common, there are also some differences that probably warrant a few words of explanation. In this large family of plants, the so-called "flower" is actually a group of

The technique for pollination of each is discussed in the text.

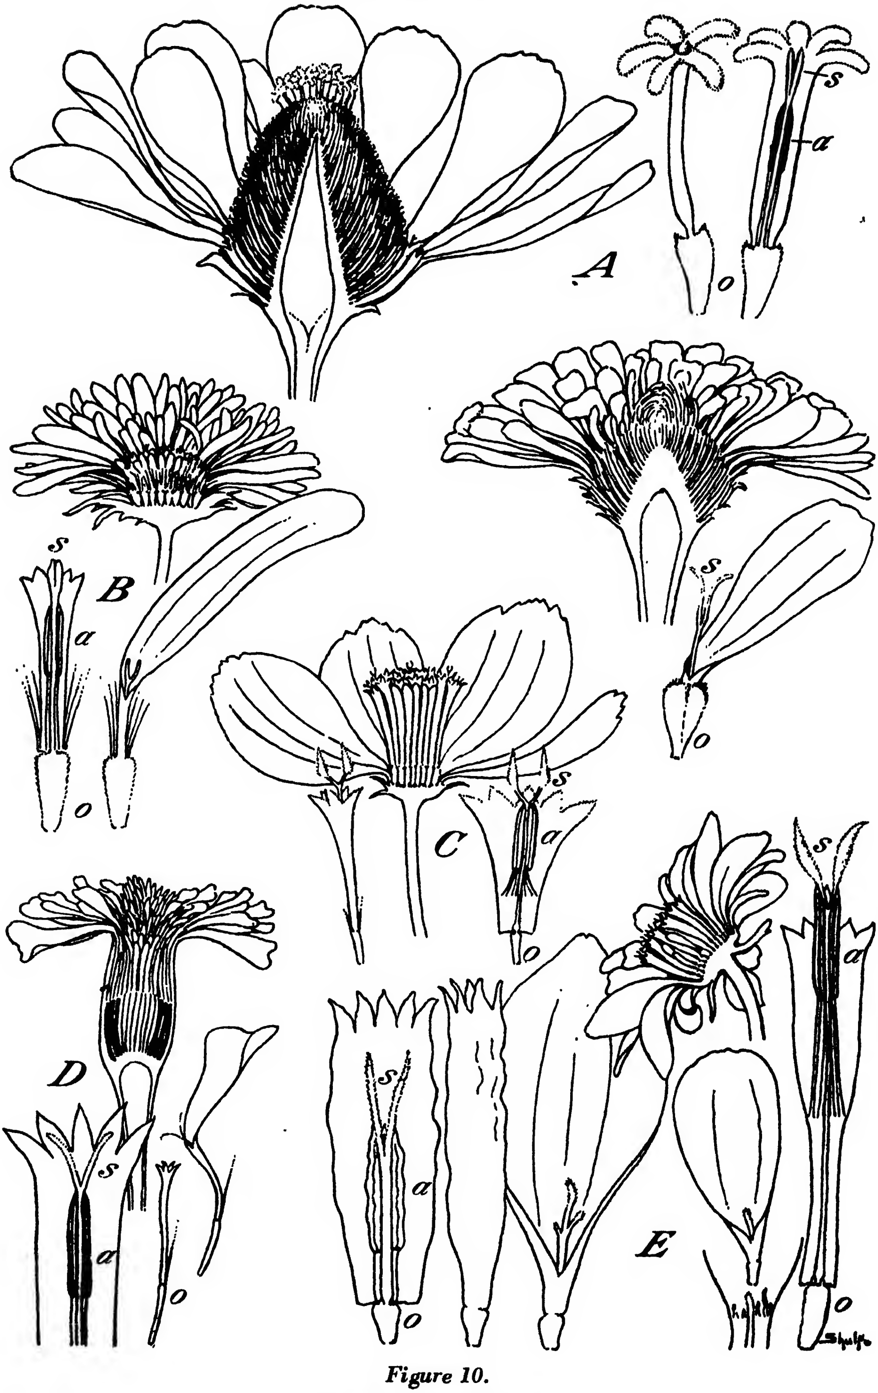

Figure 10.
(Legend on opposite page.)

many small flowers called florets, massed closely together in what is sometimes called a "head." These florets are of two distinct types. Some produce both pollen and ovules and are termed perfect flowers; others lack anthers for pollen production but have pistils for ovule production, and are called pistillate flowers. These small florets may also be classified as to the form of the corolla. In one type the corolla forms an inconspicuous tube surrounding anthers and style. These are found in the center of the head and are called disk florets. In the second type, called the ray floret, the corolla is modified into a conspicuous flat petallike structure, and extends far beyond other parts. The proportion between the two types varies considerably. The doubleness of any composite flower is determined by the number of ray florets. In extremely double flowers in this family, all the florets may be of the ray type.

The zinnia flower (fig. 10, *A*) occurs in at least four types. This information, as yet unpublished, was kindly furnished by C. F. Poole, of the Department. He is continuing his work on zinnias, which he started while a member of the staff of the College of Agriculture of the University of California.

The primitive or wild type is common in practically all races of zinnias. It is called "medicine hat" by seedsmen, and is illustrated at the top left of figure 10. The flower head has a single outer row of ray flowers, all of which are pistillate. The disk flowers are arranged in a somewhat pyramidal form and are all perfect. To the right of the medicine-hat type are shown a single perfect flower and one in which the corolla tube, which is the petal of the floret, has been split to show the anthers and style. Directly below this is shown a flower head of a second type, extremely double. Here all the florets are pistillate (female) and no pollen is found in the entire head. A single floret is shown below it in which the absence of anthers is conspicuous. Between these extremes are two intermediate types. One, more like the medicine hat, has several rows of pistillate florets and fewer perfect flowers. The second has a further reduction of perfect florets and more closely resembles the very double, purely pistillate flower head. Flower growers are interested chiefly in the more double types. These can set seed only if pollinated by some other type. A plant bearing only pistillate florets will certainly not set seed if it is grown under a cage or otherwise isolated from sources of pollen. This is probably the real explanation for some of the self-sterility in zinnias reported by some seedsmen when single plants were grown under cages. Sometimes more than one type of flower head is found on a plant. This condition has not been investigated.

From the above description it will be seen that cross-pollination in zinnias may be done without resorting to emasculation. If sterility factors are not present it is only necessary to make sure of the source of the pollen that reaches the stigmas of pistillate florets. In some

---

Figure 10.—Structure of (*A*) zinnia, (*B*) aster, (*C*) cosmos, (*D*) marigold, and (*E*) dahlia to show arrangement of the parts concerned in pollination. The anthers, stigma, and ovary are labeled *a*, *s*, and *o*, and in all instances each flower has been split open and drawn to show the relative position of these three parts. The technique for pollination of each is discussed in the text.

cases this may require the cutting away of perfect disk flowers, but in the purely pistillate double flowers no anthers are present and so no preliminary work is necessary.

As far as could be determined there is no report of any cross-breeding in the China-aster. It is likely that cross-pollinations have been made by amateurs and seedsmen, but no record of this has been available. A careful study of aster flower types (fig. 10, *B*) similar to that of the zinnia has apparently not been made. The aster flower head shown in the figure has both pistillate ray florets and perfect disk florets, and their proportion is a measure of the doubleness of the flower. If there is no complication from sterility, it should be fairly simple to control pollination. Small, curved, sharp scissors could be used to cut out all the perfect florets, and the remaining pistillate ones could then be pollinated as desired.

There is also a wide range of flower types in cosmos. The one illustrated (fig. 10, *C*) is a "single" type. All the florets are perfect, so that cross-pollination would here entail emasculation or removal of the anthers. Cross-pollination might also be done after using a stream of water to wash off all pollen after the two-parted, feathery stigmas have pushed their way through the anthers. If removal of the anthers is necessary, an excellent tool can be made by hammering flat the head of a pin, which is then bent and inserted in the end of a small wooden handle. By careful manipulation the corolla tube with anthers attached can be cut away. Unless considerable skill is attained, this operation will have a high mortality rate among the flowers on which it is used.

The marigold flower shown in figure 10, *D*, is very similar to the aster. There is, however, a wide range of flower types in marigold, as in nearly all other composites. In this flower there are several outer rows of pistillate florets, and those in the center disk are all perfect. The two types of florets are shown below the flower head with a perfect floret split open at the lower left to show anthers and stigma. Cross-pollination in this flower is essentially the same as in the aster.

In the dahlia (fig. 10, *E*) there is a range of flower types from the ordinary single to the complete double. In the single type the flower head is practically the same as the medicine-hat zinnia. In the outer row the florets are pistillate; the disk flowers are perfect. From this all gradations exist up to the fully double type, in which practically all the florets are pistillate. Since these pistillate florets do not produce pollen, few seeds are produced by the large double-flowered dahlias.

The flower shown here is an intermediate double type. To the left is a perfect disk flower as it looks when removed and split open to show style, stigma, and anthers. Self-sterility is the rule in garden dahlias. This makes crossing very simple, since emasculation is not necessary.

There are several precautions to follow in emasculating all flowers. The forceps or other tool used should be kept absolutely clean so that no pollen is carried from plant to plant. This can be done by holding it in alcohol for a minute or so before moving to the next flower. It is also necessary to keep the emasculated flower protected from any chance pollen. This is readily done by covering it with a bag until after the controlled cross-pollination has been made and fertilization has taken place.

The time to apply pollen is also sometimes a problem. In general, it should be done just as soon as the sticky fluid that develops on the

stigma makes it appear moist and shiny. This fluid holds the pollen grains and is nutritive material favorable to their germination.

Methods of Producing Superior Types of Flowers

The earliest and most commonly used method for breeding flowers is known as mass selection. It consists simply in saving for seed only the best plants of a variety. The procedure does not take into account the fact that better plants may be the result of either a better environment or a superior germ plasm. Since the seed from all the selected plants are mixed together before planting, it is difficult to evaluate any progress made. The method also does not differentiate between plants that are highly cross-pollinated and those normally self-pollinated; it is concerned only with the seed-bearing (maternal) parent. Most of our present flower varieties probably were developed in this way.

Mass Selection and Line Breeding

Mass selection does result in a gradual improvement even if some of the selected plants transmit poor germ plasm to the next generation, since the good ones have a better chance to be selected and in time predominate, gradually building up the variety. In this way desirable results are often secured, but frequently many years are required before the effects are noticeable. It is not true, however, even though commonly believed, that the selection process in itself is responsible for the gradual changing or improvement of a flower. There is little reason, in the light of our present information on plant breeding, to continue using this method. But even today it is the general practice among many flower breeders.

Following mass selection came so-called line-breeding. Here the breeder selected single plants and grew the seedlings from each selection separately. In this way the descendants of an individual plant could be studied, and the method was soon recognized as a considerable improvement over the earlier practice. It was possible to determine more readily whether an observed variation was hereditary (in the germ plasm) or simply an environmental modification. It also disclosed the status of a given characteristic in the heredity of a plant. If all the seedlings possessed the characteristic, it might be assumed that the plant was "pure" or homozygous for that characteristic and that it would be passed on to all the descendants; if some seedlings had it and some did not, the plant was heterozygous or mixed in its inheritance.

Unfortunately much of the single-plant-selection work of both amateur and professional flower breeders is done with open-pollinated plants—that is, no provision is made to protect from cross-pollination with other nearby plants. Of course, if a flower is normally self-pollinated, it may not be necessary to have this protection, but there are not many flowering plants that are entirely self-pollinated. The outstanding one supposed to be self-pollinated is the sweet pea. Here the stigma, completely surrounded by a group of anthers, is enclosed in that portion of the flower called the keel (fig. 9, *D*). When the flower matures the pollen is shed and falls on the stigma, which normally does not protrude from the petals forming the keel. In this manner the flower is supposedly protected from all pollen except its own.

Yet conditions in sweet-pea seed fields make this doubtful. If the sweet pea is entirely self-pollinated, it should be a simple matter to keep varieties pure (homozygous), since they could only acquire new genes by way of mutations. While the mutation rate in sweet peas has not been studied, the very large number of offtype plants (rogues) in sweet-pea seed fields certainly cannot be explained on this basis. In some instances these rogues are simply the result of accidental seed mixing, but this is not likely to occur in the case of the more careful growers, who keep their stock seeds separate. Very frequently, also, sweet-pea breeders encounter considerable difficulty in making a strain pure. An examination of several such cases showed that many of the flowers were not fully protected from cross-pollination, as had been assumed. The keel was not fully developed and was too short for the pistil and anthers. As a result the stigma very frequently protruded, even beyond the anthers, so that cross-pollination could easily have occurred.

There are some flowers in which the single-plant-selection method, depending on self-pollination, cannot be used. This may be due to self-sterility, as in some lily species, especially most forms of *Lilium longiflorum* Thunb., and in some iris, petunia, and *Nicotiana* species. Sometimes reasons other than self-sterility are responsible for failure of flowers to set seed when single plants are isolated. The pollen may be discharged before the stigma is receptive, or the reverse condition may occur. The structure of the flower may be such that self-pollination is impossible without the aid of some agency such as insects. Sometimes, as in species of *Lychnis*, the plants are either male (staminate) or female (pistillate). Such types obviously cannot be self-pollinated.

Single-plant selection or line breeding has many advantages over mass selections. When accompanied with self-pollination it quickly gives strains very uniform for habit of growth and other characters. All undesirable qualities are disclosed rapidly and may be eliminated within a comparatively few generations. Unfortunately, continued self-pollination frequently results in a loss of vigor. As a rule this weakened condition may be corrected by making cross-pollinations between inbred strains. This situation has received considerable attention from corn breeders and is discussed at some length in the 1936 Yearbook of Agriculture.

Hybridization

A third method of flower breeding is the making of crosses between plants to secure new individuals that combine desirable qualities from each parent. While it is true that many of the early workers did cross-pollinate flowers, few realized the necessity of carrying their work beyond the first hybrid generation, called the F_1. In other words, if none of the hybrids was desirable, all were discarded.

The rediscovery of Mendel's work in 1900 demonstrated at once the importance of continuing into subsequent generations. Mendel showed that when two plants are crossed, each contributes to the heredity of the resulting hybrid. While ordinarily these contributions are exactly equal in quantity, they may vary qualitatively. When the two bits of heredity-carrying protoplasm, male and female,

are united in one individual, the hybrid, new combinations of characters become possible in the descendants of this hybrid. These new combinations may not be seen in the hybrid, but they will appear in some plants of the population descending from it.

Unfortunately, Mendel's basic laws are still unknown to many flower breeders. Each year many thousands of hybrid seedlings are undoubtedly grown and discarded as being inferior. If many of these had been carried into the next generation, it is likely that some worthwhile plants would have appeared. It is this second generation, commonly called the F_2, in which recombinations of parental characters are found.

In some instances the hybrid between two flowers is self-sterile. This commonly occurs when the two parents are from different species. Although the hybrid sets no seed with its own pollen, some seed may often be secured by crossing it with one or both of its parents. This is commonly called backcrossing. A backcross may be made in both directions; that is, the hybrid may be crossed to the maternal or the paternal parent. Sometimes a backcross will produce fertile seed in only one way, and as a rule it is more often successful when the hybrid is used as the maternal parent.

The method of improvement by hybridization will undoubtedly play an increasing role in flower breeding. It is the only way by which new combinations of desirable germ plasm can be effected. Very frequently a variety may be desirable in many ways, yet have some one characteristic that causes it to be unpopular. In many cases this character can be replaced by a desirable one from some other variety. A cross between them will provide an opportunity to combine the desirable traits of both parents in the F_2 or later generations. Some of the characters of one parent may be recessives, in which case they will not be apparent in the hybrid, but they will appear in some members of the next generation. Here, too, will be found the recombinations, that is, the new plants produced by combinations of characters from each parent. But since the genes, or carriers of heredity, are in the chromosomes, and all the genes in the same chromosome tend to be inherited together (this is the phenomenon known as linkage), we may find undesirable qualities associated with the ones we want. When this occurs it is necessary to grow populations large enough to get a reassortment of the genes or characters, which is brought about by what is called crossing-over, or the occasional exchange of material between chromosomes when the pollen grains and egg cells are being formed.

The backcross procedure mentioned above is probably one of the most valuable methods the flower breeder can use, and it should be more widely employed by amateurs and professionals. When two plants are crossed, usually the breeder has in mind some ideal type that he hopes to fashion by combining many desirable characters from one parent with fewer characters of the other. When this is true, it is best as a rule to backcross the hybrid to the more desirable parent. The resulting offspring may be again backcrossed one or more times and then self-pollinated. In a few generations the chances are that the desired inheritance of the best parent will be piled up and by selection the desirable characters of the other parent can be

retained so that plants closely approximating the ideal will be secured. The chief merit of this method is in recovering the quantitative characters of one parent from comparatively small populations in a relatively short time.

Mutations

In addition to the breeding methods already discussed, many varieties of flowers originate as mutations or sports. Mutations may arise in the pollen grains or in the egg cells, or they may occur in cells of the stems, leaves, flowers, or other portions of the plant. Many of our varieties of roses, carnations, and chrysanthemums have appeared in this way. Sometimes a side branch bears a flower differing in color or size from the remainder of the parent plant. When the plant can be propagated vegetatively, it is usually a simple matter to introduce the changed form or mutant as a new variety. For some as yet unknown reason, certain varieties of some flowers are especially noted for the number of bud sports they have produced. This is particularly true of the Ophelia rose. Many of the present-day varieties of greenhouse carnations are also mutations of this sort.

When a mutation occurs in a sex cell it does not appear until the next generation. If it is a recessive and the parent plant normally is cross-pollinated it may not show up for several generations. It is entirely probable that some of the new characters that appear in a variety of flowers grown from seed arise as sex-cell mutations. The vast majority of the so-called "breaks", however, are not mutations but simply recombinations of already existing characters following cross-fertilization (fig. 11).

Since the chromosomes are the carriers of the hereditary units, any changes in them should have an effect on the plant. Such a change may effect a rearrangement of the genes in a single chromosome or even the loss of some of them. Sometimes a whole chromosome is lost or an extra one added, or each chromosome is reduplicated so that the entire number is doubled. Occasionally one may be broken and the fragment retained or lost. The plant that results from any of these changes is likely to be different from one with normal chromosomes.

The doubling of the chromosome number may occur in several ways. The sex cells sometimes form with all the chromosomes present rather than half the number, which is normal for sex cells. In other instances an ordinary cell in a stem or root may double up its chromosome number, and then when this doubled cell divides all its descendants will have the doubled number.

A well-known example of the doubling of the chromosome number in stem cells is the case of *Primula kewensis* W. Wats. (Kew primrose), as reported by Digby (*111*) in 1912, and by Newton and Pellew (*390*) in 1929 (fig. 12). It is a desirable primula, now quite commonly grown by many florists. It originated in this manner: A cross was made between the species *P. floribunda* Wall. (buttercup primrose) and *P. verticillata* Forsk. (Arabian primrose). The hybrid was completely sterile for many years, when there suddenly appeared on one plant a branch that bore large fertile flowers. The chromosome number of both *floribunda* and *verticillata* is 18, and that of the large-flowered branch was 36. Undoubtedly this branch arose from a cell that had doubled its chromosome number.

Another interesting instance of the origin of a large-flowered plant as a result of chromosome doubling was reported in *Campanula persicifolia* L. (peachleaf bellflower) by Gairdner in 1926 The normal species has 16 chromosomes, and from it came a seedling with 32 chromosomes. The doubling of the chromosome number resulted in a considerable increase in size, and the new variety was named Telham Beauty.

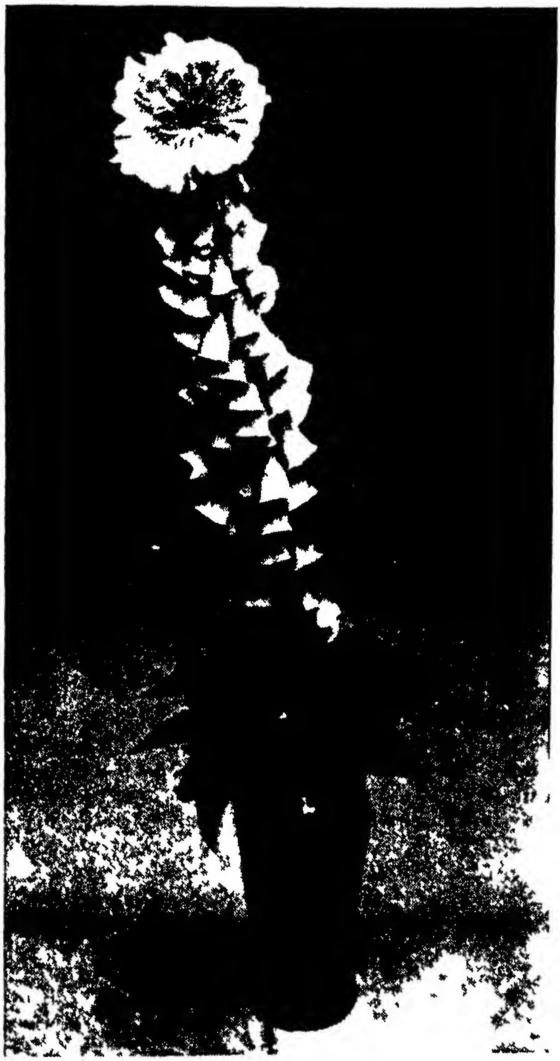

Figure 11.—A horticultural form of foxglove in which the top flowers are united to form a round, hollyhocklike flower. This photograph was sent to the senior author as representing a possible new mutation supposedly arising spontaneously in a home flower garden. It is a form that is not widely distributed but has been known for a long time. It is recessive, so that when crossed with "normal" all the hybrids are normal and the next generation is composed of 3 normal to 1 abnormal.

Quite recently, Randolph (*423*), of the Bureau of Plant Industry, in cooperation with Cornell University, has developed a method by which chromosome numbers of corn may be doubled. While no report has as yet appeared concerning its use for doubling chromosome numbers of flowers, it seems likely to play an important role in future flower breeding The results are secured by the application of heat to the flower just after fertilization has taken place The time between application of pollen to a stigma and the actual union of the two sex cells is very variable It may require only a few hours or it may take several days. The new cell formed by the union of the two is the first cell of the young embryo. This one-celled embryo usually does not divide for some time, and it is during this

period just at or before division that heat is applied. Since the temperature necessary is very likely to be different with different plants, it can be seen that a considerable amount of preliminary investigation will be needed before this method can be used with certainty.

There are on record several cases of spontaneous doubling of the chromosomes in the one-celled embryo. The one of interest here, because the parents, commonly called flowering tobaccos, are frequently found in flower gardens, is that of *Nicotiana digluta* Clausen and Goodspeed. Clausen and Goodspeed (*76*) reported a plant with 72 chromosomes coming from a cross between *N. glutinosa* L. with 24 chromosomes and *N. tabacum* var. *purpurea* with 48 chromosomes. All the hybrids should have had 36 chromosomes, but this one plant had 72. They believed that this particular F_1 plant had doubled its chromosome number shortly after fertilization. There is also evidence of a similar occurrence in tomatoes. In general the doubling of the chromosome number is usually accompanied by an increase in the size of the plant and flower.

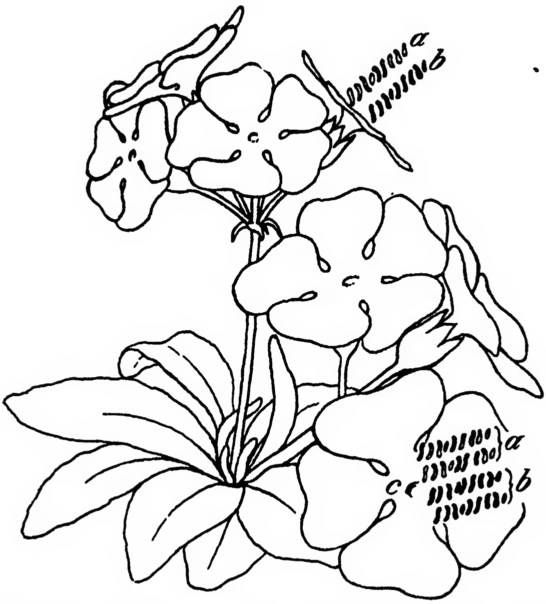

Figure 12.—Diagrammatic drawing showing the effect of the doubling of the chromosome number in a species hybrid. The plant is a cross between (*a*) the Arabian primrose (*Primula verticillata*) and (*b*) the buttercup primrose (*P. floribunda*). It has 18 chromosomes, like each of its parents (the chromosomes are represented near one of the upper flowers). Suddenly it produced the lower branch with larger flowers, and this was found to have 36 chromosomes (represented on one of the petals). Whereas the hybrid itself was sterile and set no seed, the new branch with 36 chromosomes was fertile and set seed. This fertile side branch was the progenitor (*c*) of the well-known Kew primrose (*P. kewensis*).

Chromosomes may also be modified in structure. The modification may result from the breaking of a chromosome into several parts, or from a slight change in one of the genes that it carries. There are many recorded instances of such changes occurring in nature. Frequently they cause freakish and abnormal plants, but they are also responsible for many worth-while new variations. Until recently these changes were purely chance occurrences over which the breeder had no control. Recently, however, certain external agents such as X-rays, radium, ultraviolet light, heat, and some chemicals have been shown to be effective in producing them.

Artificial Methods of Changing Germ Plasm

The use of X-rays, radium, and ultraviolet light for the production of new flower types will probably not become general. Considerable danger is involved, and the work should be done only by thoroughly trained technicians. The actual manner in which these agencies cause the chromosome to change is not known, but the very short rays seem to incite rearrangement of genes and even chromosome breaking.

Some of the earlier work showing the effect of X-rays and radium on flowers was done by T H. Goodspeed (fig. 13) and his associates at the University of California. The plants were several species of ornamental tobaccos. Both seeds and sex cells were exposed to the action of radium and X-rays. In the case of ungerminated seeds there followed a very noticeable retarding of germination, but at maturity no general effect of X-radiation of the seeds could be seen. If, however, the seed was germinating or if tiny seedlings were X-rayed, many changes in growth and form were noticed.

Figure 13.—T. H Goodspeed, professor of botany, and director, Botanical Garden, University of California, Berkeley. One of the pioneers in the use of X-rays and radium to induce mutation in plants.

In another series of experiments by Goodspeed and Avery (*145*), sex cells were exposed to X-rays. This was done by X-raying buds in which the egg mother cells were just beginning to go through the series of divisions that give rise to the egg cells or female gametes. After this treatment these buds were pollinated with pollen from untreated flowers. Now if a change occurred in an egg cell and this egg cell was pollinated by normal pollen, the new condition would show up at once if it was a dominant. If the new character was recessive, however, it would not appear until the next generation.

Following this treatment many plants were secured that differed markedly from their sister untreated plants. One of these variant plants was selected for further study and was self-pollinated. After six generations, that is, six cycles "from seed to seed", seven pure-breeding new types and seven not yet fixed have been secured. Some of these new types differ so markedly from their un-X-rayed sister plant that they probably are entirely new varieties, and even in a few instances new species. They differ from one another and from the untreated plant in habit of growth, in form of leaf, flower, and capsule, and even in the color of leaf and flower.

This series of experiments is remarkable in several respects. It is the first to demonstrate the possibility of actually securing fertile new

types of flowers by X-raying sex cells. All 14 types came from a single X-rayed egg cell, which was pollinated by an untreated pollen grain.

Recently there has appeared another report of effects of X-raying a flowering plant. In the laboratory of the General Electric Co. at Schenectady, N. Y., Moore (*374*) exposed Regal lily bulbs to X-rays. Among those so treated, two upon blooming showed an unusual behavior of the anthers. The flowers differed only slightly from the normal Regal, but the anthers did not open and shed their pollen. Since the pollen is considered unsightly when scattered on the petals, this nonshedding habit is considered by the originator as valuable. These plants are easily propagated by divisions of the old bulb so that they can be multiplied without recourse to seed and also with the certainty they will all be identical, unless there is a reversion to the normal.

Another series of interesting experiments with X-rays was conducted by Morgan (*377*), who exposed seeds, flower buds, and corms of freesias to various dosages. Very little effect was noticed on seed and flowers except when exposures were strong and for rather long periods. The corms, however, showed decided effects from the rays. The untreated corms produced single plants, while as many as five "shoots" were produced by a single X-rayed one. The treated corms also started to germinate immediately after planting, made more rapid progress, and showed curling and twisting of leaves and stems; and the flowers were split and deformed. In general, the effect of X-ray treatment in low dosage seemed to be an acceleration in the rate of growth and the stimulation into growth of structures that otherwise would have remained latent. With increase in intensity of the dosage, the acceleration was lost and the rate of growth was even retarded. The heaviest dosages killed the corms.

In another similar series of experiments, tulip bulbs were exposed to X-rays by Van Heijningen and his associates (*197*) at the Wageningen station in the Netherlands. In many instances the results parallel those with the freesia corms. After moderately strong exposures, the number of small increase tulip bulbs was slightly more than in untreated bulbs. The flowers produced by the treated bulbs in some cases had irregular incisions on the petals, quite similar to those in the so-called Parrot varieties.

Not much in the way of practical results has been accomplished as yet by using artificial physical methods to induce changes in the germ plasm. This is not surprising, however, when it is remembered that although earlier sporadic attempts had been made, less than 10 years have passed since the present type of research was started. Much of the recent and current work of this type with flowers and other plants is still in the experimental stage. Enough has been done to indicate that plants, and even parts of the same plant, differ in response to the same dosages of rays. This means that much preliminary work is necessary merely to discover what dosages to use. There has also been too great a tendency for some to rush into the work while lacking a proper background in genetics and plant breeding. Instances are known in which seeds or pollen have been X-rayed, and when nothing unusual appeared in the resulting plants the entire

lot was discarded. If any recessive changes in the germ plasm were effected, they might not appear until later generations. In this connection it is recalled that Goodspeed continued his work into many succeeding generations and located numerous definite new types. In much of the work also, the number of treated individuals is very small. If the frequency rate of valuable changes is but 2 or 3 in 1,000, there will be little chance of securing them when only 10 to 20 seeds or plants are treated.

WHAT THE STUDY OF CELLS CONTRIBUTES TO FLOWER BREEDING

THE trained breeder likes to know the number of chromosomes in the plant with which he is working. For one thing, it determines the number of individual plants he will have to grow to get a desired recombination of the characters in which he is interested. Suppose, to take a purely imaginary case, that a certain plant has oblong red petals. The breeder wants to get a hybrid with the red color, but does not want the oblong shape. Now if this plant has four chromosomes in its sex cells, the chances are one in four that these two characters are linked—that is, they are in the same chromosome and will usually be passed on together in inheritance. But if there are eight chromosomes, the chances are only one in eight that they will be linked. In the latter case, he has twice as great a chance of getting one character without the other. The smaller the number of chromosomes, the greater the chance of linkage among any two or more characters and the larger the number of individuals that will have to be raised in an attempt to break up the linkage by crossing-over.

Another point of interest to the breeder is the important part that chromosome numbers appear to play in the probability of securing fertile crosses between two species. When both have the same number, the chances for success are much greater than when they differ. There are, however, many instances of hybrids between species with different numbers of chromosomes. As a rule such crosses are more likely to be successful when the one with the greater number of chromosomes is used as the maternal parent. There are, however, a few instances where crosses have been successful even when the species with fewer chromosomes was the maternal parent.

In addition to the question of linkage, the chromosome number may throw light on other questions. For instance, the lilies commonly have 12 chromosomes in their sex cells, which means that they have twice 12 or 24 in their body cells (12 pairs). Now for years the so-called Tiger lily (*Lilium tigrinum* Ker) was noted for its persistent self-sterility. Recently it has been shown to have 36 chromosomes in its body cells instead of 24—3 of each kind instead of 2 of each kind.[4] This is an abnormal condition, but it occurs fairly commonly in plants, and it often accompanies or causes sterility. There are also plants with four times the basic or sex-cell number of chromosomes, or five times, or six times, and even some plants that retain the basic or single number in the body cells instead of doubling this number, which is the normal method. In some species of plants, different

[4] A fertile *tigrinum* has been reported rather recently. According to Stout it varies somewhat from the older common form and apparently has 24 chromosomes rather than 36. It is therefore a diploid.

Figure 14 (legend on opposite page)

varieties run a whole series of these numbers. Thus in the lilies there might be one variety with 12 chromosomes in the body cells (haploids); another with 24 chromosomes (diploids) as shown in figure 14; another with 36 (triploids); another with 48 (tetraploids); another with 60 (pentaploids); another with 72 (hexaploids). Hereafter, these names will be used to indicate the number of times the basic number is multiplied in the body cells of the plant.

Variations in Chromosome Numbers

The question now arises as to how the knowledge that the Tiger lily is a triploid can possibly aid flower breeding. To answer that, it is necessary to give some preliminary discussion. First, it will be remembered that normally the sex cells of a plant always contain half the number of chromosomes in the body cells. This reduction in the number of chromosomes is one of the things that happens when a cell gets ready for reproduction. Now there are many known triploids in plants, and without exception they are all highly self-sterile, but some will set seed when pollinated by a diploid. It is probable that these triploids arise in two ways.

(1) A tetraploid type may be pollinated by a diploid. For instance, in the China-aster the basic or haploid chromosome number is 9, so that a diploid would have 18 chromosomes and a tetraploid 36 in its body cells. When the reproductive cells are formed, these numbers are cut in half; the sex cell of the diploid has 9 chromosomes and that of the tetraploid 18. Now the two sex cells join. Nine chromosomes are added to 18 chromosomes, and the result is 27 chromosomes, or a triploid, since 27 is three times the basic number.

(2) The male or the female nucleus of a normal diploid cell may fail to reduce its chromosome number in preparing for reproduction. In this instance it would keep 18 chromosomes instead of reducing the number to 9. When it united with a normal sex cell having 9 chromosomes the total would be 18 plus 9, or 27—a triploid.

Figure 14.—Chromosomes and formation of pollen grains in the Easter lily as seen under the microscope (× 350). *A*, The cell that will divide twice to form four pollen grains. The chromosomes are all long fine threads and form a tangled knot. *B*, After the first division is well started; the knot has unraveled and the chromosomes are pairing. Since the lily has 24 chromosomes, there should be 12 pairs. *C*, The division has progressed to where 12 pairs of chromosomes can be seen very clearly. *D*, A little later stage of division, in which the chromosomes have become shorter and thicker. The 12 pairs are all clear with the exception of no. 5, which lies under no. 6. *E*, A side view of the 12 pairs just as they are about to separate. *F*, Here 12 chromosomes have moved to each of two sides of the cell and the first division is almost completed. *G*, The 12 chromosomes in each group are now organizing new cells and getting ready to divide again. *H*, There are now 12 chromosomes in each dark-stained nucleus, and each nucleus will again divide to form 4, which finally become pollen grains, each with 12 chromosomes. *I*, Occasionally in the Easter lily something happens that causes the chromosomes to break into many small pieces. Such results can be accomplished by use of X-rays, radium, and possibly heat treatment just before the cells start to divide. *J*, In this cell 11 of the 12 chromosome pairs behaved normally, but two chromosomes probably did not pair. They are the ones at top and bottom. *K*, A giant (tetraploid) cell with 48 chromosomes instead of 24. Such cells are not known to have given rise to any tetraploid lily plant.

Tetraploid lilies are not known to occur, and it is therefore assumed that the triploid form must have arisen in the latter fashion—though there may have been a tetraploid parent that has not been discovered or that has become extinct.

If a triploid is not valuable in itself, there is usually little reason for using it in a breeding program. As a rule, when it is crossed with a diploid, the resulting hybrids are inferior, usually being dwarf, self-sterile forms. If their chromosomes are examined they are found to vary in number from plant to plant. Thus a few successful crosses between the Tiger lily and other lily species have so far given only small deformed seedlings. It has already been noted that the Tiger lily has 36 chromosomes, the other species 24. While no evidence is available as to the chromosome numbers in the hybrids, it is very probable that some had 24, some 25, 26, 27, etc.

As more and more is accomplished in chromosome studies of flowers, it is likely that we shall find other instances similar to the Tiger lily. If a valuable triploid flowering plant appears and can be propagated by cuttings, it is not essential that it be fertile and bear seed. For instance, a valuable triploid carnation, chrysanthemum, rose, narcissus, or geranium could easily be increased by division. With suitable developments in technique it might be possible to create other triploid forms as fine as the Tiger lily.

Other Chromosome Peculiarities

Sometimes a variety persists in producing year after year a number of peculiar variant forms. Even though it is carefully self-pollinated the variant forms may reappear with great regularity. Such a plant cannot be made to breed true, and sometimes the situation is the result of the structure and behavior of its chromosomes. Keeping in mind that the chromosomes carry the hereditary genes it is not strange that these peculiarities of inheritance can be traced to abnormalities in chromosomes.[5] Such plants may show a peculiar behavior of their chromosomes when sex cells are formed, as has been conclusively demonstrated by cytologists working with the evening-primrose.

One of these evening-primroses, known as Lamarck's, produces several variant forms year after year. At first plant breeders thought these were distinct changes in genes in the chromosomes. They were called mutants and the change in the gene was thought to have happened when the sex cells were formed or before. Careful cytological study of chromosomes in the sex cells demonstrated that the evening-primrose chromosomes act very irregularly while pollen grains and egg cells are being formed. These irregularities result in some few sex cells receiving an unusual combination of chromosomes. Since chromosomes are the carriers of hereditary characteristics, such peculiar sex cells naturally give rise to unusual and unexpected seedlings. Unless the sex cells had been examined under the microscope, we would have continued believing that the evening-primrose produced a very large number of mutations. This might have led us into other errors by encouraging the idea that mutations are relatively common. In fact this belief does exist among many amateur and

[5] This statement has some exceptions, chiefly a few instances of cytoplasmic inheritance, dependent on the cell material outside the nucleus.

professional flower breeders. It is expressed in the claim of the sudden appearance of what are commonly called "breaks", which follow the crossing of two varieties. Thus we often see it stated in a popular article that some new flower originated as a break from the hybrid made by crossing two older varieties. It is unquestionable that mutations do occur now and then, but they are comparatively rare. The chances are preponderantly in favor of the breaks actually being recombinations of characters that already existed in the two parents.

A situation that appeared to be somewhat similar to the evening-primrose problem was called to the attention of the senior author of this paper several years ago in California. The late J. H. Franklin, of the Waller-Franklin Seed Co., told of a peculiar breeding behavior in annual larkspur. He had been working for years with a pink-flowered form called Exquisite Pink. The shade of color and the habit of the plant were very desirable, and it was popular with florists. Unfortunately he had not been able to get a pure-breeding strain. Year after year his best selections produced the same variant forms. These undesirable types included a white-flowered form, a rose, a blue, a rose with blue flecks on the petals, a white with blue flecks, and a purplish blue. He sent some seed to the California Agricultural Experiment Station at Davis, where it was grown, and the plants were studied. For 2 years, Exquisite Pink plants were self-pollinated and each time they produced the same variant types. The next year microscopic slides were made of the developing pollen grains, and some of the same general types of irregularities were found that occur in the evening-primrose. Apparently some structural peculiarities in the chromosomes were causing the difficulties. This meant that the Exquisite Pink larkspur could never breed true. When this was explained to Dr. Franklin, the strain was discarded. New selections were started with other pink-flowered forms, and at present there are several good pink larkspurs available.

One of the most popular flowers for both breeding and cytological research is the stock, *Matthiola incana* (L.) R. Br. This plant is unique in that it has two distinctive types, the single- and double-flowered forms, the latter containing no anthers or pistils and making no seed whatever. Reproduction, then, is from seed produced by the single flowered plants. The growers of stocks, both florists and amateurs, are interested almost exclusively in the double forms. For some time plant geneticists have known that there are three types of single plants. One when self-pollinated produces no doubles, the second produces about 25 percent of doubles, and the third from 54 to 56 percent. Obviously the third type is the one to use for seed. It is called ever-sporting because of the high percentage of doubles it produces.

The problem of explaining the peculiar behavior of the ever-sporting stock attracted many workers. One quite logical explanation assumes some condition that kills half the pollen grains and approximately 6 to 8 percent of the egg cells. This might be caused by what is called a lethal gene located in the same chromosome as the gene for singleness. The lethal gene would have to be recessive since if it was dominant all plants with this gene would die. Being recessive a plant can carry the gene and its normal allelomorph and be able to live. Let us use the symbol *a* for the lethal gene and the symbol *A* to represent the normal

allelomorphic gene that is dominant to *a*; then all plants of the *aa* type would die, but *Aa* plants would live.

Now singleness in these stocks is dominant to doubleness. Single-flowered plants may be pure (homozygous) for singleness, or they may be hybrid (heterozygous) for this character. A pure (homozygous) single gives only singles when it is self-pollinated. A heterozygous plant gives 3 singles to 1 double. According to the above theory, the third type, the ever-sporting race, should be hybrid (heterozygous) for singleness and for the linked lethal, which would result in 54 to 56 percent of doubles instead of only 25 percent.

In 1931 Philp and Huskins (*408*) published a cytological study on ever-sporting stocks that apparently explained the situation.[6] In order to understand their work it is necessary to recall that only one of each pair of chromosomes occurs in a sex cell. The pair of chromosomes of which one member carries the gene for doubleness and the other member the gene for singleness, therefore, never get into the same sex cell.[7] Philp and Huskins are able to show that ever-sporting single plants had one pair of chromosomes that differed from one another in appearance, one lacking a small knob on its end. This is very significant when it is remembered that the two chromosomes of a pair normally have an identical shape. From their work, they stated that the pollen grains getting the chromosome lacking the knob did not function. In other words, the absence of the small knob acted as a lethal to the pollen grains in which it occurred.

If only the "double" pollen grains can function, while both "double" and "single" eggs are good, it is easy to see how such plants produce about half doubles and half singles. The fact that the ratio is not exactly 50–50 is explained by assuming that a few egg cells getting the chromosome lacking the knob do not function. This explanation was verified to some extent by a study of pollen germinations from pure and ever-sporting singles, which showed that germination of ever-sporting pollen was only about half that of pollen from pure singles. Evidently about half the pollen grains of an ever-sporting single were being killed in some manner.

The entire situation is much clearer if figure 15 is studied. At the top are shown the seven pairs of chromosomes of a single-flowered ever-sporting stock plant. The members of each chromosome pair look exactly alike with the exception of the first. One lacks the little knob on one end, which cytologists call a satellite. A large *S* is printed before the one that lacks the satellite. This is to represent the gene for singleness, which it carries. Its mate (homologue) has a small *s* to represent the gene for doubleness, which is recessive. The chromosomes of the eggs and pollen grains produced by this single-flowered plant are also shown. They are of two types, I and II, and half the eggs are of one and half of the other type. This is also true of the pollen grains. According to Philp and Huskins, however, only those pollen grains with the satellited chromosome function, and all the eggs live except about 6 to 8 percent of those lacking a satellite. Since only one type of pollen grain lives, there will result just two types of plants. They are shown at the lower part of the diagram.

[6] This work has recently been questioned by Vestergaard and may need further investigation.
[7] This actually happens occasionally, as discussed earlier, when a diploid sex cell is formed.

One will be single, since it receives the knobless chromosome with the single gene, and the other will be double, receiving two double-flowering (*s*) genes and two satellited chromosomes. Since there are not quite so many eggs carrying the large *S* for single flowers, the result is about 54 to 56 percent of doubles and 44 to 46 percent of singles. Philp and Huskins report that all doubles examined by them had two

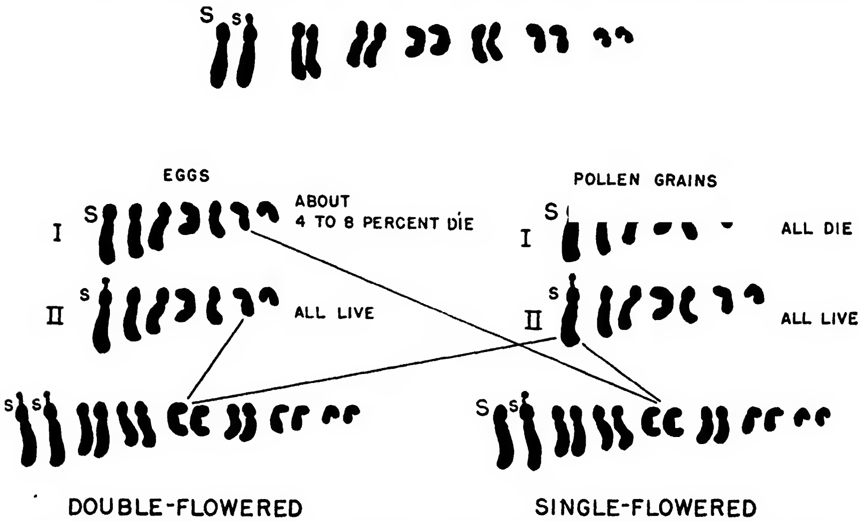

Figure 15.—The chromosome situation in ever-sporting, double-flowering stocks.

satellites, while all singles had but one. This refers, of course, only to the ever-sporting races.

Another cytologist, Frost (*135*), working with stocks, has also demonstrated the value of cytology to flower breeding. He has shown that the proportion of double-flowered plants may be increased very materially. Among the various types of stocks he had in his experimental plot was an ever-sporting form known as Snowflake. In this variety he found a peculiar single-flowered plant that had very narrow slender leaves. When this plant was self-pollinated it gave about 47 percent of singles and 53 percent of doubles. About 37 in every 100 plants had the narrow slender leaves of the parent. Also, these plants were very weak in growth and had no decorative value. The remaining normal plants descended from this narrow-leaved parent were found to be about 90 percent of doubles. Since the slender leaves are conspicuous even in the seedling stage, the plants having them may be discarded at that stage, and among the remaining plants there will be only about 10 percent of singles. In order to continue this situation, however, it is necessary that seed be saved only from the slender-leaved types.

The explanation for this interesting condition was worked out by making a cytological study of the chromosomes of the slender plants. In addition to the 14 chromosomes expected, these plants showed a small chromosome piece, which cytologists commonly call a fragment. These plants, then, had 14 + 1 chromosomes. Evidently this frag-

ment was the part that carried the gene for singleness or doubleness. Since only slender-type plants had this fragment, it was concluded that the slender leaves were also caused by its presence. Since a gene for singleness was also in the fragment, these two characters, singleness and slender leaf, behaved as linked genes do; that is, they tended to remain together from generation to generation. Thus if the slender plants are discarded in the seedling stage, it means the removal of most of the singles. This very unique scheme is not in practice as yet, probably because it is not understood by the average flower breeder.

Since the chromosome number of a plant does have considerable importance in breeding work, a list of chromosome numbers of some of the most common flowers is given in table 1.

TABLE 1.—*Chromosome numbers in some of the commoner flowers*

Name of flower	Chromosomes in— Sex cells	Chromosomes in— Body cells	Name of flower	Chromosomes in— Sex cells	Chromosomes in— Body cells
	Number	*Number*		*Number*	*Number*
Ageratum	10	20	*Dahlia variabilis*	32	64
Alyssum	8	16	English daisy	9	18
Annual larkspur	8	16	Fuchsia	11	22
Bachelor button (cornflower)	12	24	Lily, Easter	12	24
Calendula	14	28	Lily, tiger	-------	36
California-poppy	6	12	Nasturtium	14	28
Canterbury-bells	8	16	Rhododendron species	13	26
Canterbury-bells (tetraploid)	16	32	Roses, various types	7, 14, 21	14, 28, 42
China-aster	9	18	Snapdragon	8	16
Chrysanthemum	9	18	Stocks	7	14
Clematis	8	16	Sweet peas	7	14
Columbine	7	14	Sweet-william	15	30
Cockscomb	18	36	Wallflower	7	14
Dahlia (some types)	16	32	Zinnia	12	24

SOME PAST ACHIEVEMENTS AND FUTURE POSSIBILITIES

THE fundamental principles of breeding are now fairly well established, but the methods of application vary with different plants. The plant breeder who is interested in flowers and ornamental plants is faced with the problem of choosing his material from among many hundreds of species. It is obviously impossible to work with more than a small proportion of them. As a rule those breeders who have accomplished the most have limited themselves to a very few.

In preparing this article, the authors also were confronted with the task of choosing only a few representative species out of many available. In doing this it was realized that much interesting and valuable work would necessarily be left out. To some extent this omission is compensated for by the extensive appendix on research in flower breeding at the end of this article. Those especially interested in some flower not mentioned may find it included there.

AMARYLLIS

Botanically the name amaryllis should refer to the entire family Amaryllidaceae, but horticulturally it is used for plants of a single genus, *Hippeastrum*, belonging to this family.

A watchmaker named Johnson, of Lancashire, England, is credited with having produced in 1799 the first hybrid amaryllis recorded in the history of this plant. Johnson had a small garden where he followed his hobby of hybridizing plants and produced *Hippeastrum johnsoni* Bury, which even by modern horticultural standards was a distinct and outstanding variety. This hybrid is recorded as a cross between *H. reginae* Herb. and *H. vittatum* Herb. It has since been used a great deal as a parent in the production of other hybrid amaryllis.

It was at the end of the eighteenth century that widespread interest began to be centered on plants of the amaryllis family. In 1821 William Herbert published a treatise on plants included in the amaryllis family. This was followed in 1837 by his work entitled "Amaryllidaceae", which is still considered a valuable record of the amaryllis family. In this book Herbert lists under the genus *Hippeastrum* 31 "hybrid or mixed crosses" which he had secured or which had been produced by others and brought to his attention.

The family of De Graaff, of Leiden, Netherlands, was also greatly interested in the amaryllis at the beginning of the nineteenth century and produced hybrids that were of importance at that time. Following closely was the famous English firm of James Veitch & Sons, which introduced two handsome species from the Andes of Peru, *Hippeastrum pardinum* Dombr. and *H. leopoldi* Dombr., which were first flowered at Chelsea, England, in 1867 and 1869, respectively. From these two species have come many beautiful hybrids. A list of those who have made noteworthy contributions to the development of the amaryllis in the last 50 years includes such names as Arthington Worsley in England, E. H. Krelage in the Netherlands, E. L. Holmberg of Argentina, and Henry Nehrling and Theodore L. Mead of the United States.

As is the case with many horticultural plants, botanists find it difficult to classify the species and varieties of amaryllis. Because of the way plant improvement has developed in ornamental horticulture and the lack of records, it is impossible to trace the ancestry of the heterogeneous and hybrid varieties of today.

A. Worsley, writing in the Gardeners' Chronicle in 1901, stated that in his opinion a botanical classification of all the modern amaryllis varieties would divide them into but two species. *Hippeastrum vittatum* remains fundamentally as it existed 100 years ago, allowing for the superiority it has attained through selection and good culture. The other species is more difficult to trace because so many of the original characters have been lost in breeding. The type as it is now known has a short, well-expanded, large, substantial flower with wide segments and the hairy throat of *H. equestre major* Herb., the color of *H. equestre* Herb. and *H. rutilum* Herb. (rarely of *H. aulicum* Herb.), and the keel markings of *H. reginae*. The colors are now very varied. The rarer colors, especially the coppery reds and those nearest white, have of late been diligently sought and selected, and hence have increased in collections, at the expense of other colors.

It is Worsley's belief that the frequent self-colors that appear in lots of seedlings are reversions to some ancestral type, and that the first parents of all our parti-colored or marked flowers were selfs, and inconspicuously colored at that.

The confusion in the genealogy of the amaryllis goes so far as to shadow the parentage of the first recorded hybrid made by Johnson. This variety is recorded in Mrs. Bury's work published in 1831 as the progeny of *Hippeastrum formosissima* × *vittatum*. According to J. G. Baker's Handbook of the Amaryllideae, published in 1888, however, *H. johnsoni* was raised cut of *H. reginae* × *vittatum*. To Worsley both these suppositions seem untenable, for he has never been able to hybridize *H. vittatum*, and further he states that *H. johnsoni* does not bear any resemblance to *H. vittatum*. Further to complicate this matter there appear to be two distinctly different plants in the literature, both under the name *H. johnsoni*. Thus down through the list of hybrids there are many discrepancies, resulting in confusion in any attempts to trace the parentage of modern amaryllis varieties. Published descriptions frequently giving incomplete information have sometimes served further to obscure the genealogy of amaryllis.

Also to be considered is the question of sterility in hybrids. In the past doubtless many excellent but sterile hybrid amaryllis have been lost because of an incomplete knowledge of means of vegetative propagation. Fortunately the work of Ida Luyten in the Netherlands in 1926 has clarified many problems in connection with the multiplication of bulbs by asexual means.

Worsley, who is known as the dean of the amaryllis fraternity, stated in 1901 that although his efforts had been directed for many years to producing *Hippeastrum* species hybrids, he could not claim to have met with success in a single instance. He said that he was aware of but three or four undoubted species hybrids—*H. solandriflorum* × *johnsoni*; *H. johnsoni* × *solandriflorum*; *H. pardinum* × *reticulatum*; and possibly *H. reticulatum* × *vittatum*. These must be reduced to two or three if *H. johnsoni* is itself regarded as a species hybrid. He acknowledged that other species hybrids have probably been raised and the parentage left in doubt, for such species as *H. equestre*, *H. aulicum*, and the *rutilium-reginae* group are all good seed bearers when self-pollinated or when crossed with certain hybrid forms. The fact that such hybrids already have the blood of these species, he believed, accounts for the ease with which they cross back with their purebred relations.

Despite the uncertainty enshrouding the lineage of many of the varieties of modern amaryllis, breeding and selection have gone on apace, and each year more interest is being manifested in the development of this flower. In 1934 the American Amaryllis Society was launched. In its constitution its aims are stated as "the promotion of sub-order I Amarylleae, and sub-order II Alstroemerieae, order Amaryllideae." As part of its activities this organization publishes a yearbook, in which is attempted a complete inventory of all Amarylleae as well as the collecting of information from all over the world on the breeding and culture of these plants. It will contain systematic descriptions of new varieties, which will be of tremendous importance both historically and as an aid in breeding work in the future.

The American Amaryllis Society is also sponsoring national amaryllis shows, the first of which was held at Orlando, Fla., in April 1934, with 10,000 blooms. The varieties that attracted most attention were

those having blossoms of pure white or a refined shade of red. The display of amaryllis bearing yellow blossoms was not of good quality, and more breeding and selection are necessary before a pure yellow blossom can be secured.

In 1935 the second national amaryllis show was held at Montebello, Calif. The hybrid types of amaryllis exhibited by commercial plant breeders in California were the outstanding feature of this exhibition. Apparently, striking, clear colors and large sized blossoms were the characters that appealed most to the spectators at this show.

The national amaryllis show was held again in Orlando in 1936. The varieties of amaryllis of Dutch origin were the outstanding display of the exhibition. Perfection of form and color were the outstanding qualities of these varieties.

In the Bureau of Plant Industry, breeding and selection work with amaryllis have been conducted since 1909. The aims in this work have been to improve existing types of amaryllis and to obtain new colors, more shades, and a further increase in the size of the flowers, and in numbers of flowers in clusters. In 1909, 12 varieties of amaryllis were imported— Diana, Venus, Serapis, Progress, Achilles, Crimson King, Vesta, Virgin Queen, Monarch, Bacchus, Adonis, and Scarlet King. The colors ranged from dark red through pink to white with red stripes.

The late E. M. Byrnes, formerly superintendent of the Department greenhouses, undertook by cross-pollination to develop new colors from the original flowers. In 2 years' time the plants resulting from the crosses came into flower. Each year since 1909 this process of selection and cross-pollination has gone on in order to produce superior varieties.

One of the outstanding varieties of amaryllis developed at the Department greenhouses is a pure white one. This was first exhibited in 1920. Since that time this variety has been further improved in size, form, and purity of color.

Each year an amaryllis exhibition is held at the Department greenhouses. Most interest at these shows seems to be directed to the pure white flowers and those of clear, new colors. The larger flowers likewise attract much attention.

The literature fails to reveal any great amount of work on the breeding of amaryllis on the basis of our present knowledge of genetics and cytology. The fact that we have a number of supposed cases of generic hybrids in the Amaryllidaceae has created considerable interest, but it remains to be decided in some of these cases whether the botanical classification of genera has been sufficiently rigid and whether such hybrids actually are the result of crossing two distinct genera.

It is certain that cytogenetic study will be the means of elevating the breeding of amaryllis to a higher plane and of broadening its scope. One of the first steps in such a plan is to acquire and make chromosome studies of as many species as can be secured. As a result of these studies much can be learned concerning the probable parentage of some of our modern varieties. Again, cytological and anatomical studies may solve problems of apparent sterility between certain species. Chromosome studies will be of considerable help in fundamental taxonomic studies of the entire family Amaryllidaceae.

Because the amaryllis varieties are extremely heterozygous, or hybrid, in their genetic make-up, and because they can be propagated by vegetative means, it is questionable whether it is worth while to breed pure-line material that is homozygous. The time element must be considered, for with the amaryllis it takes 2 years from seed to flower while in some of the other genera of the Amaryllidaceae the time is much longer.

For the next decade it is probable that most new varieties will be derived from the hybrid kinds that now exist. However, considerably more thought and effort will doubtless be directed to careful and systematic breeding as the tools and methods of modern plant breeding become better known.

China-Aster

In popularity the China-aster (*Callistephus chinensis* (L.) Nees) is not exceeded by any other cut-flower annual with the possible exception of the earlier blooming sweet pea. The size, boldness, and attractive form of the blooms, and the sturdy stems and free-flowering habit, as well as the diversity of types available, contribute to its popularity.

A single species, native to China, is included in the genus *Callistephus*, yet this has given rise to a range of forms equaled by few of the garden flowers of today. The family Compositae includes this genus as well as *Aster*, the latter with a great diversity of species, and distinct from China-asters.

A Jesuit missionary, R. P. d'Incarville, introduced the China-aster into Europe in 1731. The original form was single, with two to four rows of ray florets of red, blue, violet, or white, and numerous yellow disk florets. The original stature was medium tall, some 18 to 24 inches in height. The "single chinensis" type now offered by seedsmen and thought to be the old original aster is a midseason type, flowering toward the end of August. Early improvement work was concentrated in France and yielded double forms such as the peony-flowered type. During the first half of the nineteenth century German breeders were so active, chiefly with quilled types, that *Callistephus* became known in America as the German aster. Double forms reached England by 1752, and a variegated blue and white type was known in 1807. By 1851 the quilled type, perfected in Germany, was well known, and dwarf types were appearing. The Comet type, dwarf and compact with lone flat rays and a loose flower head, was introduced about 1886. The Queen of the Market type, notably early flowering with wide-spreading habit and long stems adapted to cutting, appeared in the trade about 1886 from France, where it was already well known in the Paris markets. The Semple strain, tall and strong, with stiff stems and large flower heads, was developed in Pennsylvania. Other tall branching types, emphasizing strong flower stems and large size of bloom, have been developed in the United States for the florists' cut-flower requirements. Recent improvement has been accomplished chiefly by seedsmen, although the Wisconsin Agricultural Experiment Station has taken a leading part in the development of strains resistant to the fusarium wilt disease.

It is generally admitted that a satisfactory classification of China-asters, including all the forms offered by seedsmen today, is imprac-

ticable. Bailey in 1895 offered a tentative classification based on form of bloom and of florets. Beal has offered a more inclusive classification, using four classes of plant habit (tall pyramidal, tall branching, dwarf, single) with further subdivisions based on form of flower heads and florets. Seedsmen also employ the purpose of the variety in making classifications, as florists' cut-flower types, with stiff stems. One American seedsman offers nearly 200 varieties of China-asters and a European firm offers over 500.

During the last decade increasing prevalence of two diseases, wilt and yellows, threatened to wipe out the China-aster. Losses became so heavy that florists and home gardeners alike were turning to other flowers for summer and early-fall cutting, and seed sales dropped alarmingly. Partial control of both diseases has been effected as the result of recent research, in which the Wisconsin station has assumed a leading role. The wilt disease, which is caused by a soil- and seed-borne fungus of the genus *Fusarium*, has been conquered by selection of strains resistant to infection. Yellows, a virus disease spread by a species of leafhopper, may be avoided by growing plants under special cloth shelters, which exclude the insect carrier.

Jones and Riker (*274*) began selection of wilt-resistant asters in 1925. Commercial varieties were grown in "aster-sick" soil, thoroughly contaminated with *Fusarium* as a result of repeated aster culture. No one of the commercial varieties proved to be uniformly resistant to wilt, but resistant individuals appeared among most of the types tested. Selection was continued in the progeny of resistant plants through 1930. Beginning with 1929, extensive testing and selection were carried out at the Bodger Seed Co. farms at El Monte, Calif. Earlier efforts were concentrated on several flower colors in the American Branching group and on the Heart of France variety, but later study has shown that resistant lines are available within other desirable types of asters such as the Semple, American Beauty, Comet, and Royal types. Seedsmen now advertise resistant asters of all major groups except the pompons. Commercial resistant strains, maintained by selection each year, are rarely 100-percent resistant, but represent a marked advance over the unselected varieties.

In the reports on development and improvement of China-asters no mention of artificial hybridization has been found. Furthermore, the genetics of *Callistephus* seems to have been wholly ignored except for one record of an apparent mutant defect in the ray florets of a single form. All the characteristics we have in *Callistephus* today—diverse plant form and stature, divergent form and color of bloom, varying dates of maturity, resistance and susceptibility to wilt—have evidently arisen from the old original type of the species by spontaneous mutation and chance hybridization. All that man has done to improve the aster consists in growing it in immense numbers and in saving those segregates and mutants that have appealed to him as desirable.

The complete range of color now available was obtained years ago. Improvement since the early days has taken place chiefly in form of flower (fig. 16) and in plant habit. The ordinary procedure consists in saving seeds of natural variants, usually produced without protection against crossing with neighboring varieties. After a few years of

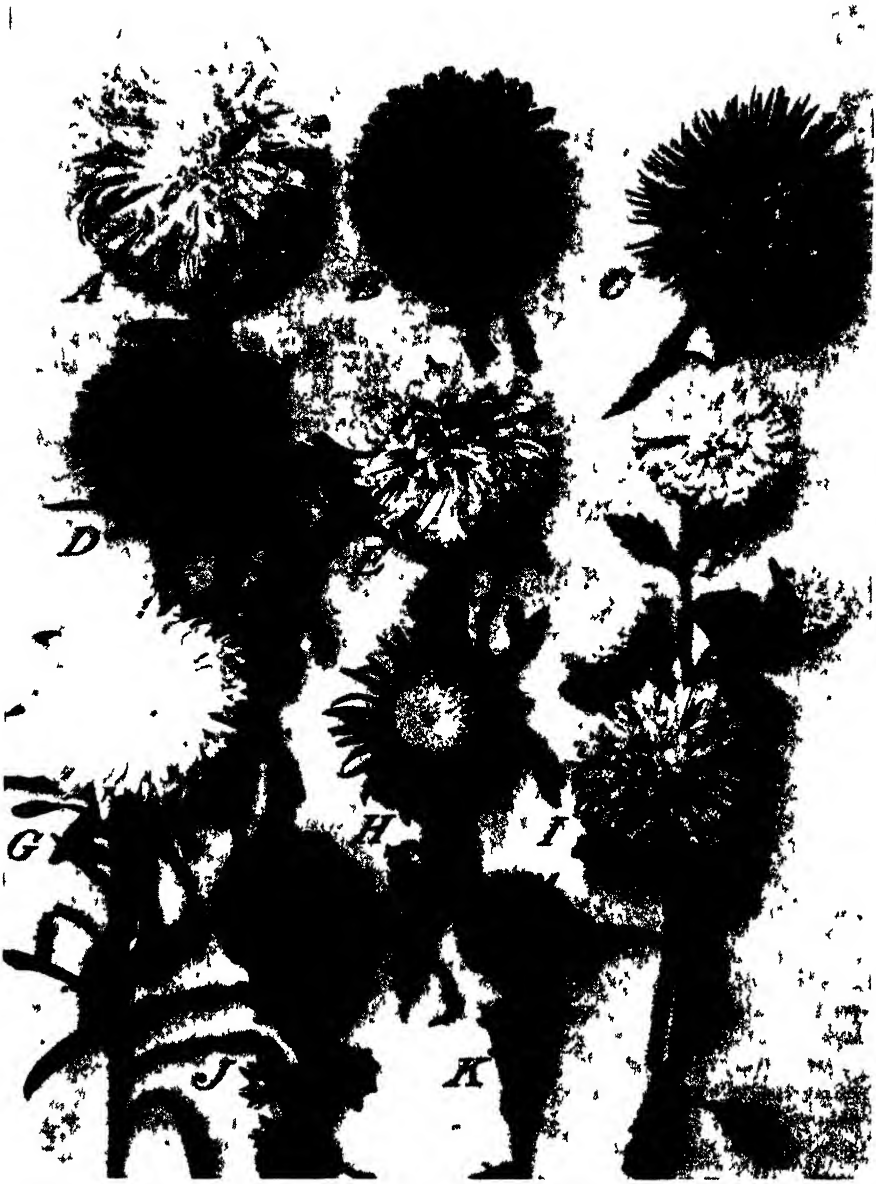

Figure 16.—A few of the many forms of asters now available *A*, Mammoth or Giant of California; *B*, Early or Late Beauty; *C*, Unicorn or Ray; *D*, King; *E*, Ostrich Plume; *F*, Queen of the Market; *G*, American Branching; *H*, Sunshine; *I*, Hohenzollern, *J*, Victoria, *K*, Tres Naive.

selection the type becomes fixed for the new character, with color variants still appearing within it. Colors are in turn fixed by further selection. As an example, the Comet type appeared on the market in

1886 as a pale pink fading to white. Six years later, rose, blue, and pure white Comet types were offered. It is commonly assumed that the percentage of natural crossing in asters is low, but Fleming (*131*) estimated that approximately 10 percent of natural crossing occurred at Summerland, British Columbia. In the earlier Wisconsin work on wilt resistance, individual plant selection was practiced under cages to exclude leafhoppers, which also insured a high degree of self-pollination.

Fleming grew the progeny of rogues in rows adjacent to the commercial strains from which the rogues were derived. From the variation shown by these open-pollinated rogue types in the next generation he presents certain tentative conclusions with respect to color dominance: white is recessive to all or to most colors; purple is dominant to red, and red to white; deep pink is dominant to white.

In future breeding of the China-aster the most important single characteristic to be sought is resistance to yellows. The search for a yellows-resistant type is complicated by the fact that affected plants develop no viable seed; hence a partially resistant type cannot be continued as a line selection. White (*544*) has noted that the Queen of the Market type, although susceptible, appears to be less severely injured by the disease than later sorts. Development of homozygous, or pure, lines by self-pollination will aid materially in segregating desirable qualities and will permit genetic analysis of such characters as color and habit.

Canna

When cannas were first recognized as suitable for ornamental purposes, they were tall leafy plants with comparatively small flowers and considerable space between nodes. A chronological history shows that *Canna indica* L. was introduced into England by Gerard in 1596. In 1762 Linnaeus listed but three species. Roscoe in 1828 admitted 21 species. Between 1830 and 1850 the younger Bouché, in Berlin, estimated the number of species at 82. Between 1840 and 1865 Année in France developed a race of garden types from *C. nepalensis* Wall. with pollen probably from *C. glauca* L. This hybrid was called *C. annaei* Andre. Dwarfer cannas with larger flowers appeared when a cross was made by Année in 1863 of *C. iridiflora* Ruiz and Pav. with *C. warscewiczi* Dietr.

From this point on, the interest in securing newer and better types increased rapidly, and there were many horticultural forms developed. As tastes for bedding cannas changed, the new varieties entering into commerce were dwarfer and the flowers larger and of higher quality. Because such types had been originally developed as a result of the work of plantsmen in France, the dwarf kinds are known as French, or Crozy, cannas. The latter name is used because many of the superior types were sent out by Crozy and Sisley of Lyons. Vilmorin of Antibes, Lemoine of Nancy, and Maron of Saint-Germain-les-Corbeil have all contributed to the garden canna as we know it today.

More recent than French cannas are the Italian or so-called orchid-flowered types. The latter name is employed because the flowers of these new cannas resemble the flower of an expanded *Cattleya* orchid. These varieties were first developed in Italy by M. Dammann & Co., at San Giovanni a'Teduccio, Naples. The Italian varieties are recorded as crosses of *Canna flaccida* Salisb., a native of the southern

United States, with garden forms and with *C. iridiflora*. They show improvement in the flowers, which have soft flowing margins and superior colors of golden vermilion.

During the latter part of the nineteenth century new canna varieties were being brought into the United States in large numbers. In 1893 Wintzer (*555*), of West Grove, Pa., became interested in the development of new varieties, with the object of improving the strain and developing new and desirable varieties suitable for "our trying climate."

Wintzer was particularly interested in producing a canna with a clear yellow bloom. As a result of continued hybridization and selection he developed the variety Buttercup. It was rather dwarf, early, and a free bloomer, held its flowers well above the foliage, dropped the faded ones, and the blossoms endured the sun without bleaching. Another quality that Wintzer attempted to develop in cannas was the production of rootstocks that would store well during long winters. He developed two pink-flowered varieties, Martha Washington and Betsy Ross, with small, hard rootstocks, a type resistant to decay in storage. Some of Wintzer's best varieties, including the white Mont Blanc, have resulted from using seedlings that were of no merit commercially but carried characters that he wished to introduce into the progeny. It is possible that in another decade the breeding of new canna varieties will be again stimulated and advanced by new practices and techniques.

The varieties of ornamental cannas offered in the trade today represent types that show great improvement over the original botanical species. There was a time about the beginning of the twentieth century when cannas were much in demand for the extensive bedding work that was then the mode in public parks, cemeteries, and other landscaped areas. In an effort to produce new forms and colors, gardeners year after year hybridized plants with desirable characteristics. In the last 20 years the popularity of bedding plants has waned, and consequently, many of the canna varieties have been lost. This makes a reconstruction of the lineage of the remaining varieties more difficult because many of the intermediate types between the true species and the modern complex hybrids have disappeared.

Even earlier, as a result of the mixing of species due to hybridization, there was considerable confusion in regard to the classification of canna varieties and the parentage of the varieties then in the trade. J. G. Baker, in England, writing in the Gardeners' Chronicle in 1893, concluded from a study of the canna literature from every available source, that the least conservative estimate could not give the genus *Canna* more than 16 species, although 90 had been listed previously. Granting that this confusion existed nearly a half century ago, activities of the last 50 years have done little more with canna classification than to aggravate the situation.

In recent years the canna has received attention in the technical field of cytogenetics. Honing (*213*) in the Netherlands, Belling (*46*) in the United States, and Tokugawa and Kuwada (*513*) in Japan have made contributions to the studies of inheritance in the canna. The work of these men contributes knowledge of practical nature, which can be adapted to the development of superior varieties of cannas for ornamental purposes. These studies have pointed out the advantages and shortcomings of triploid varieties in the canna, a type

which is desirable as an ornamental but usually not suitable for further breeding work. More details of the nature of triploid plants can be found in the paragraphs devoted to genetics earlier in this article.

Belling (*45*) in 1921 studied the behavior of homologous chromosomes in a triploid canna. This variety he secured under the name Gladiator. To the horticulturist it was a noteworthy variety, for it was sterile and the flowers, instead of setting seeds, dropped after they had matured and gave way to new blossoms. The production of seeds in ordinary fertile, diploid cannas is a detriment to continued flowering.

In nearly all cases triploid varieties are partially or totally sterile and thus often incapable of hybridization. In the past much time and labor have been expended in fruitless attempts to cross ornamental plants where one or both of the desired parents used were sterile and incapable of contributing to the production of hybrids. The work of Belling on cannas points out limitations and also opportunities in future breeding work with this plant.

Fortunately for the horticulturist, the canna is readily propagated vegetatively; consequently plants with sterile flowers, if worthy of perpetuation, can be increased in this way. Belling did find, however, that most of the 46 clones of cannas that he investigated had the diploid number of chromosomes, which is nine pairs in somatic cells. It would be from varieties of cannas with the normal nine pairs of chromosomes that high interfertility could be expected in connection with the development of new varieties.

Honing, working in the Netherlands, has published a series of papers since 1914, all concerned with technical genetical studies of the canna. He has reported on the inheritance of pigment in stems, leaves, and fruit papillae of *Canna indica*. As a result of crossing *C. indica* with *C. glauca* he obtained a single hybrid plant that in subsequent generations gave progeny that differed widely among different sowings for the factors of red leaf margins, wax layers on the leaves, and the number and color of staminodes. He also made a genic analysis of the inheritance of flower and leaf characters in the cross mentioned above.

At the Tokugawa Biological Institute, Tokyo, Japan, cytological studies were made on some garden varieties of cannas by Yoshichika Tokugawa and Yoshinari Kuwada. A report of their work was published in the Japanese Journal of Botany in 1924. It included a study of the chromosome number of various varieties of garden cannas. They found that there were either 18 (diploid) or 27 (triploid) chromosomes in the varieties coming under their observation.

These cytological studies in Japan also pointed out that the process of meiosis in canna is generally of somewhat abnormal tendency both in the diploid and triploid varieties. This abnormality of division is possibly the cause of some sterility, which is well recognized in certain canna varieties. Finally the work of Tokugawa and Kuwada showed conclusively that the triploid cannas are larger than the diploids with respect to the stomata openings of the leaves, the size of the cells of the epidermis of the staminodia, the thickness of the leaves, and lastly, the size of the entire flowers. It was also noted that the staminodia of the triploid plants not only are larger than those of the diploid plants but also present a desirable delicate wavy appearance

in their surface. While this Japanese paper is a technical treatise, it serves as a valuable addition to the knowledge that a practical breeder of cannas must have to carry on his work effectively.

Carnation

The carnation (*Dianthus caryophyllus* L.) is one of the oldest flowers still under cultivation. It was first mentioned and described in 300 B. C. by a Greek philosopher, Theophrastus. The original type was a single flower with five petals, measuring about 1 inch in diameter and of a pinkish-mauve color. It grew wild over much of Europe, and it still existed in Normandy as late as 1874.

In England, during the reign of Queen Elizabeth, William Turner published an extensive description of this flower. By this time the double form had made its appearance and already existed in a wide range of colors. Just when or how the double form arose will probably remain an unsolved mystery. The flower was very popular in England, and early in the eighteenth century it was used in a successful cross with sweet-william. Most of the early selection work was done by English amateurs, who rapidly developed a wide range of forms and colors. They were interested both in the outdoor garden types and in the large, double-flowered varieties of the florists. In this article the discussion deals almost entirely with the latter type, which is now one of the most important flowers grown under glass in this country.

The florists' carnation occurs in three distinct forms, the single, the double, and the superdouble, or bullhead. The second type includes all the commercial varieties. The bullheads are so extremely double that the calyx splits badly as the flower expands. The first published report that threw some light on the question of inheritance of doubleness appeared as an abstract in the 1904 Proceedings of the American Society for Horticultural Science. At that time Norton (*396*), of the Department of Agriculture, told of some experiments he was carrying on in the breeding of carnations. He reported that from the seed of individual capsules he secured all three types of carnation flowers. From one there were 6 doubles (bullheads), 15 semidoubles (commercials), and 7 singles; from another 74 doubles, 147 semidoubles, and 52 singles. These proportions are approximately 1 to 2 to 1, and they agree fully with what is expected in the progeny from a hybrid when one of the two genes affecting the same character is not fully dominant to the other. At that time Norton suggested that the practical florist should cross the single with the extreme double type and thus secure a greater proportion of intermediate true florists' types. The common practice, which still persists, was to cross two commercial double varieties, and always a large proportion of resulting seedlings were singles and bullheads.

In 1907, at the meeting of the American Breeders' Association, Norton (*397*) reported that several crosses between singles and extreme doubles, made in 1905–06, yielded 250 seedlings, which were, with one exception, commercial doubles. Since no protection from outside pollen was used, the one single seedling may have been an outcross. It was pointed out that single and very double seedlings were usually discarded no matter how desirable their other characters

might be. By pollinating a good single with the pollen of an extreme double that has some new desirable quality, a complete series of standard double seedlings can be secured, some of which may show the new character.

In 1912 Stuart (*498*) presented a more comprehensive publication on this question. The breeding work, begun at the Vermont Agricultural Experiment Station, was completed at the Arlington Experiment Farm, Arlington, Va., after Stuart joined the staff of the Department. The earlier work of Norton was confirmed and the following facts established: When a single was crossed with a single, all the hybrids were singles; a single crossed with a commercial double gave about 1 single to 1 commercial, but when crossed with a bullhead it gave practically all commercial doubles; when 2 commercial doubles were crossed they gave about 1 single to 3 doubles. Unfortunately the doubles in Stuart's report were not classified as to bullheads and commercial types.

The results were analyzed as follows: (1) The commercial carnation as grown by florists is an unfixed hybrid from a cross between a single and superdouble; (2) the bullhead type is incompletely dominant to the single, and the hybrid resulting from crossing them is the intermediate or so-called commercial double.

Unfortunately, the development of superior double carnations is not so simple as the preceding account seems to indicate. Frequently the investigator is hampered by having abnormal plants appear in his progenies, from which very little or no seed can be secured. According to Connors (*81*) and his associates, who carried on carnation breeding at the New Jersey Agricultural Experiment Station for 15 years, there are many types of carnations with respect to the relative development of pistils and stamens. These types include plants bearing male flowers only, plants with all stamens transformed into petals, and asexual types in which pistils and stamens are rudimentary and nonfunctional. It was possible to further subdivide these groups so that 10 types in all are recognized.

In spite of the many difficulties and the meager information on inheritance in the carnation, a very large number of choice varieties have originated as seedlings. Many florists have devoted considerable space and time to this work. One of the leaders was Ward, who devoted considerable time to the production of better florist types and presented his observations on carnation breeding (*533*). At that time he stated that in raising varieties from hybrid seed very few improvements are produced. He estimated that only about 1 in 1,000 seedlings had any merit, and probably but 1 in 5,000 or 10,000 was a decided advance. He also felt that even this low frequency would decrease rather than increase because of the higher standard that was set from year to year.

The list of seedling varieties is constantly changing as old ones are replaced by newer and better types. It has been the practice of many commercial growers to try out a small number of some of the new ones each year. It may happen that one from New England is very inferior in the Colorado section, and one from Colorado may lack quality in Illinois. This has demonstrated, in this country, that it is necessary to develop varieties for a given locality.

Many carnation varieties originate as bud sports. It is a relatively simple matter to propagate these if desirable. These sudden changes may affect any part of the plant. Sometimes the leaves are broader, or deeper or lighter green, or the plant is dwarfer, more compact, or taller. The flower may be modified as to color, size, length of stem, or structure of petals. Since the flower is of primary importance, bud sports are most likely to be noticed when floral characters are involved.

Unfortunately there is no authentic evidence on the frequency of bud sports in carnations. Isolated observations in various sections of the country seemed to indicate, however, that they might occur at a rather high rate. Unquestionably many of the best of our current varieties arose in that way. As a result growers have become accustomed to keeping a careful watch over their benches during the growing season. Since, under the stress of commercial operations, there is always the possibility of mechanical mixture of rooted cuttings, it is impossible to give an accurate account of the situation.

There are a number of carnation disease problems in the solution of which the plant breeder should be useful. Two of these diseases, carnation rust (*Uromyces caryophyllinus* (Schrank) Wint.) and stem rot (*Corticium vagum* B. and C.) may at times become very troublesome. Varieties resistant to these diseases, provided they were also of high quality, would be very acceptable. There is some evidence that resistance to rust already exists in some of the better commercial varieties. In 1932, a test of 36 varieties was made at the Waltham Field Station, in Massachusetts, and they were grouped for rust resistance as very susceptible, moderately susceptible, slightly susceptible, and resistant. The standards for grading resistance were not stated, nor were the severity and uniformity of the infection given.

The problem of color inheritance has received very little attention as yet. The highly heterozygous conditions of the carnation and the very frequent functional sterilities encountered have discouraged research along these lines. As facilities for flower breeding are increased, it is likely that some attention will be given to these problems.

The condition known as carnation splitting is another problem that should receive more attention from the flower breeder. It was studied by Connors, who stated that it was caused by two conditions—the formation of an unusually large number of petals through transformation of stamens and pistils, and the development and growth of secondary buds within the flower.

As early as 1903, Ward had assumed that splitting was entirely hereditary, and he advised the selection of seedlings that produced flowers with an unsplit calyx. Later, Connors stated that the experience of the New Jersey station indicated splitting was influenced by both hereditary and environmental factors. It is needless to say that a good nonsplitting variety would be a valuable contribution.

Since there is a rather definite regional adaptation of varieties, it seems that a sound carnation breeding program should include facilities for testing all seedlings in as many different locations as possible. When the work is carried on at only one location, there is loss from discarding seedlings that might prove very valuable in another region.

Chrysanthemum

The culture of improved forms of chrysanthemums antedates the beginning of the Christian era by several centuries. Apparently they are native to China, and are mentioned in Chinese literature as early as 500 B. C. The Japanese grew them extensively at an early period and did considerable work in developing improved types. A form with 16 petals was chosen as the flower emblem of the Emperor. In both China and Japan, single-stemmed varieties were generally grown long before the plant was introduced into western Europe.

The earliest record of chrysanthemums in Europe is of an importation in 1688. It seems strange that this attractive flower was not known to Europeans at an earlier period. The following year several varieties were reported as being grown in the Netherlands, but for some unknown reason they soon passed out of cultivation.

It was not until 1764 that chrysanthemums made their appearance in England. They soon became popular, and additional varieties were imported from China in 1789. During the following 20 years, eight new types were introduced from China.

All the early varieties introduced into Europe were brought in as living plants. The first attempts to grow seedlings were not made until about 1827. At this time a Frenchman, M. Bernet, flowered several fine seedlings from seed he found in withered flower heads the previous autumn. Following this it is very probable that many amateurs began to grow seedlings, but unfortunately we have no records of any new developments.

In 1846 Robert Fortune brought two small-flowered varieties from China and introduced them into English gardens. They were not well received by the English, but when sent to France they soon became rather popular and were used extensively in hybridizing. It seems probable they were the progenitors of our modern small-flowered varieties.

The early history of chrysanthemums in the United States is rather obscure. According to the 1828 catalog of William Prince, they were introduced into Hoboken by John Stevens in 1798. The plants were probably a dark purple form, which had reached Europe from China in 1790. In 1826 the Prince's Nursery listed 26 varieties, and by 1835, according to Hovey's American Gardener's Magazine and Register, 50 distinct varieties were available in this country.

There is no record of the origin of any of these early chrysanthemums. Propagation by cuttings was very simple, and strains were perpetuated in this way. Undoubtedly this was a strong factor in retarding breeding. The fact that so few different types existed in this country in 1835 is an indication that very little actual improvement by breeding had been attempted.

One of the earliest breeders in this country was Robert Kilvington, of Philadelphia, who exhibited a new seedling named William Penn before the Pennsylvania Horticultural Society in 1841. It was a large white double flower, almost globular in shape. It seems strange that this did not immediately stimulate more work, but no other contributions appeared for some time. About 1850 Samuel Brookes, of Chicago, became very much interested in chrysanthemums and did considerable work to stimulate interest in the flower.

A general interest in chrysanthemums was slow to develop in this country. In 1844 an impressive display was made of many of the available varieties at the fall show of the Massachusetts Horticultural Society. Two years later there was a large exhibit before the Pennsylvania Horticultural Society, where the chrysanthemum was described as the coming flower. A special chrysanthemum show was not held, however, until 1868. At present there are many chrysanthemum exhibits each year.

Previous to 1850, chrysanthemums were not grown as greenhouse plants. About this time a few varieties were tried under glass, and development of special florists' types was soon under way. The development of this branch of the florists' business soon extended the blooming period and made it possible to market the large showy types that were being introduced from Japan. About 1883, Hosea Waterer imported about 50 varieties from Japan. Shortly following this, a large white variety appeared that was so attractive it is said to have been sold for a fabulous sum. This variety was sent to Mr. and Mrs. Alpheus Hardy by an appreciative friend in Japan. It was named Mrs. Alpheus Hardy and undoubtedly was one of the stimulating influences that led to a quickening of interest in chrysanthemum breeding in this country. Some of the successful breeders of this period were T. H. Spaulding, E. Fewkes, Pitcher & Manda, V. H. Hallock, W. C. Pyfer, E. G. Hill, and F. Dorner & Son. By 1894, there were listed 163 varieties of American origin.

In the latter years of the past century, one of the most prolific of modern chrysanthemum breeders, Elmer D. Smith, of Adrian, Mich., began his work. He had introduced 445 new varieties by 1928, and many others have been added since that time. Other American breeders who contributed many new chrysanthemums during this period are E. M. and J. W. Byrnes and F. L. Mulford, of the Department of Agriculture. More recent entrants in the work have been V. R. De Petris, of Detroit, Mich., and Alex Cumming, Jr., of Bristol, Conn., who has specialized with outdoor chrysanthemums.

The efforts of these breeders have been mainly to develop greenhouse or so-called forcing chrysanthemums. A program to develop hardy outdoor types has been under way in the Department for some time. The work was started by growing outdoors as extensive a collection of varieties as possible, and securing data on their time of bloom and winter hardiness. The work was carried on at first at the Arlington Experiment Farm, but in recent years certain selections have been sent to various cooperating State experiment stations for trial. By selecting each year the earlier flowering types and growing seedlings from them, races have been developed that bloom as early as July in the vicinity of Washington, D. C. (fig. 17). The earliest strains are followed successively by others until heavy frosts kill the plants. The work has demonstrated very clearly that time of bloom is actually a hereditary trait transmitted from parents to seedlings.

The problems involved in chrysanthemum breeding are to some extent very similar to those faced by the rose breeder. The history of the early chrysanthemum varieties is not known, but it seems likely that most of them arose as mutations or bud sports from other varieties. While there are no data on this point, the evidence all points in

that direction. So far as can be determined, little or no breeding work was attempted in China or Japan, and all varieties were maintained by the rooting of cuttings. If a new color or other bud sport appeared, it was simply increased by cuttings and soon became established. Had the Japanese and Chinese been growing seedlings there would certainly have been many more varieties available in

Figure 17.—The chrysanthemum breeding plot at the United States Horticultural Station, Beltsville, Md., where hardy early-blooming varieties are being developed Already a wide range of types and colors have been developed, and the blooming date continues from late July to killing frosts. In the background are cages built over 8 plants to protect them from cross-pollination.

those countries when the flower was first brought to Europe. This point is strikingly confirmed by the fact that Smith was able to develop over 450 new seedling varieties in a little over 30 years. Some of these may have been bud sports, but by far the larger number were seedlings.

The keeping of parentage records has been fairly thoroughly done by some breeders. Since the modern chrysanthemum is really of rather recent origin, and probably does not involve a very complex mixture of species, such records should have some value. If they all were available it seems very likely they would show that certain parents produce more good seedlings than others. While there is little or no scientific data on the inheritance of plant characters in chrysanthemums, breeders have learned through experience that certain varieties are likely to transmit their flower color. The variety Harvard, for example, usually produces red seedlings in crosses, and Thanksgiving Pink transmits its pink color. These observations seem

138904°—37——60

to indicate a probable dominance of these colors over other shades, and also that these varieties may be pure for their respective colors.

One of the greatest difficulties encountered by the chrysanthemum breeder is the failure of many fine varieties to set much seed. In some instances this may be due to an actual sterility, but it is generally the result of the extreme doubleness of the flower. Not much can be done about this unless a single can be found, which when crossed with a double gives all double seedlings. Under such conditions, all crosses could be made with the single as maternal parent.

The production of bud sports or mutations has also played a rather important role in the development of the chrysanthemum. The mutation tendency is undoubtedly higher in some varieties than in others. In the absence of any scientific data we are forced to rely on general observations as to the frequency of such changes. According to some growers, the sport of a variety very frequently reverts to the parent type. The mutations that have been observed are mostly flower color changes. Very probably there are others affecting foliage and other characters.

The possible causes underlying the sudden appearances of bud sports are mentioned in another section of this article. If more were known about them we might be able to produce controlled mutations in greater numbers. If they result from some environmental influence, then varieties of chrysanthemum must differ markedly in their response to it, because some varieties mutate more readily than others. This indicates an inherent mutation tendency. In other words, chrysanthemums may have some rather unstable characters and may mutate under certain environmental conditions.

Dahlia

Francisco Hernandez, physician to Philip II of Spain, was sent on an expedition to New Spain (Mexico) in 1570. The purpose of this journey into the New World was to study the natural history of this intriguing land to the westward. After Hernandez returned to Spain he published in 1615 four books on the plants and animals of Mexico. In one of these books he described three types of plants which nearly 200 years later were to be called dahlias. To these three plants he gave the Aztec names acocotli, cocoxochitl, and acocoxochitl, which mean; respectively, "water pipe", "hollow-stem flower", and "water-pipe flower", the allusion being to the hollow stems of the plants.

From Hernandez's writings it is apparent that the Aztecs had worked on the improvement of these plants, for this report indicates that they varied in color, form, and degree of doubleness. The illustrations he published show that somewhat double dahlia flowers existed in Mexico in the sixteenth century.

Vitalis Mascardi in 1651 published a work in Rome in which there is an illustration of a double-flowered dahlia. Again, in 1787, a Frenchman, Nicholas Joseph Thiery de Menonville, searching in North America for the valued cochineal bug, described dahlias, growing in a garden near Oaxaca, which had large asterlike flowers, stems as tall as a man, and leaves like those of an elder tree.

It was not until after 1789, however, that the Old World awakened to the possibilities of the dahlia as an ornamental plant. In this year

Vincente Cervantes, director of the Mexican Botanic Gardens, sent to the Royal Gardens in Madrid seed of dahlias from Mexico which were destined to play a tremendous part in the development of the superior types of garden dahlias as we know them today. It was to Abbe Cavanilles, director of the Royal Gardens, that these seed were sent, and from them were produced flowers of brilliant hues typical of the dahlias to be found growing in Mexico.

Cavanilles named this plant, which was practically unknown in Europe, Dahlia, after Andreas Dahl, an eminent Swedish botanist living in Berlin, who had been a pupil of the great Linnaeus. Among the plants that Cavanilles received from Mexico he recognized two species, *Dahlia pinnata* Cav. and *D. coccinea* Cav. The former, which showed great variation in its progeny, has since been called *D. variabilis* Desf. and *D. rosea* Cav., but according to the rules of botanical nomenclature the name *D. pinnata* must stand. *D. coccinea* does not cross readily with other species, and its flower color is confined to scarlet and shades of orange.

At the time Cavanilles received the shipment of dahlias from Mexico a great deal of interest was being manifested by botanists and plantsmen of Europe in plants from the New World. Within a few years seeds of the dahlia were sent to a number of botanic and private gardens in Europe. In 1798 seeds were sent to Kew Gardens in England, but apparently plants from the seeds died before they reached maturity. By 1803 an English plantsman had flowered *Dahlia coccinea*, for in Curtis' Botanical Magazine of 1804 appeared a colored figure with the statement, "Our drawing was taken in June 1803 at Mrs. Fraser's, of Sloane-Square, who has the credit of introducing this ornamental plant among us from France."

From 1804 to 1806, shortly after Alexander von Humboldt sent seed from Mexico to Paris and Berlin, a phenomenal increase in the number of dahlia varieties occurred. Within 12 years nearly every color that we have today had appeared in the flowers. In 1806 the Berlin Botanic Gardens had growing 55 single and semidouble varieties. Two years later the first perfect double dahlia was raised by Hartweg at Karlsruhe, and the year following a variety with single white flowers was developed.

By about 1810 the dahlia became exceedingly popular and growers sought assiduously to improve and create better double flowers within the genus. Both in the British Isles and on the Continent new forms, showing doubleness and brilliant colors, were developed. In the Botanical Magazine for 1817 an illustration revealed a rose-colored dahlia that originated in France and showed the form of the decorative dahlia as the type is now known.

From 1810 to 1850 interest in the dahlia increased tremendously. The ease with which hybrid seed could be secured, because of relatively self-sterile flowers, the short time required to produce new varieties, and the extreme variation secured both in sizes and colors of the flowers all contributed to the popularity of this new plant. Of particular interest in revealing the quality of dahlia varieties of that time is The Annual Dahlia Register for 1836. This contains particulars of the introduction of the dahlia into England and, most important, has as illustrations upward of 50 highly colored figures of dis-

similar dahlias. It also contains an index of 700 varieties of the dahlia that were recognized as such at that time. The illustrations in this book show double flowers exclusively, all with a colorful array of petals in very dense, round heads, arranged very geometrically. It was this stiff, formal, double flower that was so popular in the first half of the nineteenth century, and the type in which interest waned to a marked degree in Europe shortly afterward.

Seed of the modest dahlias that had been sent abroad from North America were returned to their native shores and yielded plants with flowers of an endless array of color patterns and degrees of doubleness. In the United States the craze for new dahlia varieties was nearly as acute as it was in Europe, and likewise, interest in the stiff, formal flower began to wane about 1860.

The first National Dahlia Society was organized in Great Britain in 1870, and about that time the diminutive pompon type of dahlia was developed, but these two events did not serve to recreate any great amount of interest in varieties then existing.

About 1864, however, an event happened that brought renewed interest in the dahlia through the discovery of a species with characters far different from and superior in many ways to those in the dahlia varieties known at that time. One M. J. T. Berg, of the Netherlands, received a collection of plants from Mexico. Included in this shipment was one dahlia root with just sufficient reserve food remaining within it to send up one shoot. In the fall this shoot produced a brilliant, blood-red flower of a shape never before recorded. The quilled petals, typical of the dahlia of that time, were lacking, and in their places were petals that were recurved, with pointed ends. The plant was tall and sturdy and carried its flower well above the foliage.

This new dahlia was given the name *Dahlia juarezii* Hort. in honor of the then President of Mexico. It received the name "cactus dahlia" because of its resemblance in form and color to the blossoms of a cactus. This plant was to play an important part in the development of superior varieties and to become the progenitor of two new classes of dahlias, now collectively referred to as the cactus and hybrid-cactus types. The species reached England and was first illustrated in the Gardeners' Chronicle in 1879.

All efforts to trace the origin of this new dahlia failed until 1916, when Wilson Popenoe discovered the probable ancestral home of *Dahlia juarezii* in Guatemala. The primitive species he found there has a single row of eight long, spreading, crimson rays turning backward along the margin. This species was named *D. popenovi*, and it is believed to be one of the ancestors of *D. juarezii*.

It was fortunate that *Dahlia juarezii* was discovered, for in the latter part of the nineteenth century there was, both in the United States and abroad, a reaction against formalism in all arts. The stiff formal dahlia flowers that had been the rage for the past half century were outmoded. This served as a challenge to the breeders of dahlias, and, having in their possession a new species of dahlia exhibiting characters that were in demand, they began to breed new varieties to suit the public's fancy.

This activity went on for a number of years, and the progeny resulting from crosses with the new-found *Dahlia juarezii* created

great interest, particularly at dahlia exhibitions. The very fact that the flowers were displayed mostly at flower shows, however, ultimately created still another problem for the plant breeder. Interest had been centered chiefly in new and superior blossoms, while the structure of the plant upon which these flowers were borne was neglected. Consequently the new varieties possessed very weak stems and were suitable only for cut-flower exhibition purposes. As interest in outdoor displays developed, breeders were faced with the task of increasing plant vigor to reach parity with the excellence of flower quality.

Within the last 20 years much has been accomplished in securing superior varieties of dahlias. Varieties having weak short stems have gradually been supplanted by more vigorous types, and breeding has reached a high level. The number of named varieties now existing is well over 7,000, for in 1924 J. B. S. Norton published a book entitled "Seven Thousand Dahlias in Cultivation", and the number has been added to greatly since that time.

Many dahlia societies have been organized in both the United States and Europe and these have stimulated interest in the improvement of dahlia varieties. In the United States the American Dahlia Society has functioned for two decades. One of its outstanding activities is the publication of a quarterly bulletin dealing with all aspects of the culture and breeding of the dahlia. This organization also stimulates interest in the development of superior varieties by conducting flower exhibitions and trial gardens where new varieties are grown, evaluated, and exhibited.

These developments have led to considerable confusion in attempts to classify, especially for exhibition purposes, the various garden types now existing. In an effort to simplify the classification of the host of new varieties that have been developed, the American Dahlia Society had adopted a classification based on the form and size of the flower. Fourteen classes are provided for the systematic arrangement of all the various types of dahlia flowers. A number of these classes are subdivided according to the size of the flower.

Other countries also have their classifications for dahlias. A great deal of pioneer work in this direction was performed by the Royal Horticultural Society and the National Dahlia Society in Great Britain.

Worthy of special comment in considering the development of superior dahlia varieties are the trial grounds where new varieties are grown, studied, and evaluated. The American Dahlia Society has such a garden in cooperation with the Connecticut State College at Storrs. Each year a field day is held at the trial grounds, when new varieties are inspected and evaluated. Competent judges pass on the merits of each new variety, and thus the value of new kinds can be impartially reported to those interested in dahlias. Other trial grounds are conducted by State and regional dahlia organizations; these plots permit the study of the same variety under varied climatic and other environmental factors.

Scientific research has revealed in the dahlia an interesting story of the inheritance of color. In the comparatively new field of cytogenetics, investigations conducted by Lawrence (*310, 311*), curator, the John

Innes Horticultural Institution, Merton, England, are noteworthy. This work indicates how the lineage of dahlia species and varieties can be studied by modern scientific methods. Lawrence found that the colors in all available dahlia species fall into one of two color groups: (1) Pale to deep magenta over ivory-white ground color, and (2) orange to scarlet over yellow ground color. One important exception Lawrence noted was that in the so-called species *Dahlia pinnata*, more popularly known as *D. variabilis*, which is considered the source of most of the garden varieties, the flower color is made up of a combination of both of these color groups. Furthermore, through cytological studies, he found that this same plant has 64 chromosomes in the vegetative cells, or twice the number usually found in species of the dahlia. These two facts indicated that *D. pinnata* is itself a hybrid. Such work, besides aiding the taxonomist in systematizing dahlia nomenclature, is of value to plant breeders in their efforts to produce superior varieties of plants.

Lawrence's work also dispelled the widespread erroneous belief that the extreme variation of *Dahlia pinnata* showed the degree to which a species could vary following domestication. This extreme variation was shown to result from the complex genetic make-up of a hybrid which combined various specific characters brought together during the descent of the genus *Dahlia* from a primeval stock. This coupled with multiplication of chromosome numbers probably accounts for the present variability of the stock.

The dahlia, like many other perennial ornamental plants, is readily propagated vegetatively. As a consequence it is not necessary to develop lines that are pure or homozygous, as is necessary with plants propagated from seed, in order to perpetuate the same characters in subsequent generations. Ease of vegetative propagation of the dahlia is particularly fortunate because its self-sterility enforces cross-pollination, thereby maintaining a high degree of hybridity in the genus and making pure-line breeding laborious and difficult. Despite these complications, however, the development of reasonably pure-breeding stocks may have to be undertaken in the future by plant breeders, not so much in order to produce dahlias of superior ornamental value as to develop types resistant to or immune from plant pests.

Gladiolus

The superior varieties of gladioli grown today have been developed largely through work that began scarcely more than a century ago. It may be assumed from ancient writings that the Greeks and Romans made use of native gladiolus species for ornamentation, and it is certain that there were species of the gladiolus, known as Corne Flags, in Britain as early as 1597, when they were recognized as important garden plants by Gerarde. But it was not until 226 years later that the first important hybrid gladiolus was produced.

Interest in Europe was at first limited to the species native to southern Europe, Asia, and Persia. They numbered but 15 and were never very popular with gardeners. Early in the seventeenth century the development of these species came to a standstill. It was more than a century later, when new species first started coming in from southern Africa, that renewed interest was gradually stimulated in the gladiolus.

In the eighteenth century botanists and explorers became increasingly aware of the new species of plants to be found around the Cape region of Africa, but it was not until the close of that century, when the Cape of Good Hope became subject to Great Britain, that large importations to Europe were received. William Herbert, dean of Manchester, seems to have been one of the first to recognize the value of the Cape species of gladioli, for in 1820 he wrote:

I am persuaded that the African Gladioli will become great favorites with florists, when their beauty in the open border, the facility of their culture, and the endless variety which may be produced from seed by blending the several species are fully known, nor will they be found to yield in beauty to the Tulip and Ranunculus.

Dean Herbert, besides contributing valuable information to horticultural literature, was also an enthusiastic cultivator of gladioli and was regarded as an authority on Cape bulbs. He carried on considerable hybridization with the species of gladioli and recorded in the horticultural literature a large number of his successful crosses.

During Dean Herbert's time the first important hybrid appeared at Colville's Nursery, Chelsea, England, in 1823. It was derived from *Gladiolus tristis* L. var. *concolor*, with *G. cardinalis* Curt. as the pollen parent. This new variety was given the Latin name *Gladiolus colvillei* Sweet and was known commonly as Colville's corn flag. It was described as being tall and vigorous with flowers of bright scarlet with lanceolate blotches of white on the three lower petals. There are today several named varieties persisting in the trade that came directly from this outstanding hybrid. In the United States they are generally grown under glass in the East but will grow out of doors successfully in the milder climates along the west coast.

Fifteen years later the second important hybrid, which was named *Gladiolus ramosus* Paxt., was produced in France. It was first flowered by M. Rifkogel in 1838. Records indicate that this hybrid resulted from a cross between hybrids of *G. cardinalis* and *G. oppositiflorus* Herb. It bore a tall flower spike with heavy broad leaves. The flower was openly funnel-shaped and bright red with deep blotches at the bases of the three lower segments. The fact that it bloomed later than other varieties of its time made it important for at least the next 20 years.

Until 1841 there was a mild yet increasing interest in gladioli, particularly among amateurs, but that year a variety was introduced that caused the greatest stimulation ever evidenced in the history of gladiolus breeding. M. Beddinghaus, gardener to the Duke of Aremberg, had been breeding gladioli for a number of years, securing for this work as many species as were then available. Louis van Houtte, of Ghent, Belgium, realizing the potentialities of one of M. Beddinghaus' productions, immediately purchased the stock, and in 1841 *Gladiolus gandavensis* Van Houtte was introduced to the world. Van Houtte named this gladiolus after the city of Ghent and described it in glowing terms as bearing majestic flowers, numbering 18 to 20, of the most charming vermilion, the inferior petals adorned with chrome, amaranth, and brown. For a long time there was considerable controversy concerning the parentage of *G. gandavensis*. It is now accepted that this new variety resulted from a cross between *G. psittacinus* Hook.

and *G. oppositiflorus* or between hybrids from these species. Napoleon III heard of this variety, which had "created a furor in the gladiolus world", and some of the plants came into the possession of Souchet, gardener to the Emperor at the court of Fontainebleau. Souchet, using *G. gandavensis* as one of the parents, developed many new hybrids, which in time were the talk of Europe.

In England Dean Herbert kept in close touch with new gladiolus varieties and continued the pioneer work he had started, using new species and varieties in his breeding work as they became available. Representing the trade in England, James Kelway, the founder of the Langport firm, was alert to the rapid development of the gladiolus and secured hybrids from Souchet in France to develop them further and make them available for sale in England.

Queen Victoria's visit to Fontainebleau in 1855 is reputed to have stimulated a tremendous interest in the gladiolus, for she saw and greatly admired the new varieties developed by Souchet and exhibited by Napoleon III. By 1880 over 2,000 named varieties had been developed that showed characters derived from *Gladiolus gandavensis*.

Victor Lemoine was greatly interested in the development of new gladiolus varieties and the next race of hybrids of considerable importance resulted from his work at Nancy, France, around 1880. Crossing *Gladiolus gandavensis* with *G. purpureo-auratus* Hook., which was introduced in 1872, he obtained a race called *G. lemoinei* Hort. These varieties were characterized by their large flowers and the prominent blotches in the throat of the florets.

Meanwhile Max Leichtlin, of Baden-Baden, Germany, crossed *Gladiolus gandavensis* with *G. saundersii* Hook. f., which had been introduced from the Cape in 1870, and *G. leichtlinii* Baker was produced. This stock was ultimately purchased and imported by John Lewis Childs, of Long Island, N. Y., and renamed *G. childsii*. W. Van Fleet crossed a variety of *G. childsii* with *G. cruentus* Moore and secured, among many others, his famous variety Princeps. The *purpureo-auratus-gandavensis* hybrids developed by Lemoine were crossed by him with *G. saundersii* and a new race called *G. nanceianus* Hort. resulted, which was characterized by plants having remarkably large, open flowers with contrasting color mottlings in the throats.

Gladiolus primulinus Baker has been the most recent introduction to greatly influence the development of gladiolus varieties. This species was found in the Rain Forest near Victoria Falls on the Zambezi River in Africa. It was successfully introduced and flowered at Kew Gardens, England, in 1890. Since then it has played an important role in modifying gladiolus flower form and color. French, English, and American plant breeders have all taken part in developing new varieties with some of the characters of *G. primulinus*. The most outstanding characters it transmits are a light and graceful flower stem, a more or less pronounced hooding of the flowers, and a subduing of brilliant hues to soft pleasing colors. In turn the progeny from *G. primulinus* have been improved by increased flower size and more vigor in the flower stem.

Noteworthy also are the ruffled gladioli, which have been developed in the United States by A. E. Kunderd, at Goshen, Ind., starting about 1907. Later he also developed a strain having fringed and laciniated

segments, which has created much interest. Foremost among the Canadian pioneers in the development of the gladiolus was the late H. H. Groff, of Simcoe, Ontario. About the end of the nineteenth century he had developed a strain called Groff's hybrids, which were considered noteworthy, particularly because of the wide range of color they possessed.

At the present time there are many amateurs and professional and commercial growers deeply interested in the breeding of new and superior varieties of gladioli in the United States. The American Gladiolus Society, organized in 1910, did a great deal to encourage the production of new and finer varieties, as well as to straighten out nomenclature. It publishes a monthly, the Gladiolus Review, in which registrations of new gladiolus varieties are included. This organization sponsors affiliated State and regional societies and conducts an annual gladiolus show where new varieties are exhibited and evaluated.

Governmental agencies have also contributed to the development of the gladiolus. Particularly noteworthy is a series of publications during the last 20 years from the New York State College of Agriculture, Cornell University, by A. C. Beal, A. C. Hottes, and A. M. S. Pridham of that institution on the development of superior varieties of gladioli. At Cornell University there is a test garden in which most of the available species and varieties of gladiolus have been grown and studied. Likewise, at the New York Botanical Gardens a collection of gladiolus species is maintained.

Recently a technical paper has appeared written by Bamford (*10*), of the Maryland Agricultural Experiment Station, who collected many gladiolus species and varieties and made detailed chromosome counts. His work greatly expands similar studies on the same subject by M. Ernst-Schwarzenbach (1931) in France and by McLean (*326*) in the United States. Such cytological studies are of great help to the geneticist in his attempts to classify material and breed superior varieties.

This brief discussion serves to direct attention to the great complexity of the inheritance of modern gladiolus varieties. Original species have been combined and hybrids have been crossed and recrossed until the resulting multiple hybrids possess characters derived from many different species. Superior characters have been combined and varieties have been selected covering a wide range of usefulness, from the requirements of the florist who forces plants under greenhouse conditions to those of the amateur flower lover who demands a wide range of color and form for flowering through the summer.

How much more can be accomplished in the development of the gladiolus is a matter of speculation. When it is realized, however, that less than a score of the more than 150 known species have been used to any extent in the development of over 2,500 varieties of gladiolus in commerce at the present time, it seems probable that present and future plant breeders can still draw from the remaining species to give to the world even more desirable gladioli than we now enjoy.

Hemerocallis (Daylily)

The daylilies had not received much attention from breeders until the last decade of the past century. Previous to this a few species had been grown in Europe. They were first mentioned by Pena and

Lobel in 1570, when these authors described what is probably the common Lemon daylily. A few years later Lobel described a second species with single cinnabar-red flowers. These two were apparently the only ones known in Europe for the next 200 years. Unfortunately little is known of the situation in China and Japan before the nineteenth century.

In 1768 a third type was mentioned in Europe, but its exact origin is unknown. It was regarded by some as being a minor variety of one of the two older established types. About 1798 another new type appeared, this time imported from the Orient into England. No new ones were introduced until about 1934, when a semidwarf form was brought in from Japan. In 1856 another semidwarf appeared, and this was followed in 1860 to 1864 by double-flowered forms.

The first actual breeding of daylilies probably dates from about 1890. Previous to this all new types that had appeared in Europe and the United States were simply plant importations from the Orient. The development of new types from seedlings was begun about 1890 by George Yeld in England. His first introduction, named Apricot, appeared in 1892. A more recent contributor is A. B. Stout, of the New York Botanical Garden. He has attacked the breeding problem from a scientific angle, and it is to him that we owe the greatest part of the genetic information now available on this group of plants. The breeding of new forms has increased so rapidly, chiefly as a result of his research, that there are now probably more than 300 different varieties.

The breeding of daylilies is handicapped by many obstacles. Among these are self-sterility and cross-sterility, which inhibit seed setting, the hybrid nature of the available types, and the comparatively slow rate of increase after a desirable variety has been developed.

The types of sterility encountered may, according to Stout, be classified into four groups:

(1) There appears to be lack of affinity between certain species in the relations of fertilization. Yet hybrids have been obtained from many of the combinations between species.

(2) There is much abortion of pollen grains and egg cells in certain hybrids, such as *Hemerocallis flava* L. × *H. nana*, and in triploids, such as the Europa daylily. This condition greatly reduces the chance that a plant will bear seeds, but there may be a few viable pollen grains, in which case the plant may be used as a pollen parent.

(3) There is abortion of pistils in the older triploid double-flowered forms, although some viable pollen is formed.

(4) In daylilies there are many types of incompatibility. Some plants set seed only when self-pollinated, others when pollinated by sister plants, and still others only when cross-pollinated by certain other species. Studies have been made which show that in some cases of sterility pollen tubes grow poorly in the style or fail to enter the ovary. Some clones are completely self-sterile, others set a few seeds when self-pollinated.

The wide variation in any group of daylily seedlings is rather striking. Even seedlings of the older, well-established clones are usually very inferior to the parent type. This indicates, of course, that daylilies are probably heterozygous for a large number of genes. The chances of securing improved types depend almost entirely on the

number of seedlings grown. According to Stout, only 14 superior seedlings were found out of a total of 15,000 grown. Others apparently had some merit, since about 100 more were saved for use in selective breeding.

The present information on daylilies indicates that many new types can be developed by intercrossing the existing clones. Because of the heterozygous nature of the material, lack of genetic data, and general self-sterility, a scientifically planned breeding attack is difficult. About all that can be done at present is to grow large populations and select the superior types either for introduction or further breeding. It would be desirable to establish some self-fertile lines so that a genetic analysis of some plant characters could be made.

The cytological investigations of daylilies have shown some interesting results. The basic chromosome number of all the species appears to be 11. The common European form of *Hemerocallis fulva* L., which Stout calls Europa, has 33 chromosomes and is therefore a triploid. According to Belling and Stout this species shows considerable irregularity in the formation of pollen cells, so that very few good pollen grains or egg cells are formed. Further studies by Stout showed that triploidy was fairly common in daylilies and this may account for some of the prevalent sterility.

Iris

The garden irises may be grouped in several classes, such as the bearded, beardless, and bulbous types. This discussion is limited to the commonly cultivated tall bearded type. As is true of many other ornamental plants, the early history of the iris is shrouded in mystery. According to J. C. Wister, bearded irises are native to central and southern Europe and Asia Minor, in a region extending from the Alps through Italy, Hungary, Bulgaria, Palestine, and Iraq. There are no records of when man first began to cultivate the wild types, but it was probably very early, since the ancients attributed various medicinal properties to the rootstocks

Iris albicans Lange is the first species about the culture of which there is definite knowledge. This iris probably originated in Arabia and was carried all over southern Europe by the Mohammedans, who planted it on the graves of their soldiers. There are no records as to when this practice was begun, but by 750 A. D , when the Mohammedans were driven out of Spain, the species *albicans* was already well established there.

The first reference to the growing of the iris in European gardens was in 1790. At this time about a dozen wild forms were listed in several garden catalogs. The next 60 years saw a rapid increase in the popularity of irises, and it was during this period that the first iris breeding was begun. Prominent among the early workers were Lemoine, Jàcques, and Salter, who produced many new improved forms. Unfortunately there are no authentic records of what these three men did, and any varieties they may have named have been lost. The first authentic record of named iris seedlings was as recent as 1855. At this time M. Dauvesse, a nurseryman of Orleans, France, offered a half dozen or so new varieties.

Within a dozen years thereafter the growing of iris seedlings was undertaken by many people. The most prominent of these were

Louis Van Houtte and Verdier of France, Krelage, Roozen, and Van Leeuwen of the Netherlands, and Peter Barr of England.

Previous to 1890 it seems that most of the new seedlings were derived from the two species *Iris pallida* Lam. and *I. variegata* L. The results were limited by the potentialities of these two species. Sir Michael Foster about 1880 began collecting iris species and forms from all parts of the world to use in his breeding program. The results of some of his crosses were so striking that other breeders were stimulated, and soon a number of new species combinations began to appear. It is likely that errors of nomenclature may have crept into some of this early work, and there may be some doubt about the alleged parentage of some of the crosses.

Figure 18.—Grace Sturtevant, one of the leading iris breeders in the United States. Some of our finest iris varieties owe their origin to her.

Among the modern iris breeders of Europe, the late A. J. Bliss, of England, is probably the best known. He was interested in studying the relationships of many of the present varieties, but he also developed some very fine new ones. He did not specialize in one type of flower but was interested in a wide range of forms.

The history of iris breeding in the United States dates back to about 1905. At this time Bertrand H. Farr, of Pennsylvania, introduced a collection of superior new varieties from the English firm of Barr. Working with this material, he was able in 1909 to introduce some excellent new seedlings. This work soon stimulated widespread interest, and very shortly large numbers of amateur growers were producing seedlings. In an article of this length it is obviously impossible to mention all the American breeders.

One of the most careful and prolific workers is Grace Sturtevant, of Massachusetts (fig. 18). She has continuously maintained a collection of the very finest varieties to use as parent plants and has developed over 40 new worth-while introductions. Among them

Afterglow, B. Y. Morrison, Queen Caterina, Reverie, and Shekinah are of exceptional merit.

Another American breeder who developed some excellent new varieties was Edward B. Williamson, of Indiana. From about 1910 until his death in 1933 he introduced many new irises. One of the best known came from crossing about 500 flowers of the variety Amas with other varieties. Only one seed pod was formed in these crosses, and one of the seeds in it produced the seedling later named Lent A. Williamson.

J. C. Nicholls, Ithaca, N. Y., is credited with very careful work on iris breeding. He rigidly selects the parents for each cross and keeps a very careful set of records of all his work.

On the Pacific coast, the work of Sidney B. Mitchell and of E. O. Essig is noteworthy. Mitchell has developed many excellent new varieties and recently has devoted most of his time to development of new yellow types. Essig began iris breeding as a hobby and has carried on a series of careful experiments on seed germination under different conditions. He also has introduced several excellent new seedlings. Other American breeders of note are J. M. Shull, of Washington, D. C., and the Sass brothers, of Omaha, Nebr.

The methods employed by some of the better iris breeders are illustrative of the large amount of work necessary to produce really superior types. The late Edward B. Williamson formulated a plan to assure a higher degree of success with his crosses. From his early experiences he knew that many crosses would not produce seed, and the only way to discover which would was to attempt the cross. He decided to use a mixture of pollen in all crosses, reasoning that the prospect of getting some seed would be much better since there was a chance that one or more of the pollens used would be effective. The pollen was gathered from hundreds of flowers and mixed in a receptacle. From 1925 until his death in 1933 he planted each year from 70,000 to 100,000 seeds He never introduced more than 10 seedlings in any year. The percentage of worth-while varieties is thus rather low.

The methods of J. C. Nicholls are in decided contrast to those of Williamson. Accurate records of both parents are kept. Parents are selected with care, and about 3,000 seeds are planted each year. It is rarely the case that more than 1 iris worthy of varietal status is found in 1,000 seedlings.

Unfortunately little or nothing is known concerning inheritance in iris. Bliss made some preliminary observations on inheritance of leaf pigmentations and coloring of the beard, but the evidence is too meager as yet to warrant a genetic analysis of these characters.

The very early iris breeders simply planted seed and hoped something good would turn up. At the present time the better breeders choose both parents with care and control all crosses. This information about parental stocks, however, has little actual value unless the frequency of superior seedlings arising from each cross is known. Since many of the crosses give only a few seeds or none, a summation of data for the same cross from various breeders would certainly be

worth while. If such information were available a table of breeding qualities of various varieties could be made that would be of some value. Undoubtedly some of the more careful breeders have this sort of information on their own work, but it has not been collected and published.

According to the experience of some iris breeders, one of the serious problems has been sterility. Some varieties are both cross-sterile and self-sterile, others are cross-sterile and self-fertile, others cross-fertile and self-sterile, and still others both cross-fertile and self-fertile. In some cases there are differences of opinion concerning certain varieties, which indicate either an error in nomenclature or that the same variety behaves differently in various localities. In general it can be said that crosses between closely related types have the best prospect of producing seed, with less and less success as the varieties are more distantly related. Likewise, hybrids between closely related types are most likely to be fertile.

Another difficulty is slow and sometimes poor seed germination. To a geneticist attempting to work on the inheritance of some character this is a great obstacle. Whether or not it is due in some cases to poor horticultural practice, it is one of the things that will have to be overcome before much real genetic research can be accomplished.

Lily

To many people in the United States the word lily is closely associated with thoughts of Easter, and they are familiar with only the large-flowered, so-called Easter lily, *Lilium longiflorum* Thunb. This lily is widely grown by florists, who force it for sale as potted plants and also as cut flowers. Easter lilies are rarely grown in outdoor gardens except in very mild climates where they are able to survive the winters and are not exposed to late spring frosts.

One of the best known of the other lilies is the popular so-called Tiger lily, *Lilium tigrinum* Ker. This old-fashioned favorite is a very hardy species and has become widely distributed throughout most parts of the country. Not long after it was introduced from China it escaped from cultivation and is now found growing wild in many sections.

Table 2.—*Species of Lilium classified according to date described and continent of origin*

[Compiled from Stoker (*494*)]

[1] Duplicate.

Until very recently only a few lily enthusiasts were familiar with the many beautiful garden forms now available. Most of these new types are wild species from afar that have been introduced by plant explorers. Asia has furnished nearly two-thirds of these, as is shown in table 2. Until quite recently the species introduced by plant explorers more than met demands for new types. The prospect of finding striking and distinct new forms in the wild is now rapidly diminishing, for they do not readily escape the eye of the botanical explorer. Since this is true, it seems that in the future new and superior lilies must come from the plant breeder rather than the explorer.

As recently as 50 years ago only a dozen species of *Lilium* were grown in England, and few sources of bulbs or seeds were available to enthusiasts who wished to grow others. At the turn of the century interest in lilies was waning, but was revived by the introduction of the easily grown *Lilium regale* Wils. from China in 1904. Other new forms from China followed, including *L. sargentiae* Wils. and *L. willmottiae* Wils. The formation of a lily committee by the Royal Horticultural Society and publication of its Lily Yearbook, beginning with 1932, also stimulated interest in England. In the United States the popularity of lilies has kept pace with the growing interest in flowers in general, and the American Horticultural Society has appointed a lily committee this year (1937). New hybrids and more readily available stocks of lily species have also encouraged wider use in gardens everywhere.

A uniform system of naming lilies is essential to an intelligent discussion of lily breeding. Unfortunately for the general public only a few species have well-recognized common names. The use of botanical names is general even in popular accounts, and while these may have a forbidding technical appearance, yet they are in most instances the only generally accepted designations available. For example, the popular Regal lily is known to all botanists and lily enthusiasts as *Lilium regale*. Since most lily breeders become interested in the relationships of the various forms, an outline of the division of the genus *Lilium* into subgenera and sections has been included in the appendix. In this appendix also is a list of lily hybrids, including reports of species crosses from which no named hybrids have been grown. Such a list should be helpful to the amateur hybridizer in pointing out which crosses are readily made and which combinations are difficult or not yet accomplished.

On this continent notable contributions to our array of garden lilies have been made by the late David Griffiths (fig. 19), of the Department, and by Isabella Preston, of the Dominion Experimental Farm at Ottawa, Canada. Griffiths is best known for his work on the propagation of lilies, but he developed and distributed a number of fine Martagon hybrids (*152*), one of which is Star of Oregon. Miss Preston has made great numbers of cross-pollinations with the principal objective of developing hardier lilies for Canadian gardens. Some of her named productions are George C. Creelman, Davmottiae, and the more recent Grace Marshall, Lila McCann, Lilian Cummings, and Phyllis Cox. Many amateurs are active in the United States and in Canada, and some fine hybrids have resulted from their efforts.

In England the Backhouse hybrids produced by Mrs. R. O. Backhouse of narcissus fame are perhaps the best known of the newer lilies, but activity is widespread there as well as on the Continent of Europe.

In the literature of lilies the notation of hybrids has been so casual that Miss Preston felt it desirable to state: "In my notes the seed parent is placed first" (*410*). Other writers have departed from this practice so commonly that it is only by chance reference to one or the other species as seed parent or pollen parent that the reader can tell which cross is discussed. It should also be pointed out that some reported hybrids are based on inferences as to what the parents should have been to produce the observed effects, and, further, that some reported hybrids may be merely asexual offspring of the seed parent. Natural hybrids are not common in *Lilium*, at least in England, according to Grove (*155*); but Preston (*410*) reports two from Canada. *Lilium testaceum* Lindl., *L. elegans* Thunb. (syn. *L. thunbergianum* Schultes), and *L. umbellatum* Hort. are all recognized as hybrids of long standing, in the origin of which man may have played no part.

Figure 19.—The late David Griffiths (1867–1935), who did outstanding breeding work on lilies and narcissus while a member of the United States Department of Agriculture. He is also well known for his work on methods of propagation and production of tulips and hyacinths.

Several examples of supposedly hybrid seedlings that appeared to be identical with the maternal parent were recorded by Parkman (*402*) in 1878. He found that *Lilium superbum* L., emasculated and pollinated by *L. auratum* Lindl., *L. tigrinum* Ker, *L. chalcedonicum* L., or various other species, produced seedlings that were always pure *L. superbum*. When these seedlings were pollinated with other species, the second generation was still unchanged *L. superbum*. Similar results followed the application of pollen of other species to *L. umbellatum* Hort., and the Easter lily, *L. longiflorum*. Griffiths has commented that maternal inheritance is remarkably prevalent in lilies, and (*154*) that *L. regale* yields better results when used as a pollen parent because of this tendency. Stout (*497*) concedes that seedlings of maternal character in *Lilium* may result from wide crosses, without fertilization and production of true seeds. Preston (*409*) has found that seedlings of *L. regale* pollinated with *L. speciosum* Thunb. var. *rubrum* Hort. or with *L. longiflorum* are strictly maternal in character, and that the progeny of a *L. regale* × *longiflorum* cross remained pure *L. regale* in the second generation.

Further reports of similar nature could be cited. Such results might be attributed to late or incomplete emasculation or to ineffective protection against pollen of the maternal species, but such explanations cannot be pressed in the face of reports from careful hybridizers. Some form of parthenogenesis must be assumed in the production of such pseudohybrids, as is suggested by Hall and his coworkers (*191*):

> The possibility has to be borne in mind that crossing certain lilies may not result in producing true seed, i. e., by sexual union of the pollen cell with ovule. Excitation due to the foreign pollen may induce the formation from the ovule of a "seed" which is really a bud of the mother plant into which the pollen has not entered.

It has already been mentioned that many hybrid lily types of the past century in particular were noted alike for their beauty and their quick disappearance. Striking examples are Parkman's *Lilium speciosum* × *auratum* (1869) and the reciprocal cross produced by Hovey about 1880, each of which persisted scarcely long enough to be admired and photographed. Most of Burbank's productions are now only memories.

Premature passing of some hybrid types is clearly due to misfortunes of culture before the stock was developed to commercial quantity. It was Griffiths' aim to stress the need for rapid, efficient vegetative propagation to insure establishment of a desirable hybrid as soon as possible, and he devoted much of his energy to improving methods of propagation with this in mind. Some desirable hybrids are inherently slow or difficult to propagate (*151*) and may be lost through the producer's haste to market his creation. Other hybrids, of course, are genetically weak and incapable of long survival, an extreme example of which is the albino seedling.

One of the least excusable reasons for loss of a hybrid is failure to recognize the necessity of vegetative propagation if the stock is to be kept true to type. Very frequently seed of a promising hybrid lily is offered for sale and the seedlings produced are sometimes called by the name of the parent plant. This is obviously a wrong procedure, since it would be very unusual for a first-generation hybrid to breed true. Griffiths (*151*) also calls attention to the fact that there has been a tendency to treat all the hybrids coming from a cross as a variety rather than selecting an outstanding one for vegetative increase as a clonal variety. Such practices have undoubtedly added to the present confusion regarding many named lily hybrids. They are contrary to the fundamental principles of genetics, and lily breeders will do well to discard them.

Another important reason for decline or loss of lily hybrid varieties is the presence of virus diseases such as mosaic (*155*). The viruses are carried in the living cells of the plant and are spread from plant to plant by aphids. When a diseased lily is propagated by division, by stem bulblets, or by scaling, each new plant produced will have the disease. No method is known by which such diseased lilies can be made healthy. If a new hybrid is attacked, it may as well be discarded. Fortunately these diseases are not commonly transmitted through the seed. Accordingly seedling lilies are usually free from virus diseases to begin with and should be grown at a safe distance from affected parent plants and other diseased lilies.

138904°—37——61

It is generally known that some species of *Lilium* do not readily set seed when pollinated with their own pollen. As early as 1890, Focke demonstrated that *Lilium bulbiferum* L. could be divided into certain groups which would set seed only when pollen was used from a member of another group (*497*). There are many references to the failure of the Madonna lily (*L. candidum* L.) and the Tiger lily (*L. tigrinum*) to develop seeds. Preston states that *L. testaceum* and *L. hansoni* Leichtl., as well as *L. tigrinum*, are self-sterile at Ottawa, Canada. She later (*410, 411*) reports a fertile strain of *L. tigrinum* that she has named "var. diploid." Griffiths cites *L. regale* and *L. longiflorum* as species that set seed only when different plants are interpollinated. Amsler (*4*) reported that *L. brownii* Poit. and *L. parryi* S. Wats. set no seed when selfed, but did when pollinated with other strains of the same species. Stout (*497*) and others who have studied self-incompatibility in *Lilium* made systematic trials with proper attention to emasculation, bagging, and hand pollination, and showed that failure of individual plants to set seed on selfing is widespread in lilies. *L. tigrinum* and its varieties *flore-pleno, splendens,* and *fortunei* are triploids (*191*), having 36 chromosomes, and rarely mature functional sex cells. The "variety diploid", however, has the normal diploid number of 24 chromosomes and is self-fertile (*497*). In other species the failure to set seed is not due to inability to develop functional gametes, as is shown by the successful results of interpollinating different lines within a species. Even the triploid *L. tigrinum* will sometimes set seed with the pollen of *L. leichtlini* var. *maximowiczi* (Regel) Baker.

Stout (*497*) mentions occasional instances of failure of lilies to form functional pistils or stamens. He also found poorly formed, nonfunctional pollen in the hybrid *L. testaceum*, which he explained as caused by hybridity and a like condition caused by triploidy in *L. tigrinum*, but he holds that incompatibility is the most important reason for failure to set seed in *Lilium*. In the species *L. henryi* Baker, *L. speciosum* Thunb., *L. superbum*, *L. elegans* Thunb., *L. bulbiferum* subsp. *croceum* (Chaix) Baker, *L. dauricum* Ker, *L. philadelphicum* L., *L. auratum* Lindl., *L. humboldtii* Roezl and Leichtl., *L. kelloggii* Purdy, *L. willmottiae*, *L. roezli* Regel, *L. longiflorum*, he found self-sterility to be the rule but some few individuals set a little seed with their own pollen. Among 59 plants of the common wild lily, *L. canadense* L., 4 fully self-fertile individuals were found, 6 partially self-fertile and 49 wholly self-sterile. Interpollinations of self-sterile plants were successful in nearly all cases. Over 100 plants of *L. hansoni* studied were fully self- and cross-sterile and may represent a single clone. This strain was, however, reciprocally fertile with a new strain of *L. hansoni* received from Manchuria. Stout found no fully self-fertile individuals in *L. candidum*, and cross-fertility was rare and partial until a new stock of unknown source was encountered. Species in which Stout found no self-fertile individuals are *L. hansoni*, *L. candidum*, *L. tigrinum* (excluding the "variety diploid"), *L. parryi*, *L. chalcedonicum* L., *L. brownii*, *L. grayi* S. Wats., *L. sutchuenense* Franch., and *L. maximowiczii* Regel (= *L. leichtlini* var. *maximowiczii*).

Now that the pitfalls of the past are better understood, lily breeding is undoubtedly on a surer basis and prospects are brighter than ever before. The importance of vegetative propagation of hybrids is

becoming recognized, and the methods of vegetative reproduction have been improved. All hybrids start as seedlings and are, therefore, usually free at first from virus diseases, since, as pointed out earlier, these diseases are not commonly seed-borne. This point has become widely appreciated, and efforts are being made to grow as many lilies as possible from seed. When mosaic-free stocks of garden lilies are more generally available, the prospects of increasing a hybrid clone to commercial proportions before it becomes affected will be greatly enhanced.

Some of the possibilities of hybrid combinations may be seen from the tabulation of reported hybrids in the appendix. Crosses are in general more successful within one section of the genus, but a number of successful combinations of Archelirion with Martagon and of Leucolirion with Martagon (see the appendix) are on record. Combinations not yet accomplished may succeed for the persistent breeder. Cytology reveals no discouraging differences in chromosome numbers, except in the case of the triploid *Lilium tigrinum.*

Some of the specific objectives of hybridizers are extension of the flowering season (*155*), extension of the color range in reliable garden forms (*151*, *155*, *410*), development of garden types even hardier than *Lilium regale* (*410*), and incorporation of superior vigor and adaptability in difficult garden subjects, such as *L. leichtlinii* Hook. f. (*155*), *L. humboldtii* (*153*), and others (*151*). Griffiths suggests *L. henryi* Baker as a promising parent carrying vigor and apparent tolerance to diseases.

Unfortunately, little is known concerning inheritance in lilies. Some of the species that are self-fertile do not give uniform seedlings, which indicates that they themselves are hybrids. This situation is to be expected because of the widespread self-sterility existing in the genus which makes cross-pollination necessary for seed setting.

Nasturtium

The native home of the nasturtiums (*Tropaeolum* spp.) seems to be the western coast of South America. They were found there by the early Spanish explorers and introduced by them to Europe from Peru. This probably happened sometime in the latter part of the sixteenth century. The two species that found favor in Spain were *T. minus* L. and *T. majus* L. From Spain they soon spread over most of Europe. In England they were known as "Indian Cresses", the name Indian being used because they came from the Spanish colonies in South America, which at that time were described as the Indies. At first the smaller-flowered *T. minus* was the most widely grown, but on the introduction of varieties of the larger-flowered *T. majus*, the small species was soon neglected. At the present time both types are found growing wild in many sections along the west coast of South America. The two species cross very readily, and many of the so-called Tom Thumb varieties are supposed to have originated in this manner.

The range of colors and color patterns in the modern nasturtium is one of the widest in the flower kingdom. In addition, some varieties are known to bear flowers of various shades on the same plant. The number of varieties listed today is very large, practically all having been developed by professional and amateur efforts.

Not much is known as to the inheritance of flower color. Rasmuson (*427*) has done some work and reports dark yellow as dominant to light yellow, and presence of red to its absence. He also crossed varieties bearing variegated flowers with some nonvariegated flower types. From these crosses he was able to determine that variegation was dominant. In the same investigations it was shown that the dark green color of the leaf was determined by two genes, green being dominant to yellowish green, and both to variegated.

In habit of growth the nasturtium may be divided roughly into three types—the tall or climbing, the bush, and the dwarf bush. When a cross is made between a pure tall and a bush, all the hybrids are tall, and in the next generation there is a ratio of 3 tall to 1 bush. This, of course, shows that climbing is dominant and controlled by a single gene.

Recently considerable interest has been aroused by the introduction of a double form which was named Golden Gleam (fig. 20). The origin of this variety is something of a mystery. It was found about 10 years ago by J. C. Bodger in a flower garden near El Monte, Calif. According to the owner, the seed had been brought into California from Mexico, where it had been introduced from Spain. A search for the type in Mexico, especially in the locality where it was reported, was unsuccessful.

The seed from the California plant was sown the next year and all seedlings proved to be doubles and true also for color. Within a few years the seed was increased to considerable quantities and the new variety introduced. Since other double-flowering plants of the same type were not found, it seems that Golden Gleam probably arose as a mutation from a single-flowered variety. There have been other double nasturtiums, however, one being known as early as 1730, when it was described and figured in colors in the Catalogus Plantarum. The horticultural flore-pleno type mentioned in Bailey's Cyclopedia is probably the same thing. This type, which is still grown to some extent in Europe, differs considerably from Golden Gleam. It is supposed to be entirely double, without production of pollen. Golden Gleam, on the other hand, has anthers and a pistil and sets seed.

Shortly after the discovery of Golden Gleam, cross-pollinations were made to develop other colors. This work was undertaken by Bodger and Burpee. As a result, several mixtures of colors and a scarlet double form appeared on the market a few years ago.

The inheritance of doubleness in nasturtiums has recently been worked out by Eyster and Burpee (*125*). According to these workers, singleness is a simple dominant to doubleness. When a pure single variety is crossed with a double, all the hybrids are single. In the second hybrid generation from such a cross, 78 plants were single and 27 double. This is very nearly a perfect 3:1 ratio. Since it is such a simple situation, we may expect to have all colors represented in the double type in a very few years.

A second double nasturtium has also appeared quite recently. It differs very markedly from both the Golden Gleam type and the earlier double reported from Europe. In the single flower there are five petals while, according to Eyster and Burpee, Golden Gleam varies from an occasional 5-petaled to a 15-petaled flower. The mean petal number

Figure 20.—The double-flowered nasturtium Golden Gleam. This variety was found growing in a garden at El Monte, Calif. It was reputed to have come from Mexico, but a diligent search in that country failed to locate any plants or information regarding it. (Courtesy of Bodger Seeds, Ltd.)

seems to be slightly under 10. The new double type, which is called superdouble, has from 40 to 50 petals, no pistil, and several modified stamens. It does form some good pollen, so it may be regarded as a staminate flower.

The origin of this new extreme double seems to have been spontaneous. It was first noticed in a greenhouse of several thousand double-flowered plants. Since it lacked pistils it could not set seed and had to be propagated by cuttings. The presence of some pollen, however, made it possible to use it as a male parent in crosses with singles and with doubles of the Golden Gleam type. When it was crossed with pure single plants, about half the hybrids were singles and about half superdoubles. Likewise, when crossed with Golden Gleam a 1:1 ratio of doubles and superdoubles was secured. From these results it is apparent that the new superdoubles are all heterozygous (impure) for the new character, which is obviously a simple dominant to both singleness and doubleness. If they had been homozygous (pure), all the hybrids would have been superdoubles in both instances. From this it can be seen that the production of new colors in superdoubles involves an actual hybridizing process. They can be made only by crossing a superdouble with a single or double of some new color. If the gene for superdoubleness is not in the same chromosome as the gene or genes for color, it will be a comparatively simple matter to provide the extreme double in the full color range of the ordinary single nasturtium. If the color gene and the superdouble gene are in the same chromosome the desired result can still be secured, but it will require the growing of a much larger population in order to get the new combination. Unfortunately, adequate linkage data are not available for nasturtiums.

Rose

The rose is one of the most widely grown and admired of all the flowers. There now exist several thousand named varieties in a wide range of color and form, including types for almost all conceivable conditions of growth. The greenhouse forcing roses, hardy outdoor varieties, climbers, bush, and polyanthas are some of the many types now grown. This wide variation and development has largely occurred in comparatively recent years.

The rose is one of the oldest of our cultivated flowers. It first appears in the early art of long-destroyed civilizations and is frequently mentioned in the Bible and in Greek mythology. It was undoubtedly the favorite flower of many of the rulers of Greece and Rome and was used as a symbol on their banners and shields. This early popularity continued on down through the Middle Ages, and roses were the symbols for the great houses of York and Lancaster in the so-called Wars of the Roses in England.

The genus *Rosa* is a large one with several races, widely distributed, and native mostly in the North Temperate Zone. However, a few species are found near the Equator and even above the Arctic Circle. Many of the finest are native to eastern Asia, but they have not been so highly developed there as in the western part, especially about the eastern end of the Mediterranean Sea.

In Europe during the sixteenth century only a few rose varieties were cultivated and at least half were singles. Two hundred years later there had been only a slight increase in the available varieties. In England at this time there were 21 species in cultivation, and about 30 double varieties. Importations were very rapid after 1789. In this year the Crimson Chinese Monthly, *Rosa chinensis* var. *semperflorens* Koehne, was introduced. Three years later the Macartney, *R. bracteata* Wendl., made its first appearance, and in 1796 *R. rugosa* Thunb. This was followed by *R. multiflora* var. *carnea* Thory, the first rambler rose, in 1804; *R. banksiae* R. Br., in 1807; *R. chinensis* var. *odoratissima* Lindl., the tea-scented rose, in 1809; and the Fairy rose, *R. chinensis* var. *minima* Rehd., and Eduard, a Bourbon type, in 1810. About 1816 a rambler rose, Seven Sisters, *R. multiflora* var. *platyphylla* Thory, appeared. This was followed in 1823 by the microphylla or small-leaved type, *R. roxburghii* Tratt., from China. While only meager records are available, it seems very probable that these new species were used in crosses with some of the native species such as *R. gallica* L., *R. rubiginosa* L., and the so-called Ayrshire roses. By 1829 R. Desportes briefly described 2,562 species or varieties then under cultivation in France. This enormous increase in so short a period is very interesting. It is extremely improbable that it was in any way caused by a sudden tendency to production of sports or mutations. Other factors are more likely to have been responsible, among which importation from other continents and the growing and selection of seedlings were probably two of the most important.

Cultivated roses were probably brought into the United States by the earliest colonists. Very little is known concerning them during these early days, and it was not until after the Revolutionary War that any account is found of the naming of a new variety. This rose, called Mary Washington, may very well be the first truly American production. Shortly following this the Champney or Noisette roses were developed, and soon after, in 1840, Feast Bros., of Baltimore, introduced hardy climbers having our native *Rosa setigera* Michx. as one parent.

At the beginning of this century, most of the rose varieties grown in the United States had originated in Europe. These importations were very frequently disappointing in their behavior, and it was soon realized that varieties should be developed under local environmental conditions. This situation stimulated the efforts of American rose breeders, and today there are hundreds actively engaged in this fascinating work. In an article of this length it is obviously impossible to cover all the contributions of these workers.

One of the earlier pioneers in the breeding of modern roses was the late E. G. Hill, of Richmond, Ind. His first activity with roses began in 1851 when he was employed in the nursery of T. C. Maxwell & Bros. at Geneva, N. Y., where he became familiar with the very best varieties then available. In 1865 the Hill family moved to Richmond, Ind., and in 1881 father and son launched the well-known firm of E. G. Hill. About 1891 Hill began importing the newer hybrid teas to test for cut-flower production under American conditions, and during this last decade of the past century he undertook his own breeding work. It was not until 1904 that two roses resulted which he believed

were superior. These were General MacArthur and Mrs. Theodore Roosevelt. In 1905 Richmond was selected from a large group of red seedlings. These popular varieties were followed by many others.

Another American breeder who introduced many well-known varieties is John Cook, of Baltimore. His first successful hybrid, Souvenir of Wootton, was introduced in 1888. Other well-known varieties developed by him are My Maryland, Radiance, Panama, and Francis Scott Key.

Alexander W. Montgomery, Jr., of Hadley, Mass., is another who has contributed valuable new varieties. Two of his introductions, Hadley and Mrs. Charles Russell, are still very popular. The Dorners, in La Fayette, Ind., have also produced several valuable roses. Probably the best known of these is the widely grown Hoosier Beauty.

The methods used by most of the amateur and professional rose breeders are probably very similar. In general, some ideal type is determined upon and the breeder attempts to secure it by crossing two varieties, each possessing some of the desirable characters. In many instances, the eventual result is far different from the predetermined ideal, in fact, may even surpass it. In general, only a few really successful new roses occur in a population of several thousand seedlings. As an illustration of the odds against securing a really desirable new seedling when varieties are crossed, the following is quoted from an article by Hill (*206*) in the American Rose Annual for 1917:

> From the 1914 crosses there were germinated over 2,500 seeds. Each little plant was given special culture, being planted in a bench where it received the same care as that required by the most important forcing varieties. In 1915 the first weeding out of the seedlings occurred, and by 1916 the 2,500 seedlings had been reduced to about 800. These were tested in blocks of five, receiving the most rigid attention and critical scrutiny.
>
> By the opening of 1917, the seedlings have been reduced to some fifteen sorts which Mr. Hill considers worth while going farther with. Of these fifteen several have been selected, named and registered, and propagation is proceeding with the idea of later dissemination.

From this group of 15 came: (1) Columbia, resulting from the cross Ophelia × Mrs. Shawyer; (2) Double Ophelia, from a cross between Ophelia and an unnamed seedling variety; (3) Rose Premier, from a cross between Ophelia and Mrs. Charles Russell; and (4) Mary Hill, from a cross between Ophelia and Sunburst.

Again quoting:

> Others of the fifteen sorts are full of promise and will be reported upon later. It may be observed that all of these roses are selected primarily from the forcing or commercial cut-flower standpoint, but it is by no means improbable that several of them may also prove as fine for outdoor use as General MacArthur.

A careful study of these results is very interesting. Suppose all 15 surviving seedlings are finally selected as worth while. The ratio of the total seedlings to the number of good ones is then 2,500:15, or about 1 desirable in 166. It is very probable that the ratio is often considerably greater than this, in some instances reaching odds of over 1,000 to 1.

The very wide variability exhibited by a large group of rose seedlings has been a constant puzzle to many rose breeders. As early as 1889

Lord Penzance, a prominent English rose breeder, published the following statement: "Roses of the first order are, after all, very rare in a sowing of seed, and their production is a veritable lottery, in which chance plays the principal part."

Until fairly recent years, most rose breeders did not even keep a record of parent varieties used in a cross. The lack of this information has been deplored by many observers, but it is doubtful whether such data would have the value apparently attached to it. For instance, the parentage of the widely-grown old favorite, Caroline Testout, is well-known, but it is very doubtful whether any breeder could repeat the cross and secure another Caroline Testout. It is not meant that such a result is impossible, but it is improbable. It might occur if a very large number of hybrid seedlings were grown. There is, however, a possible value in knowing the parentage of rose varieties. It is very probable that we should find certain varieties more apt to produce successful offspring than others. Such information might be helpful in planning cross-pollinations.

The extremely mixed heredity of rose varieties makes planned breeding very difficult. Since propagation is easily accomplished by budding and grafting, this heterozygous condition is not a handicap to the rapid increase of any variety.

TABLE 3.—*Roses developed by Walter Van Fleet*

Year	Variety	Type [1]	Parentage
1895	May Queen	H. W.	*Rosa wichuraiana* × Mrs. de Graw.
1895	Ruby Queen	H. W.	Queen's Scarlet × *R. wichuraiana*.
1895	Clara Barton	H.T.Poly.	Clothilde Soupert × American Beauty.
1895	Alba rubrifolia	H. W.	*R. wichuraiana* × Coquette de Lyon.
1900	Magnafrano	H. T.	Magna Charta × Safrano.
1895	Pearl Queen	H. W.	*R. wichuraiana* × Mrs. de Graw.
1900	New Century	H. R.	*R. rugosa alba* × Clothilde Soupert.
1902	Philadelphia	H. M.	Crimson Rambler × Victor Hugo.
1903	Beauty of Rosemawr	Bour.	
1898	Northern Light	H W.	
1900	Sir Thomas Lipton	H. R.	*R. rugosa alba* × Clothilde Soupert.
1904	Charles Wagner	H. P.	Jean Liabaud × Victor Hugo.
1902	American Pillar	H. W.	(*R. wichuraiana* × *R. setigera*) × a red hybrid perpetual.
1900	Birdie Blye	H. M.	Helene × Bon Silene.
1905	Rugosa magnifica	H. R.	*R. rugosa* × Ard's Rover.
1907	Garnet Climber	H. W.	*R. wichuraiana* × Lucullus.
1899	Dr. W. Van Fleet	H. W.	(*R. wichuraiana* × Safrano) × Souv. de Pres Carnot.
1908	Silver Moon	H. W.	(*R. wichuraiana* × Devoniensis) × *R. laevigata*.
1902	Mary Lovett	H. W.	*R. wichuraiana* × Kaiserin Augusta Victoria.
1902	Bess Lovett	H. W.	
1902	Alida Lovett	H. W.	*R. wichuraiana* × Souv de Pres. Carnot.
1918	Aunt Harriet	H W.	Appoline × *R. wichuraiana*.
1921	Mary Wallace	H. W.	*R. wichuraiana* × hybrid tea.
1923	Heart of Gold	H. W.	(*R. wichuraiana* × *R. setigera*) × *R. moyesi*.
1925	Sarah Van Fleet	H. R.	*R. rugosa* × a hybrid tea, possibly My Maryland
1925	Dr. E. M. Mills	H. R.	
1926	Breeze Hill	H. W.	*R. wichuraiana* × Beaute de Lyon.
1926	Glenn Dale	H. W.	*R. wichuraiana* × Isabella Sprunt.
1927	Ruskin	H. R.	*R. rugosa*, Souv. de Pierre Leperdrieux × Victor Hugo.

[1] Abbreviations have been used to designate the class to which the rose belongs:

H. W.=Hybrid wichuraiana.
H. R.=Hybrid rugosa.
H. T.=Hybrid tea.
H. T.Poly=Baby rambler with hybrid tea characteristics.
H. M.=Hybrid multiflora.
H. P.=Hybrid perpetual.
Bour.=Bourbon.

While American rose breeders were not at first so active as Europeans in producing hybrid teas, they have accomplished much in developing hardy outdoor roses. One of the leaders in this work was

the late W. Van Fleet (fig. 21), who continued his rose-breeding activities after he became a member of the Department of Agriculture. He was an industrious worker, making many thousands of crosses and keeping accurate records of his work. His objective was to produce continuous blooming roses for common dooryard culture under the diverse climatic conditions of this country. In order to develop such types he utilized all available vigorous species of pleasing aspect, as well as strong-growing garden forms, crossing them with highly developed florists' varieties. In this manner he hoped to secure plants that would combine the really desirable characters of the parents. Two varieties developed by him were introduced posthumously.

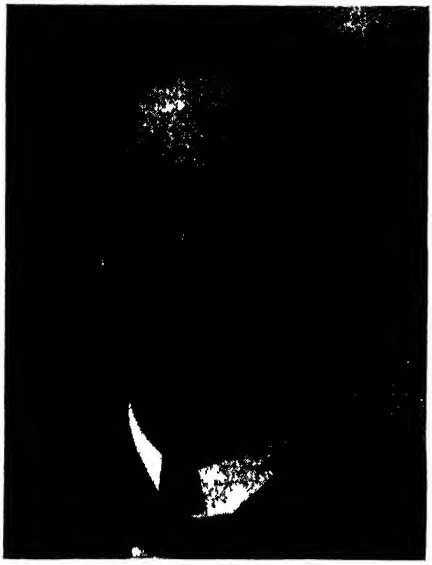

Figure 21.—The late Walter Van Fleet (1857–1922), of the United States Department of Agriculture, who did outstanding work on breeding hardy outdoor roses. He set as his goal the development of hardy dooryard roses that would bloom continuously from early spring until frost.

The complete list of Dr. Van Fleet's varieties is given in table 3, where they are arranged in the order of their introduction. It is interesting to note how few species entered into the formation of these varieties. Thirteen of the nineteen had *Rosa wichuraiana* Crépin as one parent; three had *R. rugosa*, two *R. setigera*, one *R. multiflora* Thunb., and one *R. moyesi* Hemsl. and Wilson. Some of these introductions have gained widespread recognition and are widely grown.

Another breeder of hardy roses is N. E. Hansen, of the South Dakota Agricultural Experiment Station at Brookings. He has been working for some time to develop roses to withstand the severe winters of that section. His first introduction was the variety Tetonkaha, which appeared in 1912. In 1926 a second variety, Tegala, was released, and in 1927, 13 others were introduced. All these varieties have proved hardy at the Brookings station and have been distributed in the Northwest prairie region.

The great diversity of form and habit in any group of rose hybrids is easily understood. To the geneticist it is the naturally expected outcome when two highly heterozygous plants are cross-pollinated. While the records of early hybridization in roses are none too authentic, they do at least show that the ancestry of our modern varieties is very complex. Thus the hybrid teas probably originated from a cross between a hybrid perpetual and a tea rose. The teas are supposed to have come from *Rosa odorata* Sweet. The hybrid perpetuals have a very complex ancestry. As far as can be determined, the earliest progenitor was a damask rose called The Four Seasons.

It was being grown commercially in 1790 and was probably crossed extensively with the French and Provence roses to give rise to the damask perpetual. It seems that these were then crossed with China roses, from which came the hybrid China types. According to the records of this period all roses in this last group were apparently sterile, but in 1830 a M. Guerin produced a hybrid named Malton, which proved to be fertile. A second fertile hybrid called Athalin was produced the same year by Jacques, gardener to the King, at Neuilly. It is very likely the damask parent of each was a descendant from the variety The Four Seasons. A few years later the variety Athalin was crossed with Rose du Roi, a damask perpetual. Some of these crosses were called hybrid damasks and were the direct forerunners of the hybrid perpetuals. In 1837, M. Laffay, a florist located at Bellevue, near Paris, introduced Prince Albert and Princess Helene, two new varieties. They were of the hybrid-perpetual type, and M. Laffay is usually credited as the originator of this group. He later produced other varieties, among which was La Reine. In 1844, groups of hybrid Chinas, bourbon perpetuals, hybrid damask perpetuals, hybrid Gallicas, and moss roses were all combined to form the hybrid perpetual group.

The hybrid teas, then, have a very diverse ancestry. This complexity has been greatly multiplied by crosses among themselves, so that our modern hybrid-tea varieties are undoubtedly a conglomeration of many ancestral characters. Is it any wonder that even in a group of thousands of hybrids from seed, no two are exactly alike?

The sudden spontaneous appearance of so-called sports in roses is a well-known phenomenon. The frequency with which they appear is not known, although some varieties are supposed to produce more than others. This, however, is probably based on the limited numbers considered worthy of introduction rather than on the total actually produced. There is little information about such sudden changes in parts of the plant other than flowers. In many instances the sport involves only a slight change in flower color, although very sharp breaks, such as from red to white, are also known.

These mutations in the hereditary material in the cells may occur at different stages of development and in different parts of the plant. When, for instance, a red rose produces a branch bearing white flowers, doubtless a change has occurred in the petal cells that carry the color pigments. The change may have occurred in the bud that produced the side branch, or it may have occurred at any time during the growth of the shoot and flower bud. Sometimes the change in hereditary material comes after the flower bud is almost fully developed. In such instances we may have bicolored flowers, each pigment being restricted to a very definite sector.

It may sometimes happen that a particular bud taken from a mutated branch fails to produce the new flower type. Such a situation is called a reversion by rose breeders, but it probably indicates that the mutation occurred after this bud had been formed.

No one as yet has been able to induce a sport in roses or explain the forces that bring about the change under natural conditions. Some of the future research on roses will undoubtedly be concerned with such matters. It is possible that exposure of buds to X-rays, radium,

heat, or some chemical might induce radical changes. Until such time one must depend on the chance occurrence of mutations. Unfortunately the erroneous idea has become current that special credit is due the introducer of a new rose sport. Actually the rose breeder has no control whatever over its appearance. He is simply fortunate in having the mutation occur in one of his plants. Such introductions should not be classed with actual breeding work where planned cross-pollinations are made and thousands of seedlings grown. Even in the latter case, our present methods are very little advanced over what they were 45 years ago, when Lord Penzance called rose breeding a lottery.

The contributions of science to rose breeding have been concerned chiefly with pollen studies, studies of the chromosomes of the various species, and methods of hastening seed germination. The classification of the genus *Rosa* into species has been a very difficult problem. Various workers have from time to time revised the classification, and there has not been any general agreement among them. This confusion is probably caused by the lack of agreement on what constitutes a species, as well as by the undoubted heterogeneous nature of roses. In early days, as well as now, natural crosses between wild roses probably occurred, giving rise to new intermediate forms. When rose growing became so popular, amateurs began making cross-pollinations between all available types, thus further complicating the situation.

At the present time most rose varieties and so-called species are actually mixtures of many types. Classification as botanical species is practically impossible. Undoubtedly many of our present so-called species are simply hybrids, as is indicated by the degrees of partial sterility found.

An interesting study of the pollen of several wild species and some species hybrids was made by Erlanson (*120*). Her method consisted in staining the pollen and counting the percentage of poor, shriveled grains. She found that poor pollen exists in all our native American rose species. It averaged about 20 percent infertile in all except *Rosa acicularis* Lindl. and *R. palustris* Marsh., where it was about 10 percent. Even relatively fertile individual plants had as much as 25 percent infertile pollen. In hybrids the percentage of poor pollen was usually very much greater than in the wild species, and the conclusion was reached that any wild rose plant with over 70 percent of infertile pollen and setting little or no fruit was probably a first-generation hybrid.

Observations of the chromosomes of roses have also thrown some light on the species problem. Rose species have been found with 14, 21, 28, 35, 42, 49, and 56 chromosomes in the body cells. These numbers increase each time by 7 and are called a polyploid series. According to Hurst there are distinctly different seven-chromosome groups. He assumes at least five such groups, which he designates as A, B, C, D, E. Different combinations of these five chromosome sets would certainly explain much of the wide variability in the genus.

One of the greatest handicaps faced by rose breeders is the matter of irregular seed germination. Seed from some species sprouts readily, while that from others may not start growth for several years. In

1926 William Crocker, of the Boyce Thompson Institute at Yonkers, N. Y., published results of his studies on after-ripening and germination of rose seeds. The seeds were stored at various temperatures in moist granulated peat. The best temperature for both species and hybrids was found to be 41° F. In some cases the acid in the peat injured the rootlets of some roses, but this can be remedied by neutralizing the peat with a little lime or by using nonacid peat if it is obtainable.

The future of rose breeding depends to a considerable extent on the accumulation of fundamental information on inheritance of rose characters, and on breaking away from many of the established practices. As stated earlier, the accumulation of parentage records is of little value unless it is accompanied by information on numbers of seedlings grown. Undoubtedly some parents will give better progenies than others. This information for some varieties is probably known by some breeders but is not generally distributed. It also seems advisable to start self-pollinations of many present varieties, since they are already so heterozygous that they will probably give rise to something of value. Above all there is a need for systematic investigation by trained workers at institutions well equipped for genetic and breeding work with roses. Such a program would undoubtedly clear up much of the present confusion

SNAPDRAGON

The early history of the cultivated snapdragon (*Antirrhinum majus* L.) is not known. Some records indicate that it was first grown in Italy, whence it spread to the remainder of Europe. At the present time the species is found growing wild in many spots along the Mediterranean coast west of Italy. In one of the earliest published accounts, in 1578, there were described several color variations and two distinctive leaf types, the narrow and the broad. A little later, five varieties, white, purple, blush, yellow, and variable, were known. Soon after this a double-flowered form and one with variegated leaves appeared. At the beginning of the nineteenth century several striped and spotted varieties were listed by various growers. By 1824 a wide range of colors existed from rich orange and yellow to white, with the same types in reds and purples as well as many bicolor forms.

The first-named botanical varieties of *Antirrhinum majus* did not appear until about 1830 or 1835. Among these were *reticulatum*, *youngii*, and *carophylloides*. In 1844 a deep blood-red double-flowered type appeared. The earlier doubles had ranged from white to rose. In the next few decades countless horticultural varieties were introduced each year and were sold as high as $1 per plant. At this time propagation was entirely by cuttings. In 1850, George Parsons, of Brighton, England, introduced a variety that was a distinct change in the arrangement of the colors of the flower. It was white with a deep rose band in the form of an edging to the petals. It was distributed by E. C. Henderson & Sons, in 1852, under the name of Hendersonii.

The snapdragon did not come into its own until the latter half of the nineteenth century. All the earlier varieties had been propagated only by cuttings, and very little had been done with seedlings. The

climate of Scotland and England was very favorable for the production of snapdragons of fine quality, and the flower soon became very popular. The demand for newer and improved varieties stimulated the growing of seedlings, and hundreds of new types were soon developed.

At the present time snapdragons are roughly divided into two groups—(1) florists' varieties and (2) types for outdoor culture. Some varieties, of course, may be placed in both groups. In England and Europe generally, the chief interest is in the outdoor sorts, while in the United States the forcing or greenhouse types are the most important.

The snapdragon flower is so constructed that smaller insects find it very difficult to gain entrance to the nectaries. It requires considerable effort even on the part of a large bumblebee to open the two parts of the corolla. The flower is, nevertheless, frequently visited by large bees, and undoubtedly considerable cross-pollination occurs. Because of this situation, varieties of snapdragons grown for seed should be separated a considerable distance from others. This is especially important for florist varieties, where it is essential that strains be true for type and color.

The practice of growing snapdragons from seed did not become very general until early in the present century. In England and France, seed had been offered by various seedsmen for some time. Most of the old standard varieties, however, were still increased solely by cuttings. In this country, nearly all florists propagated entirely in this manner. As a result many local varieties arose but were not widely distributed. In 1913, snapdragon rust suddenly appeared in the vicinity of Chicago. It had been known in California and along the Pacific coast since 1896. Within a few years after its appearance the disease spread to all sections of this country, to Mexico, and to Canada. The result was almost disastrous to greenhouse snapdragons and practically eliminated propagation by cuttings. The moist conditions and warmth in the cutting bench were also the optimum conditions for snapdragon rust. This situation, and the fact that the disease was not seed borne, stimulated development of better seed-propagated strains. Within a short time a great number had appeared, and today the total list includes many hundreds of varieties.

Most of the present-day varieties have probably arisen from chance crosses made when the commercial seed crop was produced. Even though the seedsman rigidly removes all off-colors and types, the seed produced will usually contain some crosses made by bees. The florist or grower then finds offtype plants the next year. In addition to this source of contamination it is also very probable that some strains usually contain a few hybrids, which carry recessive characters that do not show up until the next year.

Following the widespread distribution of rust, the popularity of the snapdragon began to wane in this country. The florists were able to control the disease under glass, to some extent, by careful attention to watering and maintaining a temperature unfavorable to its development. Plantings outdoors, however, continued to suffer, and the snapdragon began slowly to disappear from parks and home gardens. In California the growing of snapdragon seed was a rather precarious

undertaking. In some years a fair crop might be secured, but on the average the yields were very poor. Many attempts to control the disease by spraying were on the whole unsuccessful.

In 1922 E. B. Mains, then at Purdue University, found two snapdragon plants that showed some resistance to rust. In 1927 he distributed seed to several investigators. Continued selections and self-pollinations in descendants of these strains finally resulted in the development of highly resistant strains of snapdragons. The inheritance of this resistance has been studied by Emsweller and Jones (*117*), White (*545*), and Mains (*327*). In all cases resistance was due to a dominant gene. The inheritance of resistance is shown in figure 22. At the upper left are shown a flower and leaf of a susceptible variety; in the upper right a flower and leaf of a resistant plant; directly between and below, a flower and leaf from the hybrid resulting from a cross between susceptible and resistant. Since resistance is dominant, the first-generation hybrid is completely free from rust. At the bottom are shown flowers and leaves from four of the second-generation plants. Three are resistant and one is susceptible. This count of 3 to 1 is the typical Mendelian ratio when a single pair of contrasting genes is involved. The actual figures from such a cross made in California were as follows: All of the 562 first-generation hybrid plants were completely resistant. One of them was self-pollinated and 550 second-generation plants were grown from the seed. In this large population 405 plants were resistant and 145 were susceptible. A perfect 3:1 ratio would have been 413 resistant to 137 susceptible. The ratio actually secured was off just eight plants. Such a small deviation is not significant, and the ratio secured undoubtedly represents what is called a simple monogenic segregation. Resistance was also found in other *Antirrhinum* species imported from western Europe by the Division of Plant Exploration and Introduction, but these were not used in the breeding of the rust-resistant strains mentioned.

Recently in several localities in California, some of the supposedly resistant plants have again succumbed to rust. Such a situation is not unusual, being common in grain varieties bred for resistance to certain strains of the cereal rusts. It is possible that the condition in California is caused by a new strain or physiological form of the rust organism. Since the rust parasite on the snapdragon is itself a small plant, it is not unusual that it should produce a new strain able to attack otherwise resistant plants. If this should prove to be the situation, the production of rust-resistant strains of snapdragons will be more difficult in those sections where more than one physiological race of rust occurs.

The genetics of the snapdragon has been extensively studied by a large number of workers. The inheritance of color is very complex. According to Miss Wheldale, magenta is in general the most dominant color and yellow the most recessive. By this is meant that magenta is dominant to practically all other colors, while yellow is usually recessive to all others. This explains why seedsmen find that yellow varieties and strains are usually very easy to purify. Since yellow is recessive, plants can exhibit this color only when pure for it. In the same investigations, crimson was dominant to bronze, bronze to

Figure 22.—The way in which rust resistance is inherited in the snapdragon: *A*, Flower and leaf of the susceptible variety; *B*, those of a resistant plant; *C*, resistant hybrid resulting from cross-pollination of *A* and *B*: *D*, *E*, *F*, *G*, flower and leaf from each of four plants descended from the resistant hybrid *C*; this second hybrid generation had a ratio of 3 resistant plants to 1 susceptible.

yellow-tinged bronze, magenta to rose doreé, and rose doreé to ivory-tinged rose doreé. Delilah forms, in which corolla lips are colored and tube is colorless, were recessive to the corresponding nondelilah. For example, crimson was dominant to crimson delilah.

Stock, Double-Flowered

The early history of the stock (*Matthiola incana* (L.) R. Br.) is very obscure. The first authentic records indicate that it was known to the Greeks and Romans and prized by them chiefly as a medicinal herb. By 1542 at least three colors, purple, red, and white, were known, but only in single-flowered types.

The first mention of a double form was in 1568, when a Belgian botanist, Dodvens, described it in a paper dealing with sweet-smelling flowers suitable for chaplets or garlands; and in 1581 an actual illustration appeared. At this time the flower was described as being so double that it was completely sterile. It is not known just when the double form appeared, but it was probably a mutation from the single. From the scant records of the period it seems that the only method of reproducing it was by cuttings. It was not until 1629 that any statement appeared indicating that double-flowered plants could be obtained from seed of singles.

Unfortunately, one of the earliest descriptions of double-flowered stock stated that the doubling was the result of special treatment and frequent transplantation. This belief was held for a long time and many special practices based on superstition developed in the culture of stocks. One of the most interesting descriptions of such practices appeared in a book on gardening in 1675:

Single Flowers Doubled

Remove a plant of stock when it is a little woodded and not too greene, and water it presently; doe this three days after the full, and remove it twice more before the change. Doe this in barren ground, and likewise three days after the new full Moon remove againe, and then remove once more before the change. Then at the third full Moon, viz., eight days after, remove againe, and set it in very rich ground, and this will make it bring forth a double flower; but if your stocks once spindle, then you may not remove them. Also, you must shade your plant with boughs for three or foure dayes after the first removing; and so of Pinks, Roses, Daysies, Featherview, etc., that grow single with long standing. Make Tulipces double in this manner. Some think by cutting them at every full Moone before they beare to make them at length to beare double.

As mentioned earlier, the double-flowered stock plants were propagated by cuttings, but how they came from seed of the singles remained a mystery until it was cleared up by the genetic and cytological research of Saunders (*463*), Frost (*135*), and Philp and Huskins (*408*). For a long time it was generally believed that the double-flowers produced some pollen, which fertilized the singles and formed seed that produced doubles. Directions are still occasionally given for selection of seed from single-flowered plants surrounded by doubled-flowered. An examination of the double flowers, however, discloses no pollen whatever, and it seems certain that if any is ever produced, it is only on exceedingly rare plants.

The differences between a single and a double flower are very striking. The single has four petals, four stamens, and a pistil. When fertilized it produces a long, narrow, flattened fruit containing

138904°—37——62

from 30 to 60 seeds. The double flower is composed entirely of petals, which vary from 40 to 70 per flower. There is no trace of stamens or pistil, and, of course, no seed is formed.

The double-flowered plants are desired by both florists and gardeners, and because of this there is active competition among growers of stock seed to produce high double-throwing strains. Accurate counts made by seedsmen have revealed many strains with 80-percent and a few with as high as 90-percent doubles. Usually, however, the proportion secured by florists and home growers is far less. The seedsmen themselves encounter sharp fluctuations; a strain producing as high as 80-percent doubles one year may drop to 50-percent or less the next. As a result of this apparent instability, seedsmen, florists, and gardeners have entertained a belief that doubleness must be controlled by some external environmental factor or factors.

Modern genetic research has now found the fairly simple explanation of this situation. It also points the way to production of reasonably nonfluctuating, double-throwing strains that produce the maximum percentage of doubles. When a large number of single plants are self-pollinated and all seedlings of each one saved, it has been discovered that the singles are of three sorts. Type 1 produces only single-flowered plants, type 2 produces 3 single-flowered plants to 1 double-flowered, and type 3 produces about 54 percent of double-flowered plants and 46 percent of single-flowered. The single-flowered progeny of type-1 singles never produce any doubles in their selfed progenies; they are pure for singleness. The single-flowered progeny of type-2 singles are of two kinds, one-third being pure for singleness and two-thirds like type 2, that is, producing progenies with 3 singles to 1 double. Most of the single-flowered progeny of type-3 singles repeat the performance of their parents, each again producing about 54-percent doubles.[8]

It is now easy to understand how fluctuations in percentage of doubles may occur from generation to generation. Even though a seedsman practices careful plant selection and saves seed only from the high-double strains, he cannot predict with accuracy the ratio of doubles to singles from year to year. It seems highly probable that nearly all stock seed is a mixture of all three types of singles. The percentage of doubles that will develop in any strain, then, is influenced by the number of pure and heterozygous singles that were in the seed field. Since at present there is no certain method of distinguishing the three types of singles except by a progeny test it seems that with ordinary methods of seed production the number of doubles will continue to fluctuate from generation to generation.

The preceding explanation accounts for yearly changes in the proportion of doubles, but it does not explain the occurrence of strains with more than 54 to 57 percent. In fact, it sets such an amount as the maximum proportion that can be secured. How can the strains with over 80 percent of doubles be explained? Miss Saunders has given the explanation. About 20 years ago she noticed for several years the high percentage of doubles developing in a bed of stocks. It occurred to her that some sort of artificial selection could account

[8] It has been shown that occasional pure single plants appear even in type 3 They, of course, bring down the percentage of doubles expected from this type and are an additional source of confusion

for it. A few years later she planted 8 to 10 seeds in each of a large number of pots. When the seedlings were well established, those in each pot were numbered according to their size. When the plants finally bloomed, it was found that most of the large ones were doubles and the small ones singles. In 1923 White (*546*) at the Maryland Agricultural Experiment Station conducted a very similar experiment. He grew a large number of seedlings and then graded them into groups on the basis of size. When the plants bloomed, he too found that most of the large ones were doubles.

S. L. Emsweller has also investigated the problem in genetic studies with stocks. The seedlings were not graded by size, but as soon as the first true leaves were developed, about 150 plants from each of several varieties were transplanted into small pots. All seedlings of a progeny were saved. When the small plants were established, the height, spread, and stem diameter of each were measured each week until the plants began to bloom. They were then classified as doubles and singles, and the mean height, spread, and stem diameter for each group were computed for the weekly intervals. In all cases it was very clear that the double plants were more vigorous than the singles, even in the seedling stage. This does not mean that the smallest double plant was larger than the largest single; there were always a few plants of each type that overlapped It was possible, however, by selecting only the very largest seedlings, to secure 85 to 90 percent of doubles (fig. 23).

Thus the occurrence of unusually high double strains is readily explained. If anyone, florist or gardener, has more seedlings of stocks than are needed, he will invariably discard the weak, small ones and save the largest. On the California flower-seed ranches, stock seed is sown in rows in the field When the seedlings have become well established they are thinned by hand, and naturally the stronger plants are left. This readily explains the frequent occurrence of rows with 80 to 85 percent of doubles. Such rows, of course, came from parent plants that gave the highest possible percentage of doubles.

In the light of these facts, certain recommendations for growing seed of stocks can be made. In the absence of definite information on natural crossing in stocks, it is advisable to self-pollinate all plants selected. A small sample of seed from each selfed plant should be sown in a separate row. Random samples of these seedlings, the first 50 in each row, should be transplanted, the lots again being kept separate. These trial plantings will indicate the genetic type of the parent of each row. Seed from pure singles will give only single-flowered plants; that from simple hybrids, about 3 singles to 1 double; and that from the so-called ever-sporting type, slightly more than 50 percent of doubles. The seed of all pure singles and simple hybrids can then be discarded and a seed crop grown from plants that produced the maximum number of doubles. Such a procedure would require 2 to 3 years but would certainly give high-quality seed. In many sections of California it is possible to maintain such a planting for several years. Emsweller has done so and secured a greatly increased seed yield the second year. It is recognized, of course, that this method would involve extra expense, but it has been profitable with delphinium, hollyhock, and columbine, and it should be with stocks also. If seed

of this type were generally available, and florists and gardeners rigidly discarded all weak seedlings, they should have little trouble in securing stocks running close to 90 percent double. This means that over twice the ordinary amount of seed should be planted, since slightly more than half the seedlings would be discarded in thinning out on the basis of size.

There are several types of stock plants (fig. 24) varying in habit of growth, earliness, and flower color. Unfortunately the importance of

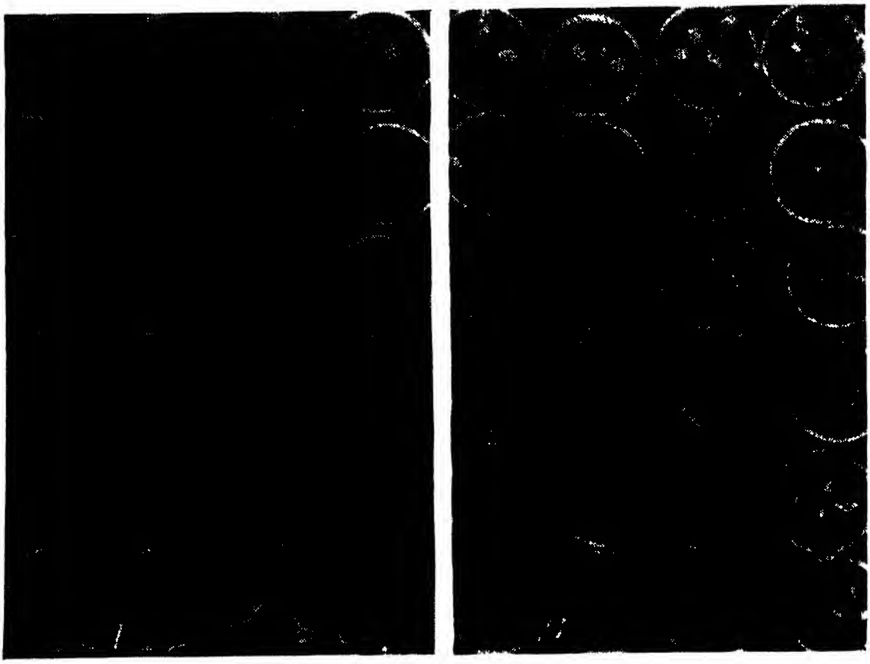

Figure 23.—Stock seedlings selected for size after transplanting: *A*, Group of the extremely large plants, 90 percent of which were double-flowered; *B*, smallest plants, 18 percent of which were double-flowered.

the problem of double flowers has retarded work on inheritance of these characters. Some data are available, however, on inheritance of tall versus dwarf plants and branching versus nonbranching. Tall is dominant to dwarf, and in the second hybrid generation there will be found three tall plants to one dwarf. The situation is not so clear-cut for branching crossed with nonbranching. The first-generation hybrid is branched, and in the second generation there is a close approach to a ratio of 3 branching to 1 nonbranching. These nonbranching plants, however, have some tendency toward branching, which the original nonbranching parent plant did not have.

The future breeding work with stocks will probably be concerned with the inheritance of other important characters. There is also need for the discovery of some simple seedling characteristic to enable florists and gardeners to select with certainty double-flowered plants in the seedling stage.

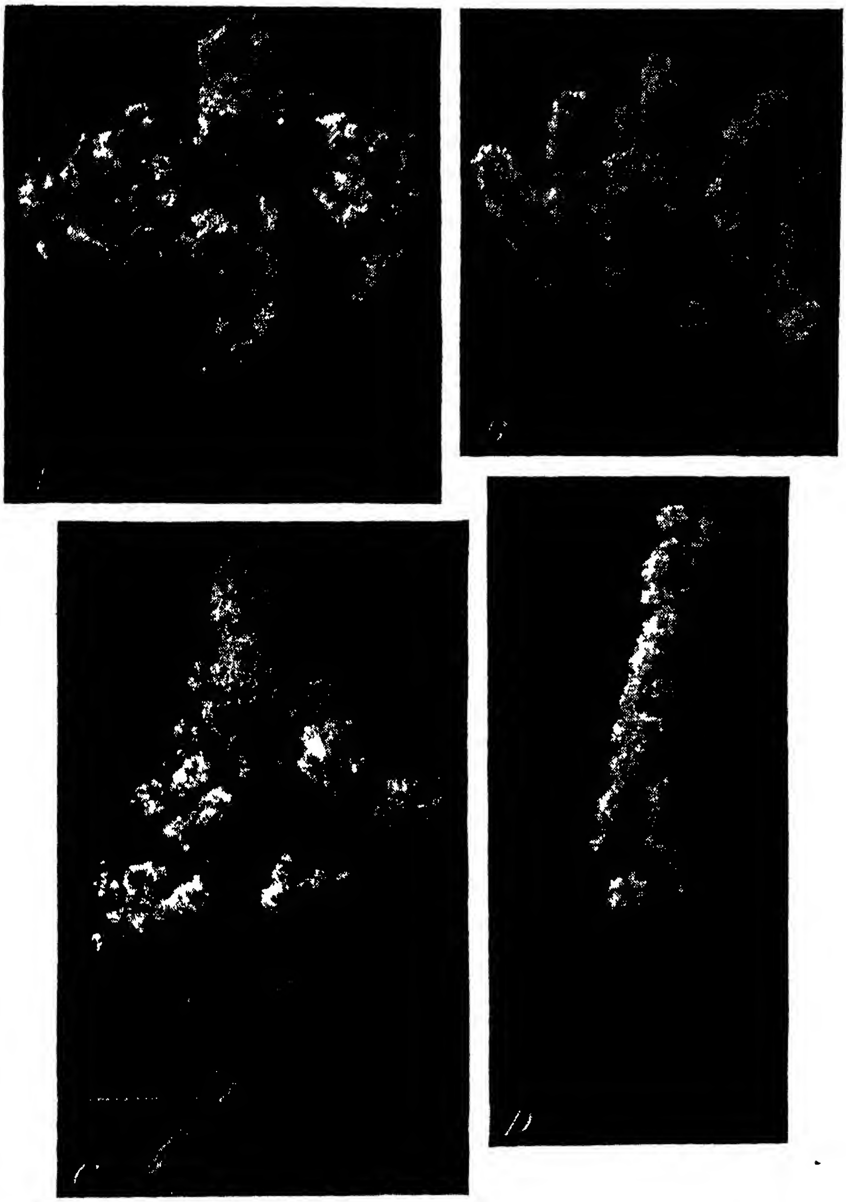

Figure 24.—Four types of double-flowering stock showing variation in growth habit. There are many varieties of each kind including a wide range of colors. (*A*) The tall ten weeks and (*B*) the dwarf ten weeks types are used mostly for bedding, are very early bloomers, and are easy to grow. (*C*) The imperial (branching) and (*D*) the column (nonbranching) types are grown mostly under glass by florists. The column sorts (*D*) are valued for their tall single spike and for adaptability for close planting, thus yielding more salable flower spikes per square foot of greenhouse bench.

Sweet Pea

The sweet pea (*Lathyrus odoratus* L.) was introduced into the Netherlands and England from its native Sicily in 1699. From a figure and description published in 1700 the original type is recognizable as a tall plant reaching a height of 6 or 7 feet, with short flower stems bearing two blooms each. The individual bloom was small and fragrant. The standard was erect, narrowed at the base and cleft at the top. In color the standard was reddish purple, the wings light bluish purple. Figure 25 shows a type closely resembling the wild *Lathyrus odoratus* in comparison with a modern flower.

The evolution of 500 or more distinct garden varieties from this unassuming beginning has been admirably traced by Beal (*40*), and the significance of mutation and hybridization in the process has been interpreted by Babcock and Clausen (*8*). White forms appeared in 1718. In 1731 Painted Lady—pink and white in place of the purple and blue of the original type—was introduced. Scarlet, a brighter self-colored variety presumably derived from Painted Lady, appeared in 1793. Then followed in 1806 a blue variety, in 1817 a striped type, and in 1824 the so-called yellow, more properly primrose. New Large Purple, listed in 1845, implies an improvement in size of bloom. Marked increase in size also occurred in the Countess Spencer variety (1904). The original two flowers per stalk were increased to three with the advent of Invincible Scarlet in 1865 and Crown Princess of Persia in 1868, and they were further increased to four blooms per stalk in the more recent Spencer type. The form of standard was differentiated into three distinct types: grandiflora, erect but larger and broader at the base than the original, appeared in 1888; hooded, with edges inrolled, is an early type; Spencer, with waved standard, is a more recent development. Changes in habit of growth include two recessive dwarf types, the cupid (prostrate) and the bush (erect), and the commercially important winter-flowering type. The winter-flowering sorts are distinguished from other sweet peas by prompt growth and flowering under winter forcing conditions and by lower stature and shorter flower stems. Blanche Ferry, the first of the winter-flowering types, was selected by the wife of a quarryman in northern New York for 25 years before it reached the trade in 1889. Beal has traced the subsequent development of the winter-flowering group from this and subsequent mutations.

All of the changes mentioned thus far are considered in Babcock's analysis to be due to mutation from the original type. The first hybridization in the sweet pea was undertaken about 1880 by Thomas Laxton, of Bedford, England. Thereafter intensive use of crossing served to incorporate the desired colors in the commercial grandiflora, hooded, and Spencer types and to vary the color and form of blooms in the important winter-flowering group. The number of favorable mutations occurring in the sweet pea in two centuries of culture is truly remarkable. These have served as the material from which practical breeders have constructed the varied horticultural varieties of our day.

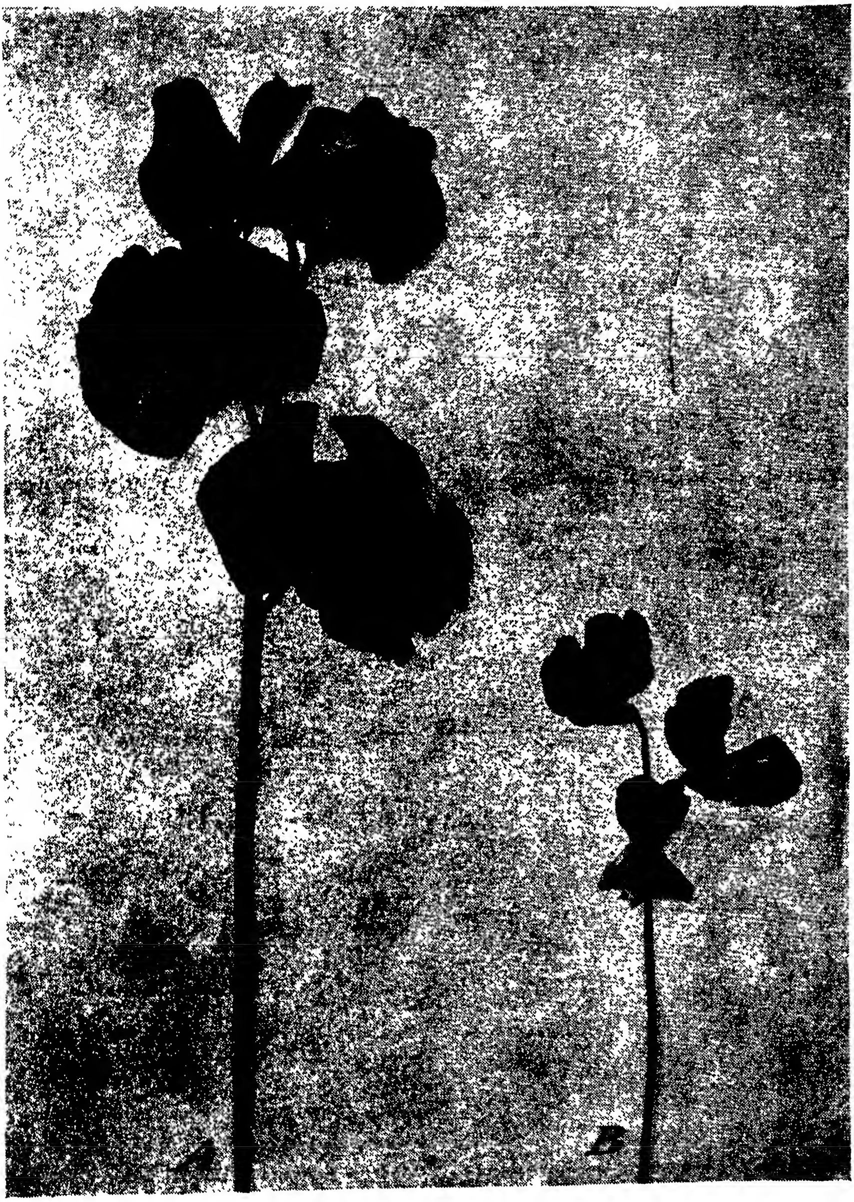

Figure 25.—A modern sweet pea (*A*) and a type closely resembling the wild form (*B*), from which it arose. The greatest part of this development has taken place in the last 25 years.

Hurst (*223*) has presented some examples of the actual procedure followed in producing new combinations by hybridization. W. Cuthbertson produced the Waved King Edward variety as follows.

Parents	King Edward Plain red		Countess Spencer Waved pink	
First generation (F_1)		Plain red		
Second generation (F_2)	Plain red (9)	Plain pink (3)	Waved red (3) ↓ Waved King Edward	Waved pink (1)

The expected proportions of the F_2 population are supplied by Hurst since Cuthbertson did not count the classes. Out of the desired waved red class in F_2, one-third of the plants should be pure breeding and two-thirds segregating again 3 red : 1 pink. Cuthbertson also raised Primrose Spencer by a similar procedure. Hurst also explains the synthesis of Black Knight Cupid in his own experiments:

Parents		Black Knight Tall purple dark-wing				Pink Cupid Cupid red light-wing		
First generation (F_1)				Wild purple Tall purple light-wing				
Second generation (F_2)	Tall purple light- wing (27)	Tall purple dark- wing (9)	Tall red light- wing (9)	Cupid purple light- wing (9)	Tall red dark- wing (3)	Cupid purple dark- wing (3) ↓ Black Knight Cupid	Cupid red light- wing (3)	Cupid red dark- wing (1)

Black Knight Cupid was then "fixed" by saving the progeny of the one-third of this class that were true breeding, and discarding the two-thirds that segregated in the third generation into 3 purple : 1 red. The synthesis of combinations in this manner is simple when the desired genes are available in different varieties and their mode of inheritance is known.

In addition to the many valuable mutations that have made possible the range in color and form of modern sweet pea varieties, other mutations of minor value and actually harmful types have

appeared. Among the mutant forms of minor or novelty interest may be mentioned the "snapdragon" type in which the standard is folded around the wings. This is inherited as a simple recessive to the normal type. Recently Wright has described a variety producing two or even three flower stalks at each node, without loss of size or beauty of the flowers. This may be regarded as a new mutant, evidently of minor commercial value, for no further reference to it has appeared. The change from "long" pollen to "round" is an example of a mutant neither useful nor harmful from the horticultural viewpoint, while "contabescent" anthers, a recessive mutant bearing abortive anthers, and the monstrous "cretin" type with abortive pistil, illustrate harmful mutants. Stone's report of a somatic mutation from recessive cupid to normal tall illustrates that the mutation process is still active in sweet peas.

Although hybridization has been widely employed, natural crossing between varieties of sweet peas is probably infrequent. Until recently there was no authentic record of a successful cross of *Lathyrus odoratus* with any other species of the genus. Barker (*11*) reports success with only one cross between species out of many attempted. This hybrid, *L. odoratus* Kitty Clive × *L. hirsutus* (a weak annual), was fertile; segregation occurred in the second hybrid generation, but the *L. odoratus* type was not recovered. No noteworthy ornamental type appeared in this or later generations. A few seeds were obtained on pollinating the first-generation hybrids from *L. odoratus* × *hirsutus* with pollen from one of the perennial species of *Lathyrus*.

The modern sweet pea leaves little to be desired in form of flower and variety of color. A true yellow is not available though long sought, and brighter shades of present colors are still desired, as well as reds and pinks that do not sunburn. The duplex type, a recent novelty with extra petals producing the effect of added size of bloom, seems worthy of fixing and of hybridizing to extend the range of color and types available. Resistance to diseases, particularly of the root rot group, is needed. A hardier race of sweet peas to endure winter cold and permit fall planting and one enduring summer heat would serve to extend the range of satisfactory garden culture of this excellent annual.

LITERATURE CITED

Literature citations for this article, covering 564 references on flower breeding, are omitted from this volume because of space limitations but are available in the 1937 Yearbook Separate on Improvement of Flowers by Breeding.

APPENDIX

Supplementary Data on Lily Breeding

Classification of the species Lilium

Subgenus *Eulirion:* True lilies. Bulb perennial; leaves linear, lanceolate or lanceolate-ovate.

Section 1. Leucolirion: Trumpet lilies. Flowers trumpet-shaped, horizontal or nodding; perianth segments falcate or spreading at the apex; stamens not divergent.

Examples: *Lilium candidum* L., *L. formosanum* Stapf., *L. longiflorum* Thunb., *L. regale* Wils.

Section 2. Archelirion: Lilies with open, bowl-shaped flowers. Perianth segments widely spreading, broadest below the middle; stamens divergent.

Examples: *L. auratum* Lindl. only, according to Wilson; but also *L. speciosum* Thunb. and *L. tigrinum* Ker according to Baker. Grove adds *L. henryi* Baker and *L. leichtlinii* Hook. f. and comments that the dividing line between Archelirion and Martagon is arbitrary and may need revision.

Section 3. Isolirion: Lilies with erect flowers. Perianth segments falcate, not revolute at apex. Leaves whorled or scattered. Stamens divergent.

Examples: *L. bulbiferum* L., *L. philadelphicum* L., *L. concolor* Salisb.

Section 4. Martagon: Lilies with nodding flowers and strongly revolute perianth parts. Leaves whorled or scattered. Stamens divergent. The Turkscap group.

Examples: *L. martagon* L., *L. chalcedonicum* L., *L. hansoni* Leicht., *L. amabile* Palibin, *L. cernuum* Komarov, *L. superbum* L., *L. willmottiae* Wils.

Subgenus *Cardiocrinum:* Heart-leaved lilies. Bulbs monocarpic (flowering only once); leaves long-petioled, ovate-cordate.

Examples: *L. cordatum* (Thunb.) Koidz., *L. giganteum* Wallich.

List of Lily Hybrids Arranged in Alphabetical Order of the Seed Parents

Species names of the seed parents are followed by the author of the name, the date the name was assigned, the section in which the species is usually placed, and the region to which the species is native. Under the seed-parent headings are listed the pollen parents reported to cross, named hybrids, if any, in quotation marks, and sometimes comment on the results. The practice of indicating a hybrid species by inserting the sign of multiplication (×) before the species name, as *L.* × *testaceum*, has been followed.

Lilium amabile Palibin, 1901. Martagon. Chosen.
× *L. martagon.* Preston reports one success.

L. auratum Lindley, 1862. Archelirion. Japan.
× *L. speciosum* var. *melpomene*="*L.* × *hovcyi.*"
× *L. speciosum* (?)="Mrs. Anthony Waterer."
× *L. speciosum.* Preston reports success.

L. auratum var. *platyphyllum* Baker, 1880. Archelirion. Japan.
× *L. speciosum* var. *magnificum*="*L.* × *parkmanni* var. *haywardi.*"
× *L. speciosum* var. *melpomene* (?)="*L.* × Crimson Queen."
× *L. speciosum.* Stout reports success.

L. auratum var. *rubrovittatum* Duchartre, 1870. Archelirion. Japan.
× *L. auratum.* Stout reports success.

L. bulbiferum L., 1753. Isolirion. Europe.
× *L. croceum* (syn. *L. bulbiferum* subsp. *croceum*). Griffiths reports one worthy hybrid.
× *L.* × *thunbergianum* (syn. *L.* × *elegans*). Berckmüller reports many crosses. According to him the varieties *incomparabile, erectum, grandiflorum, multiflorum,* and Sappho of *L.* × *umbellatum* of commerce are referable to the cross *L. bulbiferum* × *L.* × *thunbergianum.* Berckmüller

further suggests that the name *L. umbellatum* should be restricted to the progeny of this cross and that a new name should be created for those newer varieties of *L.* × *umbellatum* of commerce that are referable to the cross *L. croceum* × *L.* × *thunbergianum.*

L. bulbiferum subsp. *croceum* (Chaix) Baker, 1873. Isolirion. Europe.
× *L. concolor.* Preston reports one success.
× *L. dauricum.* Stout reports success.
× *L. davidi*="*L.* × *crovidi.*" *L.* × *crovidi* × *L.* × *cromottiae*="*L.* × Golden King."
× *L.* × *elegans*="*L.* × Coolhurst hybrid."
× *L.* × *elegans.* Preston and Stout report successes.
× *L. tenuifolium* (syn. *L. pumilum*). Preston reports two natural hybrids.
× *L.* × *thunbergianum* (syn. *L.* × *elegans*). Berckmüller reports many successes and from the resemblance of the progeny to such newer varieties of *L.* × *umbellatum* of commerce as Golden Fleece, Orange King, Invincible, Splendidum, Mahogany, and Vermilion Brilliant, he considers that a new name should be created for this cross, reserving the name *L.* × *umbellatum* for the cross *L. bulbiferum* × *L.* × *thunbergianum.*
× *L. tigrinum*="*L.* × *manglesi.*"
× *L. willmottiae*="*L.* × *cromottiae.*"

L. canadense L., 1753. Martagon. Eastern America.
× *L. grayi.* Stout reports success.
× *L. superbum.* Stout reports success.
× *L. tenuifolium* (syn. *L. pumilum*). Preston reports success.

L. candidum L., 1753. Leucolirion. Europe to Western Asia.
× *L. chalcedonicum.* Griffiths reports promise.
× *L. parryi.* Grove reports success in 1914.
× *L.* × *testaceum.* Preston reports success.
× *L.* × *testaceum.* Griffiths reports success but no hybrids of promise.

L. chalcedonicum L., 1753. Martagon. Greece
× *L. candidum*=*L.* × *testaceum*, natural hybrid (1830?). It is generally agreed that *L. testaceum* is of this origin, but the exact time and place of origin are uncertain. Hybrids closely resembling *L. testaceum* have been reproduced at least three times.

L. concolor Salisbury, 1806. Isolirion. China.
× *L. dauricum*="*L.* × *elegans.*" Berckmuller produced this cross and found the progeny conformed to the description of *L. thunbergianum* Schultes. The latter species is therefore presumably a hybrid and synonymous with *L.* × *elegans.*
× *L. tenuifolium* (syn. *L. pumilum*). One success by Van Fleet, according to Griffiths.

L. dauricum Ker, 1809. Isolirion. Northeastern Asia.
× *L. croceum* (syn. *L. bulbiferum* subsp. *croceum*), Stout reports success.
× *L.* × *elegans.* Stout reports success.
× *L.* × *thunbergianum* (Syn. *L. elegans*). Preston flowered seedlings.
× *L.* × *umbellatum.* Preston flowered seedlings.

L. davidi Duchartre, 1880. Martagon. China.
× *L. pseudotigrinum* (?). Preston reports success.
× *L. tigrinum* var. *fortunei.* Preston reports success. (Probably *L. tigrinum* var. *diploid.*)
× *L. willmottiae* = "*L.* × *davmottiae.*" Preston states that the cross *L. davidi* (the *sutchuenense* form) × *L. willmottiae* was made in 1922. A number of seedlings sent out as "Ottawa hybrids" were later called *davmottiae*, which has resulted in lack of uniformity.

L. × *elegans* Thunberg, 1811. Isolirion hybrid. Japan. Not known wild. Berckmüller has shown that *L. elegans* Thunberg (syn. *L. thunbergianum* Schultes) is a hybrid, *L. concolor* × *L. dauricum.*
× *L. croceum.* Preston and Stout report success.
× *L. dauricum.* Stout reports success.
Preston reports *L.* × *thunbergianum* × *L. dauricum* successful

L. grayi S. Watson, 1879. Martagon. Eastern United States.
× *L. canadense.* Stout reports success.

L. hansoni Leichtl., 1874. Martagon. Northeastern Asia.
× *L.* × *dalhansoni.* Preston reports success.
× *L.* × *marhan.* Preston reports success.

× *L. martagon*. Griffiths reports interesting seedlings.
× *L. martagon album* "*L.* × St. Nicholas." Preston also reports success.
× *L. medeoloides* (?). Stout reports success.
× *L. tenuifolium* (syn. *L. pumilum*). Stout reports 42 pollinations failed, 40 yielded capsules, only 3 seeds germinated.

L. henryi Baker, 1888. Martagon. China.
× *L. auratum*
× *L. candidum*
× *L.* × *princeps* seedling
× *L. regale* — Preston reports success.
× *L. speciosum*
× *L.* × *testaceum*
× *L. tigrinum*
× *L. leucanthum* var. *chloraster* = "*L.* × *kewense*."
× "3 Asiatic Martagons" successful according to Griffiths.
× *L. sutchuenense* (?). Stout reports that plants from bulbs received from C. P. Horsford under this name were self-fertile and fertile with *L. willmottiae* pollen.

L. humboldtii Roezl. and Leichtl., 1871. Martagon. California.
× *L. parryi* { "Frances Larrabee", "Mercer Girl", "Vashon"

L. humboldtii var. *bloomerianum* (Kellogg) Jepson, 1922. Martagon. California.
× *L. humboldti* var. *magnificum*
× *L. parryi* (?)
× *L. roezli*
} Stout reports success.

L. humboldtii var. *magnificum* Purdy, 1897. Martagon. California.
× *L.* × Amos Perry = "*L.* × *gloriosum*."
× *L. humboldti* var. *bloomerianum*
× *L. roezli*
} Stout reports success.
× *L. pardalinum* Kellogg. "Cyrus Gates", "Douglas Ingram", "John McLaughlin", "Kulshan", "Sacajawea", "Shuksan", "Star of Oregon." These are all F_1 seedlings from Griffiths' crosses. Further lines of garden merit were expected from intercrossing and backcrossing these.

L. kelloggii Purdy, 1901. Martagon. California.
× *L. canadense*
× *L. humboldti*
× *L. parryi*
× *L. parvum*
× *L. roezli*
} Feeble fertility is reported by Stout.

L. leichtlinii var. *maximowiczii* (Regel) Baker, 1871. Martagon. Eastern Asia.
× *L. dauricum* var. *venustum* f. *batemanniae* = "*L.* × *horsfordi*." Griffiths also reports a hybrid worth introducing.
× *L. tigrinum*. Preston reports one success.
× *L. willmottiae* = "*L.* × Maxwill."

L. leucanthum Baker, 1901. Leucolirion. China.
× *L.* × George C. Creelman
× *L. regale*
× *L. sargentiae*
} Griffiths reports successful crosses, the first two yielding promising hybrids.

L. leucanthum var. *chloraster* (Baker) Wilson, 1925. Leucolirion. China.
× *L. regale* = "*L.* × *centigale*."
× *L. sulphureum* (syn. *L. myriophyllum* var. *superbum*).

L. longiflorum Thunberg, 1794. Leucolirion. Eastern Asia.
× *L. regale*. Preston reports one success.

L. × *marhan* (*L. martagon* var. *album* × *L. hansoni*). The Netherlands, 1886.
× *L.* × *dalhansoni*
× *L. hansoni*
× *L. martagon* var. *album*
} Preston reports successes.

L. martagon L., 1753. Martagon. Europe and Asia.
× *L. hansoni*. Stout reports success.

L. martagon var. *album* Hort., 1880.
× *L. hansoni* = "*L.* × *marhan*." The varieties "Ellen Willmott" and "E. J. Elwes" were derived from "*L.* × *marhan*."

× *L. bolanderi* S. Wats.
× *L. callosum* Sieb. and Zucc.
× *L. carniolicum* Bernh.
× *L. columbianum* Hanson
× *L. davidi*
× *L. grayi* S. Wats.
× *L. kelloggi* Purdy
× *L. maritimum* Kellogg
× *L. medeoloides* A. Gray
× *L. pardalinum* Kellogg
× *L. willmottiae*
} Grove reports successful crosses but no progeny of note.

L. martagon var. *dalmaticum* Elwes, 1877.
× *L. hansoni* = "*L.* × *dalhansoni.*"
× *L. medeoloides* = "*L.* × *Marmed.*"

L. martagon and varieties.
× *L. hansoni* = "Backhouse hybrids": "Brocade", "Golden Orb", "Mrs. R. O. Backhouse", "Sceptre", "Sutton Court", etc.

L. myriophyllum var. *superbum* (Baker) Wilson, 1925. Leucolirion. Upper Burma. (Syn. *L. sulphureum* Baker 1892.)
× *L. regale* = "*L.* × *sulphurgale.*"
F_2 seedlings are also sold as "*L.* × *sulphurgale.*"
L. × *sulphurgale* × *L.* × *princeps* = "Crow's Hybrid."

L. neilgherrense Wight, 1853. Leucolirion. Southern India.
× *L. wallichianum* = "*L.* × *burnhamense.*"

L. pardalinum Kellogg, 1863. Martagon. California, Oregon.
× *L. humboldti* = "*L.* × *pardaboldti.*" "Dimsdale variety" is a selection from the hybrid.
× *L. washingtonianum* Kellogg
× *L. humboldti*
× *L. parryi*
× *L. maritimum*
} Purdy believes that Luther Burbank's hybrids fall into these four groups, and an additional untraceable group. Many other species crosses were attempted but not kept separated. Some excellent types were produced but L. *burbanki*, which bears the originator's name, is "a nondescript medley"—Purdy.
× *L. columbianum.* Considered promising by Griffiths.
× *L. superbum.* Successful but not promising.—Griffiths.

L. parryi S. Wats., 1878. Leucolirion. California.
× *L. humboldti* var. *magnificum* = "*L.* × Amos Perry."
× *L. pardalinum* = "*L.* × *burbanki.*"
= "Napier's variety."
"*L.* × Frances Fell."
= "*L.* × Peter Puget." Grove states this cross yields fine hybrids, some of which are yellow-flowered.
× *L. parvum* var. *luteum* = "*L.* × *roemeri.*"

L. parvum Kellogg, 1863. Martagon. California, Oregon.
× *L. pardalinum*
× *L. parryi*
} According to Grove these hybrids are attractive but lack "staying power."

L. philadelphicum L., 1762. Isolirion. Eastern North America.
× *L. dauricum* = "*L.* × *phildauricum.*" Skinner discusses his recent crosses in a letter to Preston.

L. pseudotigrinum (?).
× *L. callosum.* Preston reports one success.

L. pumilum DC., 1813. Martagon. Northeastern Asia. (Syn. *L. tenuifolium* Fischer 1812.)
× *L. martagon album* = "*L.* × Golden Gleam." According to Grove, "Golden Gleam" was originally an authentic hybrid but has since been propagated by seed.
× *L.* × *elegans*
× *L. martagon*
× *L. martagon* var. *album*
× *L. regale*
× *L. speciosum*
× *L.* × *testaceum*
} Preston reports successful crosses.

× *L. chalcedonicum*
× *L. monadelphum* Skinner reports successful crosses.
× *L. regale*

L. regale Wilson, 1912. Leucolirion. China.
× *L. tenuifolium.* Claimed by Theodore Albert.
× *L. auratum*
× *L. candidum*
× *L. longiflorum*
× *L. speciosum* var. *rubrum* Preston reports successful crosses.
× *L.* × *sulphurgale*
× *L.* × *testaceum*
× *L. tigrinum*
× *L. sargentiae*
× (*L. sargentiae* × *L. regale* seedling) Stout reports success.
× *L.* × George C. Creelman.
× *L. leucanthum*
× *L. sargentiae* Griffiths reports successful crosses.
× *L. sulphureum*
× *L.* × *sulphurgale*
× *L. browni* Griffiths mentions possible successes.
× *L. longiflorum*

L. roezli Regel, 1870. Martagon. California.
× *L. parryi.* Grove records a fine hybrid of good constitution.
× *L. columbianum*
× *L. humboldti* Stout reports success.
× *L. parryi*

L. sargentiae Wilson, 1912. Leucolirion. China.
× *L. henryi* = "*L.* × *aurelianense.*"
× L. × *aurelianense.* Debras reports seedlings growing, also seedlings of "*L.* × *aurelianense*" selfed.
× *L. regale* = *L.* × *princeps* (syn. "*L.* × *sargale*"). First appeared as a chance seedling. J. W. Crow had some interesting seedlings from the cross *L.* × *princeps* × *L.* × *sulphurgale.*
= "*L.* × George C. Creelman."
= *L.* × Pride of Charlotte. This hybrid is reported to come true from seed. Preston and Stout also report successful crosses.
× *L.* × *aurelianense.* Debras reports success.

L. speciosum Thunberg, 1794. Martagon. Japan.
× *L. auratum.* Preston and Stout report successes.
× *L. candidum*
× *L. henryi*
× *L. regale*
× *L. speciosum* var. *album* Preston reports successful crosses.
× *L.* × *testaceum*
× *L. tigrinum*
× *L. tigrinum* seedling raised by Crow did not reach flowering size.

L. speciosum var. *album* Hort.
× *L. tigrinum.*

L. speciosum var. *magnificum* Hort.
× *L. speciosum* var. *melpomene.* Remarkable hybrid. Griffiths.
× *L. regale*
× *L. tigrinum* Early crosses were successful but seedlings were lost. Preston

L. speciosum var. *rubrum* Hort.
× *L. auratum* = "*L.* × *parkmanni.*"
× *L. tigrinum.* Preston reports early seedlings were lost.

L. superbum L., 1762. Martagon. Eastern North America.
× *L. canadense*
× *L. roezli* Stout reports success.

L. × *testaceum* Lindl., 1845. This hybrid, *L. chalcedonicum* × *candidum*, was first recognized in Germany in 1836 and probably originated in the Netherlands about 1830.
× *L. candidum* = "White Knight." Preston and Stout also report success.
× *L. chalcedonicum* = "*L.* × *beerensi.*" Griffiths reports this cross promising.

L. tigrinum Ker, 1810. Martagon. Eastern Asia.

× *L. elegans* var. *wallacei* (syn. *L. dauricum* var. *wallacei* (Wallace) Wilson). Stout reports success.

× *L. leichtlini* var. *maximowiczi*="*L.* × *tigrimax*." Stout also reports success.

× *L.* × *tigrimax*. Preston reports success. Stout reports success with pollen of the F_1 hybrid *L. tigrinum* × *maximowiczi*.

× *L. sutchuenense*. Stout reports success.

× *L. willmottiae*. Preston has flowered seedlings.

L. tigrinum var. *fortunei* Hort., 1866. Preston describes a form of *L. tigrinum* referred to this variety by Wilson, which is self-fertile. In a recent paper Preston names this form *L. tigrinum* "var. diploid."

× *L. auratum*
× *L. leichtlini* var. *maximowiczi*
} Preston reports success.

L. × *umbellatum* Hort., 1874. Berckmuller considers that this form is a hybrid—*L. bulbiferum* × *L.* × *thunbergianum* (*L.* × *elegans*). The name *L. umbellatum* has been used by Dutch hybridizers for various hybrid lilies of the upright-flowered type.

× *L. bulbiferum*. Griffiths reports one seedling of merit.

× *L.*×*willcrovidi*="*L.* × Fire King."

L. willmottiae Wils., 1913. Martagon. China.

× *L.* × *crovidi*="*L.* × *willcrovidi*."

× *L. dauricum* seedling="*L.* × Grace Marshall"
"*L.* × Lila McCann"
"*L.* × Lilian Cummings"
"*L.* × Phyllis Cox"
} Preston.

× *L.* × *elegans* "Mahogany"="*L.* × *scottiae*."

× *L. davidi*
× *L. grayi*
× *L. speciosum*
× *L. tigrinum* var. *fortunei*
× *L.* × *umbellatum*
} Preston reports successes.

× *L. tigrinum*
× *L. pseudotigrinum*
× (*L. henryi* × *L. sutchuenense*)
} Stout reports successes.

× *L. farreri*
× *L. monadelphum*
× *L. regale*
× *L. washingtonianum*
} Successful crosses reported by Skinner.

Genetic Studies on Ornamental Plants

The utilization of genetic science in practical breeding of flowers is in its infancy. The following brief survey indicates the scope of genetic work on ornamental plants. It will be noted that the characters studied are often of little floricultural interest, and that plants of minor ornamental value have received attention, while many flower favorites have been nearly or wholly ignored. The object of genetic research has been largely to extend knowledge of the operation of the laws of heredity. Ornamental plants have been studied chiefly because they offer easily recognizable characters, and because they are convenient to grow.

The material assembled here is necessarily brief. No claim to completeness is made. Those interested in specific plants will usually find further details in the original publications cited in the bibliography, which appears in the 1937 Yearbook Separate, Improvement of Flowers by Breeding. References are indicated by italic figures following the names of authors in parentheses. Much of the literature up to 1929 is covered by Matsuura (*339*), and up to 1930 by Warner, Sherman, and Colvin (*532*).

Abutilon. (Klebahn, *301*.)

In crosses between *Abutilon striatum* and *A. thompsoni* flower and leaf characters proved hereditary. A range of color shades in F_1 suggested hybridity in the parents. The F_1 proved largely sterile.

Althaea. (Saunders, *458*.)

In a cross of double-flowered × single-flowered the F_1 was intermediate; the F_2 ratio was 1 single: 2 intermediate: 1 double.

Amaranthus caudatus L. (De Vries, *530*.)

The red-leaved type is dominant to the green.

Anagallis arvensis L. (Heribert-Nilsson, *200;* Weiss, *538.*)

Scarlet-flowered × blue produced scarlet flowers in F_1; in F_2 scarlet and blue in no usual Mendelian ratio. Pink (nearly white) × red-flowered yielded red flowers in F_1; in F_2, 3 red : 1 pink-flowered.

Anemone. (Hildebrand, *204;* Rosén, *442, 444.*)

Dark-blue flower color (*Anemone hepatica*) × white (*A. acutiloba*) produced light blue in F_1. Light blue (*A. angulosa*) × dark blue produced an intermediate color in F_1. Blue and red are dominant to white. Red × white often yielded blue in F_1, and in F_2 a ratio of 9 blue : 3 red : 4 white.

Antirrhinum calycinum Lam. (Saunders, *462.*)

Red corolla color is dominant to white, and glabrous stems and capsules to hairy. In the F_1 of red × white corolla, the red color is both diluted and retarded, i. e., the flowers developed in later growth are deeper red than early flowers of the same plant.

Antirrhinum hispanicum Chav. (Baur, *34;* Filzer, *128;* Sirks, *484.*)

In a cross between two self-sterile plants, the F_1 was divisible into two classes, one fertile with either parent, the other with one parent only. Filzer explained Baur's data by assuming three genes for sterility, one of which was common to the two parents.

Antirrhinum majus L. (Bateson, *16;* Baur, *27, 28, 29, 30, 31, 32, 33, 35, 36, 37, 38, 39;* Gairdner and Haldane, *140;* Hackbarth, *160;* Hertwig, *201;* Herzberg-Frankel, *202, 203;* Hiorth, *208;* Kuckuck, *306;* Saulescue, *448;* Scherz, *468;* Schiemann, *469;* Stein, *492, 493;* Stubbe, *499, 500, 501;* De Vries, *529;* Wheldale, *541, 542, 543.*)

Research has given information about some 200 genes in this plant. Color inheritance is complex. Wheldale interprets color expression on the basis of at least seven interacting genes. Baur adds to these a number of basic genes further conditioning, modifying, or intensifying color expression. Baur and his students and others have studied in a large number of mutants the inheritance of form of flower, form of and color distribution in leaves, and stem peculiarities. Most of these mutants, which appeared spontaneously in Baur's cultures, are defective types, and all but one, "crispa" (conditioning wavy leaf margins), are recessive. "Crispa" is dominant, distinctly deleterious in the heterozygous condition, and lethal when homozygous. Mutations have been artificially induced in snapdragon by treatments with radium (Stein), X-rays, ultraviolet light, and temperature shocks (Stubbe). Dwarfs and leaf defects are common; all the induced mutants are inferior types. In general the mutants are similar to spontaneous mutants but appear in higher frequencies. Stubbe records the appearance of some mutants not observed previously, and Stein reports a tendency to gall formation induced by radium. Baur found chemical treatment of stem tips ineffective, and Hiorth obtained no gene mutations from heat-treated pollen grains.

Several instances of linkage have been determined in the snapdragon. Gairdner and Haldane have reported a case of balanced lethals, i. e., two closely linked genes, each causing death of the individual when homozygous, permitting a heterozygous plant to breed nearly true, through elimination of the two homozygous classes.

Antirrhinum species hybrids. (Baur, *34;* Brieger, *55;* Gruber, *156;* Gruber and Kühl, *157.*)

Baur has studied the inheritance of fertility and sterility in several species of *Antirrhinum. A. ibanyezi, A. molle, A. glutinosum, A. hispanicum,* etc., are fully self-sterile; a form of *A. majus* is fully self-fertile. Crosses between self-sterile and self-fertile forms yielded in F_2, 15 self-fertile : 1 self-sterile. Gruber's and Brieger's results indicate that the inheritance of sterility is often more complex. Gruber and Kühl found the radial (peloric) flower character linked with genes for self-sterility.

Aquilegia vulgaris L. (Baur, *30, 32;* Brieger, *54;* Kristofferson, *304.*)

On selfing a dark blue plant, Kristofferson obtained a ratio of 9 dark blue : 3 red : 3 light blues : 1 white. Two genes were assumed, one having additional effects on plant color extension, producing self-color when dominant and white-margined when recessive. Baur found two types of chlorophyll defects—"chlorina" (yellowish green) and "variegata" were each monogenic recessive to the normal green. Chlorina is also a monogenic recessive to variegata. Brieger found flower colors segregating in the pattern of 9 blue : 3 red : 4 white,

with modifying genes controlling intensity of color. Spurless is determined by two polymeric dominants over spurred.

Aquilegia species hybrids. (Anderson and Schafer, *5*, *6*; Blaringhem, *51*; Skalińska *487*.)

Anderson and Schafer found wide petals dominant over narrow and medium length spurs over very long or very short ones in first-generation species hybrids. They observed 16 percent of natural crossing between two strains of *Aquilegia vulgaris*, but none between *A. vulgaris* and *A. skinneri*. Skalińska reports that anthocyanin flower color is linked with straight spurs. *A. californica* × *A. flabellata* yields a fertile F_1 generation and shows both parental types in F_2. The reciprocal cross differs in F_1 and shows no paternal type in F_2. Blaringhem has reported on inheritance in crosses of a mutant type having only female flowers with normal *A. vulgaris*, and also with *A. sibirica* and *A. chrysantha*.

Arabis albida Stev. (Correns, *97*.)

Correns studied three types of periclinal chimaeras in this plant. One type, "leucodermis", is inherited only through the female parent, not through the pollen (maternal inheritance); the other two types are Mendelian recessives.

Argemone. (Correns, *85*; Meunissier, *344*.)

Yellow-flowered *Argemone mexicana* × pale yellow *A. ochroleuca* yielded F_1 plants of intermediate color. *A. mexicana* × *A. platyceras* (white-flowered) produced plants of intermediate type in F_1, and in F_2 a new color type and several new forms in other characters.

Arum maculatum L. (Colgan, *77*.)

Colgan raised 11 seedlings from a plant having black spots on the leaves; of these 5 bore spotted leaves, 6 lacked spots.

Aster tripolium L. (Fleming, *131*.)

Fleming reports that purple flower color is dominant to pink and that pink is dominant to white.

Atropa belladonna L. (Bateson and Saunders, *23*.)

Differences in color of flowers, fruits, and stems, which distinguish the variety *lutea* from the type of the species, showed monogenic inheritance.

Barbarea vulgaris R. Br. (Anderson, *7*; Dahlgren, *105*.)

One type of variegation shows maternal inheritance only. Another type differs from the normal green type by duplicate recessive genes. Somatic segregation also occurs.

Begonia. (Bateson and Sutton, *26*.)

Inheritance of double versus single flowers showed irregularities not fully accounted for.

Bryonia dioica Jacq. (Jones and Rayner, *275*.)

Absence of bloom on the berry proved to be a monogenic dominant to its presence. In a cross between a variety with deeply lobed, rough, dark-green leaves and a variety with less deeply lobed, smoother, and paler leaves, the F_1 was intermediate, and new types appeared in the F_2 population. Number of carpels and number of vascular bundles in the stem were also studied.

Callistephus. (Fleming, *131*.)

From the results of natural crossing it is inferred that purple flower color is dominant to red, and red to white. Deep pink is dominant to white.

Campanula carpatica Jacq. (Pellew, *403*, *404*.)

Blue flower color is a simple dominant to white, but irregular segregation occurs in formation of the pollen grains, so that 97 percent carry the gene for blue, and only 3 percent carry the gene for white. Paler shades of blue are usually recessive to darker shades. White or "patched" seedlings proved recessive to the normal green type.

Campanula medium L. (Correns, *87*; Lathouwers, *309*.)

The "hose-in-hose" or "cup and saucer" type with petaloid calyx proved to be a partial dominant to the normal. In F_2 a ratio of 3 "hose-in-hose": 1 normal appeared. Lathouwers also crossed rose-flowered × white; the F_1 generation was dark violet; in F_2 segregation occurred in the ratio of 9 colored: 7 white, the colored forms falling into the ratio of 9 dark violet: 3 violet: 3 lilac: 1 rose-flowered. This was interpreted on the basis of two complementary genes for formation of anthocyanin and two further genes for color singly conditioning lilac and violet, and together producing dark violet, with rose the double recessive.

Campanula persicifolia L. (Bateson, *18.*)

A dwarf form very distinct from the normal type in appearance proved to be a monogenic recessive to the normal.

Canna. (Honing, *213, 214, 215, 216, 217.*)

Honing studied the behavior of some 18 genes in *Canna glauca, C. indica,* and in segregates from crosses between these species. The inheritance of red leaf margin is complex; in one cross the presence of three complementary genes was indicated, in other crosses monogenic and digenic ratios appeared. A monogenic difference was found responsible for the deep scarlet flower color of *C. indica* as contrasted with yellow flowers of *C. glauca.* Further studies of intensity of flower color, flaking in the flowers, etc., indicated that several genes were involved with ratios disturbed by linkages and lethal genes. Other characters of staminodes, leaves, stems, fruits, seeds were studied.

In crosses of *Canna indica* and *C. aureo-vittata* the proportion of red-margined leaves in the progeny is said to be influenced by differential growth rates of pollen tubes of differing genetic constitution, and also by the constitution of the plasma, so that reciprocal crosses may differ, particularly with respect to the proportions of plants with red-margined leaves. The appearance of a giant type as a somatic mutation is recorded.

Cattleya. (Hurst, *222, 223, 224;* Reychler, *436;* Reychler and Kamerling, *437.*)

In crosses of various Cattleya species, rosy purple flower color proved dominant to white, with two complementary genes involved. Certain albinos therefore produced colored forms on crossing. Other albinos behaved as monogenic recessives to colored. The yellow color of *Cattleya dowiana* var. *aurea* is recessive to the rosy purple color; yellow color in other cattleyas is partially dominant to rosy purple. Reychler mentions a collection of 175 seedlings derived from a cross of two mutants of *C. labiata.*

Celosia cristata L. (Kanna, *282;* Kihara, *300;* Terasawa, *507.*)

"Mosaic" inflorescence (a mixture of red and yellow) yielded on selfing a few reds in addition to the mosaic type. On selfing these reds a ratio of 3 red: 1 mosaic resulted. Kanna also found red dominant to mosaic. In his mosaic lines two types of bud variations were noted. A series of four multiple allels governs flower color (yellow or red) and stem color (green or red). Striping is produced by a recessive gene, which may mutate to the dominant colored condition.

Centaurea cyanus L. (Mekel, *341.*)

A system of three genes is presented to explain inheritance of blue, pink, and white flower color.

Cheiranthus cheiri L. (Blaringhem, *50;* Nelson, *388;* Sirks, *481.*)

The abnormal form *Cheiranthus cheiri* var. *gynanthus*, in which stamens are replaced by extra carpels and petals are much reduced, is a monogenic recessive to normal. In flower color dark red and yellowish brown are independent monogenic dominants to light yellow; dark red is epistatic to yellowish brown. The spontaneous appearance of a female plant with stamens aborted is again recorded by Blaringhem.

Chelidonium majus L. (Dahlgren, *104;* Heijl and Uittien, *196;* Sax, *467;* De Vries, *528, 529, 530.*)

Doubleness is recessive to singleness, but several degrees of doubling appear in F_2. The laciniate leaf type and the "minus" leaf type are independent monogenic recessives to the normal leaf type.

Chrysanthemum. (Miyake and Imai, *362;* Shimotomai, *470;* De Vries, *528.*)

De Vries found yellow flower color dominant to white in *Chrysanthemum roxburghi.* A hybrid, *C. marginatum* (90 chromosomes) × *C. morifolium* (54 chromosomes), is highly fertile and appears to be established as a constant 144-chromosome type; *C. decaisneanum* (74 chromosomes) × *C. indicum* (36 chromosomes) produced a sterile hybrid. A clone with flowers variegated white and magenta, which occasionally produces pure white flowers, is shown to be a chimera.

Clarkia elegans Douglas. (Bateson, *17;* Rasmuson, *432.*)

Four genes for color are recognized; the order of dominance is purplish red, salmon red, light red, and white.

Clarkia pulchella Pursh. (Rasmuson, *432;* De Vries, *528, 530.*)

Three genes for color are recognized; purple is dominant to purplish red; completely colored flowers are dominant to colored with white margins, and colored flowers dominant to white.

Clitoria ternatea L. (Rant, *424*.)

Blue flowers are dominant to white; peloric flowers to nonpeloric.

Coleus. (Correns, *102*.)

A variegated form of *Coleus hybridus*, "albopicta", is influenced by environment, but probably is inherited as a dominant.

Collinsia. (Hiorth, *207*, *209*, *210*, *211*; Rasmuson, *431*.)

Hiorth found white-spotted leaves, red-nerved leaves, and white flowers to be linked in *Collinsia bicolor*. Later he reported a study of 12 genes in this species, which fall into five or more linkage groups. The cross *C. bicolor* × *C. bartsiaefolia* produced a nearly sterile F_1, which was further almost sterile on backcrossing to either parent. Various backcrosses and F_2 and F_3 generations were nevertheless produced. Two partly fertile tetraploids, larger than the diploids, were extracted, one from an F_2 progeny and one from the progeny derived from selfing a backcross plant. Rasmuson reports two complementary genes for flower color in *C. bicolor;* one of these independently produces a red tinge in the stems, which is dilute in heterozygous condition. He also finds that the occurrence of spots on the upper lip of the flower in *C. tinctoria* is a monogenic dominant to the lack of spots. Yellow variegated plants in this species are simple recessives to normal.

Coreopsis tinctoria Nutt. (De Vries, *528*.)

Yellow flowers are dominant to brown (var. *brunnea*).

Cosmos bipinnatus Cav. (Miyake, Imai, and Tabuchi, *363*, *364*.)

A gene for full coloration and a gene for crimson, each acting only in the presence of a basic gene for color production, are postulated to explain the flower color classes crimson, pink, shaded, and white. Basal blotch on the ligulate flowers is considered to be a monogenic dominant to absence of the blotch. The character "double ring" of color on corollas is determined by two complementary genes. The inheritance of pollen color and an abnormal flower type, "bracteoid", have also been studied. Linkage between two genes has been established.

Cypripedium (and *Paphiopedilum*). (Hurst, *220*, *222*, *223*, *224*.)

Rose purple color is conditioned by two complementary genes; hence certain pairs of albinos yield colored offspring on crossing. A third gene produces dilution of color when recessive.

Dahlia variabilis Desf. (Lawrence, *310*, *311*, *312*.)

The dahlia has been shown to be an octoploid, having eight times the haploid number of chromosomes, i. e., a gene or its allelomorph may be represented from one to eight times in a given individual. The yellow and ivory flower colors are both dominant to white, yellow showing tetrasomic inheritance, and ivory, disomic inheritance. Magenta, purple, orange, scarlet, and crimson flower colors are the result of anthocyanin pigments showing over yellow and ivory flavone ground colors. Anthocyanin color apparently shows tetrasomic inheritance. Ivory and yellow flavone colors come from different ancestors, and the chromosomes bearing them do not pair. Similarly the two anthocyanin color genes occur in two different quadrivalent sets of chromosomes. Lawrence has also studied inheritance of a recessive albino flower type which is unstable, producing frequent somatic variation.

Delphinium ajacis L. (Demerec, *110*.)

Demerec studied inheritance of two unstable (mutable) genes, rosa-alpha and lavender-alpha, which frequently revert to their normal allels.

Delphinium orientale Losc. (Beckman, *43*.)

One dwarf type (nana) is a simple monogenic recessive to normal. A second dwarf (nanella) is also recessive, but shows irregular segregation. Double flowers are monogenically recessive to single. The abnormal "ranuncula-flower" type of double is dominant to the common double. Five genes for color are postulated to explain the inheritance of corolla color. The wild color (red-violet) is dominant over all other colors. A case of linkage is reported.

Dendrobium. (Hurst, *223*, *224*.)

Purple flower color is dependent on two complementary genes. Certain albinos yield colored forms on crossing.

Dianthus barbatus L. (Lilienfeld, *324*, *325*.)

In some varieties the flower color may change during the lifetime of the flower. When crossed with normal types this condition was found to be dominant. Singles × doubles give singles in F_1, and a ratio of 3 singles to 1 double in F_2. Normal growth is also a monogenic dominant to dwarf. At present three linkage groups have been established.

Dianthus caryophyllus L. (Batchelor, *15;* Connors, *81;* Saunders, *458.*)

White flowers are dominant to yellow, and red yellow flowers to red. A monogenic difference exists between the bullhead type (extremely double) and the single type; the commercial standard double is the heterozygous form.

Digitalis gloxiniaeflora Hort. (Warren, *534.*)

Nonpeloric is dominant to peloric, purple to white corolla color, and purple spotting on the corolla to brown spotting.

Digitalis purpurea L. (Haase-Bessell, *158, 159;* Keeble, Pellew, and Jones, *290;* Miyake and Imai, *350;* Saunders, *452, 459;* Shull, *475.*)

Conflicting reports exist as to inheritance of some characters. These may be due to differences in the actual varieties studied. White flower color has been reported both as a dominant and as a recessive. Some foxglove plants have the topmost flower of a distinctly different type; which is called peloric. This condition is reported as a simple monogenic recessive to normal. It is also reported as very complex in inheritance.

Digitalis species hybrids. Buxton and Dark, *65;* Buxton and Darlington, *66, 67;* Hill, *205;* Michaelis, *346*)

According to Hill, reciprocal F_1 hybrids of *Digitalis purpurea* and *D. lutea* are unlike, and in each case the hybrid resembles the maternal parent in size of calyx and corolla. Michaelis also found the F_1 progeny from *D. purpurea* (56 chromosomes) × *D. lutea* (96 chromosomes) unlike the reciprocal. The F_1 chromosome number was 76 in the somatic cells. *D. mertonensis* (112 chromosomes), a fertile tetraploid giant, arose from a cross of the two diploid species *D. purpurea* and *D. ambigua* (56 chromosomes in each). It forms only sterile hybrids with other species, both diploid and tetraploid. Various hybrid combinations of diploid species are also sterile.

Dolichos lablab L. (Harland, *194*)

The climbing habit behaves as a monogenic dominant to the bush habit. Flower color, seed-coat color, and plant color are closely correlated. In the F_2 of a cross between two white-flowered varieties, flower color segregated 9 purple: 7 white, and one of the white classes showed intermediate seed and stem coloration. Two genes are assumed: one determines purplish-brown seed coat and purplish hairs on the stipules, the other is epistatic to the first and produces, together with it, purple flowers, black seed, and colored nodes.

Dracocephalum thyrmiflorum L. (Dahlgren, *107.*)

The variety *pallida* (with white flowers, green plants) is a monogenic recessive to the *typica* form (with blue flowers and anthocyanin in the plant).

Epilobium angustifolium L. (Correns, *82, 83*)

The white-flowered variety is a monogenic recessive to the red-flowered type.

Epilobium hirsutum L. (Przyborowski, *413;* Stomps, *495.*)

An abnormal type, "cruciata", is a monogenic recessive to normal. A monogenic difference was found between two types of spines on pollen grains.

Epilobium species hybrids. (Lehmann, *319, 320, 321;* Lehmann and Schwemmle, *322;* Michaelis, *345, 347, 348, 349.*)

Hybrids of most species of *Epilobium* other than *Epilobium parviflorum* and *E. hirsutum* are reciprocally alike, but crosses involving the species mentioned yield reciprocally unlike hybrids. Differences between the reciprocals are found in size of organs, including flower size, in pollen fertility, and in reaction to mildew. The role of cytoplasmic inheritance in these differences has been intensively studied. A giant form twice the normal size but with a diploid complement is described (*322*).

Eschscholtzia mexicana Greene. (Uphof, *525.*)

White flower color is a monogenic dominant to yellow, and white to orange. Orange self-color is dominant to orange base on yellow petals.

Euphorbia pulcherrima Willd. (Robinson and Darrow, *439.*)

The pink form of the poinsettia is a chimeral sport from the red. White is apparently a mutation from red.

Freesia. (Morgan, *376.*)

Several unusual types appearing from spontaneous hybridization are described.

Galeopsis. (Hammarlund, *193;* Müntzing, *380, 381, 382, 383, 384.*)

In *Galeopsis tetrahit,* immunity to mildew (*Erysiphe labiatanum*) is a monogenic recessive to susceptibility; heterozygous forms show partial resistance. Müntzing has studied crossability, cytology, and genetics of species and 80 biotypes. Three groups of species do not intercross: *Ladanum, pubescens-*

speciosa, tetrahit-bifida. Five species hybrids within the subgenus *Ladanum* were produced. A triploid that appeared in the F_2 of a cross *G. pubescens* × *speciosa* gave rise to a tetraploid on crossing with *G. pubescens* as pollen parent. This tetraploid agrees closely with *G. tetrahit* in appearance and in cytological and breeding behavior. Spontaneous *G. tetrahit* is believed to have arisen from the above species in a similar manner. On intercrossing pure lines of *G. tetrahit*, 14 combinations gave high fertility in F_1, and 6 showed partial sterility. Partial sterility is attributed to a lethal gene, which destroys all pollen grains, but only part of the ovules containing it. In *G. tetrahit* and *G. bifida*, inheritance of flower and stem color and rate of sterility have also been analyzed genetically.

Gardenia florida L. (Capinpin, *68*.)

Incomplete data on inheritance of doubleness and fertility were obtained.

Geranium robertianum L. (Dahlgren, *107*.)

White flower color, "leucanthum", is a monogenic recessive to red.

Geum. (Dahlgren, *107;* Marsden-Jones, *333;* Rosén, *443;* Weiss and Rosén, *539*.)

The inheritance of certain characters has been studied in hybrids involving *Geum* species. The presence of anthocyanin is a monogenic dominant to its absence. Large flowers were dominant to small and the F_2 segregation indicated the presence of several genes. Yellow was a monogenic dominant to nonyellow, and red was dominant to nonred. The experimental hybrid *Geum urbanum* × *G. rivale* is indistinguishable from the naturally occurring *G. intermedium;* the reciprocal cross was not successful. Inheritance in *G. intermedium* is often irregular.

Godetia amoena Lilja. (Rasmuson *429, 433*.)

Each of two types of petal spots, on crossing with unspotted *Godetia whitneyi*, proved a monogenic dominant to the unspotted condition. When intercrossed the F_1 showed both types of spot; in F_2, 1 "basal fleck" : 2 double spot : 1 "querfleck" appeared. Rasmuson suggests the two genes are closely linked. Double flowers are dominant to single, but degree of doubleness is influenced by the petal-spot genes mentioned above.

Godetia whitneyi T. Moore. (Rasmuson, *429, 433*.)

Crosses involving different flower colors showed the following monogenic dominants: White over yellow-margined white, red over lilac, rose lilac over lilac, red-spotted over lilac, red over red-spotted, large spot over small spot, and light-margined red over pure red. Single flowers are more or less completely dominant over double ones.

Helichrysum bracteatum Andr. (Dambekalns, *109*.)

Three genes affecting white and yellow involucre color are established. Sulphur and orange are simple dominants to recessive white; the two dominants together condition gold. The third gene, dominant white, inhibits expression of sulphur, orange, and gold.

Hibiscus rosa-sinensis L. (Mendiola, *342, 343*.)

Lobing of seedling leaves was found to be a monogenic dominant to entire leaves. Self-sterility appeared to be correlated with absence of lobing. Single flowers appearing on normally double plants were self-sterile; on crossing with normal singles they bred like doubles. The occurrence of flower color sports is recorded.

Hibiscus sabdariffa L. (Howard and Howard, *218*.)

Eight genes are assumed for color in corolla, calyx, pollen, stem, and leaves. One gene may affect several parts of the plant, e. g., a gene for red in corolla eye, pollen, leaves, and stem is a monogenic dominant to its absence.

Hyacinthus. (De Mol, *372*.)

Hyacinth bulbs X-rayed during flower formation may show somatic variations in flower, leaf, or pollen characters. Somatic variation in flower color on a single flower stalk may be the result of mutations induced by changes in environmental conditions during flower formation.

Impatiens balsamina L. (Bedell, *44;* Hagiwara, *177;* Kanna, *280, 281, 284, 285;* Rasmuson, *425, 432*.)

At least three genes for flower color are known. White is recessive to blue-red, and to blue. A dominant gene for intensification of flower color is also reported. In color patterns, white flecking on colored flowers is reported by one investigator as a simple dominant to nonflecking; another reported it as a recessive. There are two types of double flowers, the common and the "camel lia", which latter is correlated with a dwarfish stature. Single is a monogenic

dominant to common double; but the cross single × camellia gave in F_2, 9 single: 3 common double: 4 camellia double. In a recent study (by Kanna) 16 genes are recognized, 3 lying in each of 2 linkage groups, the others showing largely independent inheritance. Ten genes are concerned with flower color, 3 with flower type. Winged flowers, peloric double flowers, and 3 defective types—"white blotched", "deficient", and "fasciated"—are all simple recessives to normal. A nonheritable type of fasciation also occurs. Striped flowers are determined by a mutable gene.

Ipomoea hederacea Jacq. (*Pharbitis nil*). (Hagiwara, *161, 162, 163, 164, 165, 166, 167, 168, 169, 170, 171, 172, 173, 174, 175, 176, 178, 179, 180, 181, 182, 183, 184, 185, 186, 187, 188, 189;* Imai, *233, 234, 235, 236, 237, 238, 239, 240, 241, 242, 243, 244, 245, 246, 247, 248, 249, 250, 251, 252, 253, 254, 255, 256, 257, 258, 259, 260, 261, 262, 263, 264, 265, 266, 267;* Imai and Kanna, *268, 269;* Imai and Tabuchi, *270, 271, 272;* Miyake and Imai, *351, 354, 358, 359, 360, 361;* Miyazawa, *365, 366, 367, 369, 370, 371;* Sô and Nishimura, *490;* U, *520;* Yamaguchi, *556, 557;* Yasui, *562, 563.*)

In the Japanese morning-glory white flower is a monogenic dominant to colored. At least six different white types exist. Some white × white crosses give colored in F_1, and a 9 : 7 ratio of colored to white in F_2. A complex interaction of complementary genes gives various white types in combination with a variety of different colored tubes, stems, and seeds. Genes modifying color have also been studied. The color of the inside of the tube seems to be controlled by a complex interaction of genes. The inheritance of various types of corollas has been studied, and the action of complementary and inhibiting genes reported. Five abnormal flower types were all monogenic recessives to the normal. Five types of doubleness have also been found to be simple recessives to normal. At least 17 abnormal leaf types are also simple recessives to normal. The literature of *Ipomoea* (*Pharbitis*) is more extensive than that of any other plant discussed here, due to intensive studies of a number of Japanese workers with fundamental objectives. Summary papers now appearing indicate that cultivated forms have arisen mainly through recessive mutations from the prototype; of the 111 genes described, only 15 are dominant; 70 genes have been located in 12 linkage groups (there are 15 pairs of chromosomes); 21 genes are concerned with flower color; 20 genes affect form of the leaf; 10 chlorophyll defects showing genic inheritance and 4 showing plastid inheritance are recognized; 20 genes of low stability (mutable genes) have been described; a provisional map of 1 chromosome showing linkage intensity, and many calculations of crossing over between specific gene pairs have appeared.

Ipomoea imperialis. (Correns, *98.*)

Two chlorophyll deficiencies, "chlorina" (pale green) and "albomarmorata" (white spotted), proved to be independent recessives to normal green.

Ipomoea purpurea (L.) Roth. (Barker, *12;* Imai, *234, 247.*)

Inheritance of flower color is controlled by interaction of several genes. Flaking of petals is a dominant character. Flower color and stem color are intimately related. Flower doubleness was found to be a monogenic dominant over singleness.

Iris. (Bliss, *53:* Colin and Carles, *78;* Reed, *435;* Simonet, *479.*)

Observations on color in bearded iris show Mendelian inheritance of brown-tipped beard, and colored leaf bases. Simonet reports four species-hybrids not yet of flowering size. Colin and Carles find that only species having the same glucosidal reserve can be crossed. Reed has described an F_2 population of a cross between *Iris fulva* and *I. foliosa*, obtained by selfing the garden variety Dorothea K. Williamson, a hybrid between these two species. The F_2 progeny showed a great range of color including types with pure yellow flowers.

Lamium. (Correns, *101;* Müntzing, *378, 385;* Sirks, *482, 485.*)

A peloric flowered form of *Lamium album* was recessive to the normal, but the F_2 ratio indicated five or more genes were involved. Another type with protruding stamens was also recessive, differing from normal by four or more genes. Yellow pollen in *L. hybridum* proved to be a monogenic recessive to red pollen. A type with the lower lips of the flower reduced behaved as a monogenic recessive to normal in *L. maculatum*. A cleistogamous flower type in *L. amplexicaule* showed a simple factor difference from open-flowered, with no dominance. In some species the summer annual habit (surviving only by seed) and the winter annual habit (surviving vegetatively) are modifiable; in *L. purpureum* an obligate winter annual type was found to differ geno-

typically from the facultative winter annual. Inheritance of flower color, time of bloom, height, and vigor were also studied.

Lathyrus odoratus L. (Bateson, *17;* Bateson and Punnett, *20, 21, 22;* Bateson and Saunders, *23;* Bateson, Saunders, and Punnett, *24;* Bateson, Saunders, Punnett, and Hurst, *25;* Gregory, *146;* Punnett, *414, 415, 416, 418, 419, 420;* Stone, *496;* Thoday and Thoday, *508.*

In flower color the following mongenic differences were found, dominant genes being given first: White v. cream, colored v. white, purple v. red, bright v. dull color, full v. dilute color, light v. dark wings, purple v. copper, purple v. maroon. Two identical appearing whites give a purple F_1, and nine purple to seven whites in F_2. A gene for bright color, one for full color, one for light wings, and one for purple act as modifiers for both purples and reds. Other color patterns, as marbling and flaking, are either recessive or heterozygous and not fixable. The four types of growth habit are tall, bush, cupid, and bush-cupid. Cupid × bush gives the normal tall. A form with sterile anthers is a simple recessive to normal. Punnett summarized the data on inheritance in sweet pea in 1924. More recently (1932) he has described five linkage groups and two unassociated genes in *Lathyrus,* corresponding to the seven pairs of chromosomes. Stone reported a somatic mutation from the cupid type to normal tall.

Lilium. (Griffiths, *151;* Heinricher, *198;* Preston, *410.*)

In a cross *Lilium* sp. × *L. croceum,* presence of bulbils was recessive to their absence. In F_2 segregation, parental and hybrid types appeared. In *L. bulbiferum* × *L.* sp. (*tigrinum* ?), bulbils again proved recessive. Griffiths and Preston have listed successful species-crosses.

Linaria. (Correns, *91, 95;* East, *116;* Saunders, *453;* Sirks, *484.*)

Pink flower color in *Linaria* is recessive to blue; orange color in the palate is recessive to its absence. Red × white-flowered *L. moroccana* yielded blue in F_1; in F_2, nine blue: three red: four white. Orange color in the palate is dominant to its absence in *L. vulgaris.* Data on inheritance of sterility collected by Correns have been explained by Sirks according to the scheme applied to *Nicotiana, Veronica,* etc. East reports cross-compatibility of 18 species or varieties of *Linaria.* Purple flowers are dominant to white, and trailing habit to bushy, in *L. cymbalaria.* Copper-colored flecks in the corolla are dominant to nonflecked in *L. broussonnetti* × *perezi.* Four genes are concerned in development of flower color in crosses of *L. sapphirina, L. moroccana,* and *L. reticulata.*

Linum species other than *L. usitatissimum.* (Correns, *99;* Hobusch, *212;* Laibach, *307, 308;* Tammes, *503.*)

In *Linum perenne* and *L. austriacum* the long-styled type is a monogenic recessive; the short-styled type is heterozygous. Self-fertility is apparently dominant to self-sterility. Several grades of self-fertility occur. In *L. austriacum* the difference between long and short style appears to be governed by more than one gene. Tammes has summarized the genetics of *Linum* up to 1928. Hobusch was able to grow the F_1 of *L. austriacum* × *L. perenne* by culturing the normally nonviable seeds on artificial media while still immature. Studies of backcrosses and later generations indicated that the proportion of good seeds is determined by degree of relationship of the parent lines.

Lobelia. (Saunders, *465.*)

An extensive series of flower types from singles through semidoubles to full doubles with five perianth whorls and no stamens occurs in *Lobelia.* Full doubles are sterile, singles are pure-breeding, but genic analysis of semidoubles is not complete.

Lunaria annua L. (Correns, *89.*)

The white-margined leaf type, "albomarginata", is a mongenic recessive to normal.

Lupinus angustifolius L. (Fruwirth, *138;* Hallqvist, *192;* Kajanus, *276;* Roemer, *440, 441;* Sypniewski, *502;* Vestergaard, *526, 527.*)

In flower color, monogenic differences were found between blue and white, blue and red, and red and white. Some crosses between red and white, however, gave a blue F_1, and nine blues : three reds : four whites in F_2.

Lupinus species other than *L. angustifolius.* (Burlingame, *63;* Kajanus, *276; 277.*)

In *Lupinus luteus* the black-seeded type is a monogenic dominant to gray. In *L. mutabilis* blue flowers proved monogenically dominant to white. Work-

ing with *L. apricus* var. *vallicola*, *L. pipersmithi*, and *L. nanus*, Burlingame found a white-striped flower type, which segregated into dark blue, white-striped, and white. This was interpreted on a single gene basis, the white striped being the heterozygous type. Light-blue flowers were mongenically dominant to dark-blue. Dark seeds are associated with dark-blue flowers but probably not determined by the same gene.

Lychnis (including *Melandrium* and *Viscaria*). (Åkerlund, *2;* Bateson and Saunders, *23;* Baur, *30;* Correns, *85;* Shull, *473*, *474*, *476*, *477*, *478;* Tjebbes, *512;* De Vries, *528 530;* Winge, *548*, *549*.)

Lychnis species are normally dioecious, having the male and female flowers on separate plants. Much of the genetic literature concerns the technical problem of sex inheritance. Constant-breeding hermaphrodites are maintained by a system of balanced lethals. Purple flowers are dominant to white. Broad leaf is a monogenic dominant to narrow leaf; it is also apparently sex-linked. Chlorophyll deficient types are recessive to normal green. Winge (*549*) reports that "aurea", a chlorophyll defective, is a sex-linked recessive, restricted to male plants because it is lethal where homozygous. "Variegated", another chlorophyll defect, is limited to female plants. Åkerlund found *Melandrium album* more winter hardy than *M. rubrum*, the F_1 intermediate. Backcrosses to *M. album* were more hardy when the hybrid was the pollen parent than in the reciprocal backcross. Tjebbes recognized four recessive types—"broom growth", "rolled corolla", "transparent corolla", and "biennial type", isolated from inbreeding garden strains of *Viscaria* (*Lychnis*).

Lythrum salicaria L. (Barlow, *13*, *14;* East, *112*, *113*, *114*, *115;* Ubisch, *521*, *523*.)

The styles of this species occur in three different length classes Genetic investigation has been largely concerned with inheritance of style length. A two-factor hypothesis failed to account for certain midstyle types, and a balanced lethal hypothesis at present seems most tenable (East, *115*).

Malope trifida Cav. (Rasmuson, *426*.)

A white-flowered type proved to be a monogenic recessive to red-flowered.

Matthiola incana (L.) R. Br. (Bateson and Saunders, *23*, *24*, *25;* Correns, *83;* Fisher, *130;* Frost, *134*, *135*, *136*, *137;* Goldschmidt, *144;* Kappert, *286*; Lesley and Frost, *323;* Muller, *386;* Philp and Huskins, *408;* Saunders, *451*, *454*, *455*, *456*, *457*, *460*, *461*, *463*, *464;* Snow, *488*, *489;* Tschermak, *518*, *519;* Waddington, *531;* Winge, *550*.)

A cross of rose × white gave a purple F_1 and a trigenic segregation of 27 pale purple : 9 deep purple : 9 rose : 3 deep red : 16 white in F_2. There are also genes that dilute the colors. Two genes are necessary for the production of anthocyanin; if one or both are absent, the flower is uncolored. There is also a gene converting all reds to purple, and another causing the difference between the pure and dull color. Cream is due to pigment in the plastids. It behaves as a monogenic recessive to white. Doubleness is recessive to singleness (for discussion of this question, see section on double-flowering stock). Earliness in blooming is dominant to lateness as is open growth habit to compactness. Saunders has summarized the published data on breeding of stocks to 1928.

Meconopsis cambrica Vig. (Saunders, *458*.)

Doubleness is dominant to singleness, a single gene being involved.

Mimulus. (Brožek, *56*, *57*, *58*, *59*, *60*, *61*, *62*.)

Inheritance of several characters in *Mimulus quinquevulnerus*, *M. tigrinus*, and *M. tigrinoides* has been studied. Distribution of color spots over the entire petal surface behaves as a monogenic dominant to spots limited to half the surface. Single flowers are dominant to doubles, two genes being able to inhibit the double condition entirely or partly. Plants with a terminal flower differing from lower flowers showed dominance of this character. Two genes concerned in flower color have been established in *M. cardinalis*. One determines development of yellow plastids, the other anthocyanin sap color.

Mirabilis jalapa L. (Baur, *28;* Correns, *84*, *85*, *88*, *89*, *90*, *92*, *93*, *94*, *96;* Kanna, *283;* Kiernan and White, *299;* Marryat, *332;* Showalter, *471*, *472*.)

Flower color inheritance in *Mirabilis* shows many cases of intermediate hybrids that cannot be made pure. White × yellow gives pale yellow in F_1 and one white : two pale yellow : one yellow in F_2. White × crimson gives deep magenta, and yellow × crimson, orange red, in a 1:2:1 F_2 ratio in each case. White × crimson, and white × yellow both give magenta rose in F_1, and a very complex F_2. White × white gave white F_1 and F_2. In one instance two whites

gave colored F_1 types. The striped varieties are all heterozygous, segregating to self colors and striped in F_2. In other characters tall is dominant to half dwarf and to dwarf. Half dwarf is dominant to dwarf. Kanna and Showalter independently interpret flower color expression on the basis of two series of multiple allels, one series governing base color, the other modifying color expression. Mutable genes are found in each series. Showalter describes a mutant growth type, "box", which is a monogenic recessive.

Myosotis. (Chittenden, *71.*)

Two genes for flower color are assumed. Pink is dominant to white and blue is dominant to pink.

Nemesia strumosa Benth. (Riley, *438.*)

At least four intrasterile, interfertile lines occur in this self-sterile species.

Nemophila atomaria Fisch. and Mey. (Chittenden, *70.*)

Three genes are postulated to explain inheritance of flower color (lilac, black, red, pale brown) and four other genes for inheritance of color distribution. Apparently lilac is dominant to black, black to red, and red to pale brown. The spotted flower coloration is a monogenic dominant to full-colored.

Nemophila insignis Brand. (Chittenden, *70.*)

Blue flower color is dominant to mauve and to white. Mauve × white produced blue flowers in F_1.

Nemophila liniflora Fisch. and Mey. (Chittenden, *70.*)

At least three genes for flower color and color distribution are assumed. Pale-blue flower color is a simple dominant to purplish blue, and spotted eye (spotted with black) is dominant to full black eye, the two genes showing independent inheritance. One or two basic genes for flower color are also postulated. Black spotted leaves are determined by a single gene, the recessive condition being white spotted leaves.

Nigella damascena L. (Toxopéus, *514.*)

Long stems are dominant to the dwarf form. Crosses between yellow variegated and green plants give green in F_1, and 3 green to 1 yellow variegated in F_2. Single flower was a simple monogenic dominant to normal double. A second double type was dominant to single, and in F_2 no single plants appeared. In studies of color inheritance, colored was dominant to ivory white, blue to violet, and dark blue to pure white.

Nymphaea. (Anonymous, *1.*)

A dominant white is reported.

Odontoglossum. (Hurst, *222.*)

Blotched flower is dominant to self-colored, and yellow-flowered to white.

Orchidaceae. (Colman, *79;* Godfrey, *142.*)

Two lists of successful orchid hybrids, including intergenic hybrids, have appeared.

Oxalis corniculata L. (Nohara, *394.*)

Purple in leaves and in the eye of the flower is monogenically dominant to its absence.

Oxalis rosea Jacq. (Ubisch, *522, 523, 524.*)

Two genes for flower color are recognized, one producing light rose when present in the dominant form, and with a second gene, rose color; white is the recessive. Three genes for style length are assumed; each of the two genes for flower color shows linkage with one of these.

Oxalis valdiviana Hort. (Barlow, *13, 14;* Ubisch, *524.*)

The mechanism of inheritance of style length is, according to Ubisch, similar to that in *Oxalis rosea.*

Paeonia. (Saunders, *449.*)

Twenty-nine hybrid strains have flowered. An F_2 population from the cross *Paeonia albiflora* × *macrophylla* has matured. Two abnormal strains and a few types of ornamental value have appeared.

Papaver rhoeas L. (Becker, *42;* Negodi, *387;* Newton, *389;* Philp, *406, 407;* Rasmuson, *430;* Shull, *476.*)

A white margin of the petals is dominant to its absence. Seven genes for flower color have been isolated and belong in three linkage groups. Nine genes are established by Philp (*407*). Doubleness is determined by several genes. Albinism is a simple recessive to normal, and is independent of flower color. In hybrids of *Papaver rhoeas* and *P. commutatum* the characters of the latter species are largely dominant.

Papaver somniferum L. (De Vries, *528, 530;* Fruwirth, *139;* Hurst, *221;* Ishikara, Kobetsu, and Kojima, *273;* Kajanus, *278, 279;* Kasaeva, *287;* Leake and Prasad, *313, 314;* Miyake and Imai, *353, 355, 356.*)

The basal spot on petals is dominant over its absence. Color in the petal is dominant over white, and purple is dominant over red. When forms are heterozygous for color genes they usually produce progenies with considerable variations in intensity of color. Other color genes have been studied. In plant size, large is a simple dominant over small, and nonstriped petals over striped. Other simple dominants are single over double flowers, and laciniated over entire petals. The cross *Papaver somniferum* × *bracteatum* was successful; the reciprocal produced no viable seeds. The F_1 plants were perennial, very variable, including some monstrous forms. F_2 plants were obtained.

Pelargonium zonale Willd. (Ballard, *9;* Baur, *30;* Moncrieff, *373;* Noack, *392. 393;* Roth, *445.*)

Inheritance of doubleness is incompletely analyzed, singleness is regarded as dominant. A golden-leaved type, "aurea", is a heterozygous form, segregating on selfing into 1 normal green: 2 "aurea": 1 pure yellow. The pure yellow dies in the seedling stage or earlier. The "freak of nature" variety, the leaves of which have white centers and green borders, is not a chimeral type. This leaf character is inherited through both egg and pollen. The chemical nature of dominant rose-pink and recessive salmon-pink flower colors, and of other colors, is interpreted by Moncrieff.

Petunia violacea Lindl. (Ferguson, *126, 127;* Frost, *134;* Harland and Atteck, *195;* Kostoff and Kendall, *302;* Malinowski, *328, 329, 330;* Malinowski and Skalińska, *331;* Matuda, *340;* Moore and Haskins, *375;* Rasmuson, *428;* Sachs-Skalińska, *446, 486;* Saunders, *450, 456;* Savelli, *466;* Terao, *504;* Terao and Nagaharu, *505;* Terao and U, *506;* Tjebbes, *510, 511;* Ubisch, *522;* Westgate, *540;* Yasuda, *559, 560.*)

Color inheritance was mostly simple monogenic with violet dominant over red, also over lilac. Uniform coloring is dominant over green-edged flowers. Violet red × white gave an intermediate F_1, and a 1:2:1 ratio in F_2. Other colors were more complex. Doubleness exists in a wide range of degree. It is caused by stamens becoming petals. Singles × singles give all singles. Singles × doubles give a 1:1 ratio. Doubles × doubles give about 3 doubles to 1 single. In *Petunia axillaris* and *P. violacea,* the progenitors of the cultivated petunias, four pairs of genes determine pollen color. The white flower color of *P. axillaris* was inherited as a recessive in a cross with a royal purple garden form, but the parental purple was not recovered in F_2. Both *P. axillaris* and *P. violacea* are usually self-sterile, and the F_1 is only partly fertile. Garden forms are sometimes fertile, but several grades of self-sterility also occur. Harland and Atteck (*183*) interpret self-sterility on the basis of four multiple allels. By bud pollination they were able to self four normally self-sterile lines, finding one homozygous lethal, one dwarfed, the other two normal in appearance. One or more variegated types show irregular inheritance. Mutations have been induced by X-ray treatment of seed and of flower buds. Some garden petunias are tetraploid, showing irregular behavior on crossing with diploid varieties. Petunia pollen has been shown to stimulate fruit formation in eggplant (*Solanum melongena*), but no seeds are formed.

Phacelia. (Chittenden, *70.*)

Two species, *Phacelia parryi* and *P. whitlavia* were found to cross readily and furnish fertile offspring. Purple flowers proved dominant to bicolored (purple limb and white tube), and bicolored dominant to white. A recessive giant type was found in *P. parryi,* and a recessive entire-leaved form in *P. whitlavia* var. *alba.*

Phlox drummondii Hook. (Flory, *132;* Gilbert, *141;* Kelly, *291, 292, 293, 294, 295, 296, 297;* Kelly and Wahl, *298.*)

Five genes are assumed to account for the inheritance of flower color by Gilbert (*141*). Kelly interprets flower color according to a seven-gene scheme. Cream-yellow is a monogenic recessive to white. A semidouble type is apparently influenced by more than one gene. Salver-shaped corolla is monogenically dominant to funnel-shaped. Entire petals are due to one gene; the recessive form is deeply cut, and the heterozygous form is the "fimbriata" type. Stylelessness and fasciation are each monogenic recessives to normal. Attempts to cross *Phlox paniculata* with *P. drummondii* yielded infertile F_1 progeny; *P. divaricata* × *drummondii* produced an F_1 that developed a few seeds (*132*).

Polemonium. (Correns, *86;* Dahlgren, *104, 106;* Ostenfeld, *399, 400, 401;* De Vries, *528, 530.*)

Blue corolla color in *Polemonium caeruleum* is monogenically dominant to white, pinnate leaf form to bipinnate, normal petal to small narrow petals, and normal green leaves to the pale green (chlorina) type. Both the blue and the white flower colors of *P. caeruleum* proved dominant to the yellow of *P. flavum* in F_1, but these interspecific hybrids were sterile. *P. mexicanum* × *pauciflorum* yielded intermediate forms in F_1, with complex segregation in F_2 and later generations, most of the segregates proving fertile. The reciprocal cross yielded no seed, possibly because *P. pauciflorum* styles are eight times as long as those of *P. mexicanum.* Crosses of *P. caeruleum* with *P. carneum* and with *P. filicinum* yielded only sterile plants in F_1.

Portulaca grandiflora Hook. (Blakeslee, *47;* Blakeslee and Avery, *49;* Enomoto, *118, 119;* Ikeno, *228, 229, 231, 232;* Okura, *398;* Tjebbes, *509;* Yasui, *561.*)

Color of floral parts and vegetative parts are correlated with each other. The interaction of five genes for color has been studied. One special white race is a dominant white with a recessive lethal effect. Pure whites of this type are not produced. When selfed it gives two special whites to one normal white. About one-fourth of the seeds from selfing special white are nonviable. Mosaics on the corolla are heterozygous. A Mendelian analysis has not been made. Doubleness is a simple dominant to singleness. Dwarf type is a simple recessive to normal. This gene reverts to normal fairly frequently. Dwarf plants bear normal branches, and vice versa. Ikeno reported that inheritance of purple-spotted flowers did not conform to Mendelian theory. The species is normally self-fertile, but Tjebbes found a self-sterile variety within which two self-sterile but cross-fertile groups occurred. Okura identified as haploids three dwarf individuals from F_2 and F_3 generations of a cross. These produced an occasional normal diploid on being pollinated with normal pollen.

Potentilla. (Müntzing, *379.*)

Constancy of biotypes within several species of *Potentilla* is due to perfect pseudogamous maternal inheritance. Pollen is not functional, but pollination of emasculated flowers is necessary for setting of seed.

Primula. (Altenburg, *3;* Bateson and Gregory, *19;* Buxton, *64;* Chattaway and Snow, *69;* Chittenden, *70;* Correns, *102;* Dahlgren, *103; 108;* Ernst, *121, 122, 123;* Frimmel, *133;* Gregory, *147, 148, 149;* Gregory, De Winton, and Bateson, *150;* Heinricher, *199;* Huskins, *227;* Keeble and Pellew, *288, 289;* Marsden-Jones and Turrill, *337;* Pellew and Durham, *405;* Raunkiaer, *434;* Sansome, 447; Sömme, *491;* Ubisch, *523;* De Winton, *551, 552, 553, 554;* De Winton and Haldane, *553;* Zollikofer, *564.*)

According to Frimmel (*133*), three pigments occur in flower colors of the garden primrose—anthocyanin, carotin, and anthochlor yellow; 260 color tones are recognizable. Carotin inheritance is monogenic, anthocyanin is digenic, with a factor for red and another for blue, the two together developing a blue-violet; white is recessive. Colors approaching black result from association of the gene for carotin with the two anthocyanin genes. Heterozygotes are expressed as various color tones. Four forms of the "eye" of the flower in *Primula sinensis* are known. Small eye is a monogenic dominant to large eye, and white eye acts in varying degrees as dominant over both small and large eyes. A fourth type, large greenish eye, is a monogenic recessive to normal. Two types of doubleness occur. Each is a monogenic recessive to normal. In several species of *Primula* normal forms have short styles with anthers borne above the stigma, or long styles with anthers at a lower level. These are self-sterile. Crossover types with long styles and anthers at the higher level and short styles with anthers at the lower level are infrequent but self-fertile. The short-style type is a simple dominant to long-style, except in *P. hortensis*, in which two genes are assumed. In *P. obconica* fertility is lower when forms of like style length are crossed than when unlike lengths are crossed. In *P. hortensis* and *P. acaulis* fertilization of normally incompatible forms was accomplished by pollinating stubs after removal of styles. In crosses of *P. juliae* with *P. acaulis* and *P. elatior*, F_2 and backcross data were obtained; short styles were dominant over long, orange over yellow eye. In *P. vulgaris* one recessive gene is responsible for various defects in floral organs. A white-margined leaf type is recessive in *P. malacoides*. In *P. officinalis* a defective type with five extra pistils and no stamens is a simple recessive. Genetic analysis is most advanced in *P. sinensis*, in which 25 pairs of genes and 2 sets of

multiple allels are recognized. Fifteen of these genes have been located in four chromosomes. On selfing *P. kewensis*, a tetraploid species, and several types with respect to style length, fertility, greening in the corolla, and doubleness were obtained, but the parental types were not recovered. Other tetraploid forms which appeared in progenies of diploid *P. sinensis*, proved less fertile than the diploids. Only two of seven genes completely dominant in the diploid, proved completely dominant in the tetraploid, i. e., when one dominant gene and three recessives were opposed. A technical study of linkage in a tetraploid has been made.

Quamoclit. (Nohara, *395.*)

Two flower colors in *Quamoclit pennata* differ by a single gene, without dominance. Stem color may be determined by the same gene. The F_1 of *Q. coccinea* × *Q. pennata* is intermediate and sterile, although *Q. sloteri*, a fixed race, is believed to have arisen from such a cross.

Ranunculus. (Marsden-Jones and Turrill, *334;* Ragionieri, *422.*)

A double, large-flowered form is reported as the result of selection from *Ranunculus asiaticus*. Studies of inheritance of color, sex, and sterility in *R. acris* and *R. bulbosus* have not reached satisfactory analysis.

Reseda odorata L. (Compton, *80.*)

Orange-red pollen color appears to be a monogenic dominant to yellow, and self-compatibility has the same relation to self-incompatibility.

Rhododendron. (Ikeno, *230;* Miyazawa, *368.*)

In studies within the species *Rhododendron indicum* (*Azalea indica*) and in crosses of this species with *R. sinense*, single flowers were monogenically dominant to double, self-colored flowers to variegated, and short stamens to long. The prostrate habit is recessive to upright. Flower size and leaf breadth showed intermediate conditions in F_1. The hose-in-hose type in *R. indicum* var. *kaempferi* was interpreted as a dominant heterozygous form, the pure recessive being the normal type. The apetalous form (petals replaced by stamens) is a similar case but two genes are involved, the apetalous being heterozygous for both, and the normal type double recessive. "Polypetala" (petals separate instead of united) is a dominant heterozygous form, showing a single gene difference from normal.

Rosa. (Erlanson, *120;* Godfrey, *143;* Hurst, *225*, *226.*)

Incompatibility and sterility present serious difficulties in rose breeding. Hurst and Erlanson have shown that extensive polyploid series occur in roses. Hurst found 377 diploids and 629 polyploids in 1,006 species and forms of *Rosa* examined. He considers that five diploid species fundamental to the genus have given rise to many other species in various polyploid combinations. The hybrid tea roses are chiefly tetraploids, and triploid forms also appear among garden hybrids. Pentaploid, hexaploid, and octoploid forms are also found in the genus.

Rudbeckia. (Blakeslee, *48.*)

Two forms with yellow disks were distinguishable by treatment with potassium hydroxide, one turning black, the other yellow. On crossing these two yellow types, purple (normal type) appeared in F_1, and in F_2, 9 purple : 3 "black-yellow" : 4 "red-yellow."

Salvia. (Bateson, Saunders, Punnett, and Hurst, *25;* Blaringhem, *52;* Hrubý, *219.*)

Pink flower color in *Salvia horminum* is a monogenic dominant to white, while violet is the result of interaction of the gene for pink with a second complementary gene which has no effect (i. e., white) when present alone. In the course of six generations of selfing of *S. pratensis* (normally hermaphrodite and blue-flowered), decreased vigor and fertility, and segregation of types with white flowers, female flowers, mosaic leaves, etc., were observed. Attempts to cross *S. nutans* with *S. juriscici* have thus far failed, but selfing of a supposed natural hybrid yielded parental types and an intermediate type like F_1.

Saponaria ocymoides L. (Meunissier, *344.*)

A large, pink-flowered type was found to be dominant to a small white type in F_1.

Saxifraga. (Marsden-Jones and Turrill, *335;* Whyte, *547.*)

Saxifraga potternensis is a tetraploid derivative of the cross *S. rosacea* × *granulata*. Its breeding behavior is uniform.

Senecio vulgaris L. (Trow, *515*, *516*, *517.*)

A scheme of at least 12 genes has been formulated to explain inheritance of a number of differences existing between various named types of this species.

The characters studied include type and color of heads, incision of rays, color of stems, color of leaves, number of nodes. Two or more instances of linkage are recognized.

Silene. (Correns, *91;* Marsden-Jones and Turrill, *336, 338;* De Vries, *528, 530.*)

Pigmented flowers in *Silene armeria* are dominant to white. On crossing white × rose flower color Correns found a monogenic relation, in which white and rose are pure breeding forms and the heterozygote is red. This red type was like the wild form in appearance, but the latter was found to be a pure-breeding red. *S. vulgaris* showed segregation for various characters on selfing. Segregation was noted also in the progeny of a cross of this species with *S. maritima.* A type with defective petals proved to be a simple recessive to normal.

Sisyrinchium angustifolium Mill. (Miyake and Imai, *352, 357.*)

On crossing a self-colored purple with a white with purple eye, a monogenic relation was found, the self-colored proving to be partially dominant.

Tagetes erecta L. (Punnett, *417.*)

The double flower is a monogenic dominant to single, and the flat type of floret to the tubular, the two characters showing independent inheritance. Two or more genes are apparently concerned in the difference between deep orange and lemon-yellow flower color.

Tetragonolobus purpureus Moench. (Nilsson, *391.*)

Yellow flower color is a monogenic recessive to red.

Tropaeolum majus L. (Correns, *98;* Eyster and Burpee, *125;* Rasmuson, *427, 432.*)

Monogenic differences were found between dark-yellow and light-yellow flowers, between red anthocyanin and its absence. Variegated flowers are dominant to self-colored. The climbing type is a monogenic dominant to the dwarf type. Dark-green leaf color is determined by two genes. Two defective types, pale green and white-spotted leaves, each proved to be simple recessives to normal green and showed independent inheritance. Doubleness and fragrance are monogenic recessives. "Super-double" is dominant to both single and common double.

Tropaeolum species hybrids. (Fischer, *129;* Warren, *535.*)

On crossing *Tropaeolum majus* × *T. minus*, red flower proved dominant to yellow, green leaf to variegated, and tall stature to dwarf. The gene for stature was partially linked with that for leaf color. In the hybrid between *T. minus* and *T. peregrinum*, known as *T. pinnatum*, red pigment in corolla and stem proved dominant to its absence, and the relation appeared to be monogenic.

Tulipa. (Hall, *190;* De Mol, *372.*)

So-called "thieves", narrow-petaled forms, are probably mutant forms in tulip varieties. They also occur in tulip bulbs X-rayed during flower formation.

Venidium × *Arctotis.* (Warren, *536, 537.*)

A natural hybrid, *Venedium wyleyi* × *Arctotis stoechadifolia* var. *grandis*, was largely intermediate between the parents but taller and bulkier. In F_2 no clear segregation occurred, but various characters showed dominance of one or the other parental types.

Verbascum blattaria L. (Shull, *473.*)

Bright yellow corolla is a monogenic dominant to pale yellow.

Verbascum phoeniceum L. (Sirks, *480, 483, 484.*)

The inheritance of self-compatibility and self-incompatibility in this species appears to be complex and somewhat irregular.

Verbena. (Eyster, *124.*)

Light variegations in flower color are dominant to heavy variegations; variegation is dominant to dilute self-color; light self-color is dominant to darker self-color.

Veronica gentianoides Vahl. (Correns, *98, 100.*)

The short-styled form is a heterozygous dominant, the long-styled is the homozygous recessive. Style length is further affected by a series of modifying genes. A white-margined form, on crossing with the normal, produced only normal in F_1 and F_2, the defective type showing no genic inheritance.

Veronica longifolia L. (De Vries, *528, 530.*)

The white-flowered type is recessive to the pigmented form, the recessive occasionally appearing as a somatic mutation in large F_1 populations.

Veronica syriaca Roem. and Schult. (Filzer, *128;* Lehmann, *315, 316, 317, 318.*)

Blue flowers are monogenically dominant to rose and white. Self-sterility is determined by a series of multiple allels, which accelerate or inhibit pollen-

tube growth in compatible and incompatible styles. In the F_2 of a cross, four intrasterile but interfertile groups appeared.

Veronica tourneforti C. C. Gmel. (Beatus, *41.*)

In this tetraploid species, number of sepals (four or five) appears to be determined by a series of multiple allels.

Viola arvensis Murray. (Clausen, *72.*)

Study of inheritance of a spot on the style revealed unusual relations, which were explained on the assumption of three or more pairs of genes.

Viola tricolor L. (Clausen, *72, 73, 74;* Kristofferson, *303, 305.*)

The inheritance of flower color is somewhat complex, indicating gene interactions. The presence of a colored spot on the front of the style is dominant to its absence. A second type of spot requires the presence of another gene before it can appear. The prostrate habit of growth in the variety *maritima* is dominant to the erect type of other varieties. Some characters, such as variegations, are apparently non-Mendelian. They appear to depend on plastids in the cytoplasm. The velvety black flower color of *Viola tricolor* var. *nigra* is reported to be determined by three basic genes for expression of color, and five inhibitor genes, which suppress the development of velvety black.

Viola species hybrids. (Clausen, *75.*)

Clausen has reported 25 successful species crosses. *Viola tricolor* and *V. arvensis* cross with many species; *V. cornuta* with only *V. orphanoides* and *V. elegantula; V. calcarata* with only *V. battandieri*. Some new fertile types have been isolated from crosses.

Zantedeschia (*Richardia*). (Ragionieri, *421.*)

In a cross between *Zantedeschia rehmannii* and *Z. elliottiana* most of the characters of the latter proved dominant in F_1, the yellow spathe color being an exception. In F_2 spathe color, size, form, spotting of leaves, etc., showed segregation, but the number in the progenies were too small for interpretation of genic relations.

MISCELLANEOUS FORAGE AND COVER CROP LEGUMES

ROLAND McKEE, Senior Agronomist,
A. J. PIETERS, Principal Agronomist,
Division of Forage Crops and Diseases, Bureau of Plant Industry

THE large family known as Leguminosae, or legumes, contains some of the most interesting and important crop plants. The legumes are distinguished from other plant groups particularly by their flowers and seed pods. The flowers are always irregular in shape, resembling a butterfly, while the pods have two valves or parts into which they readily divide, as in the case of garden beans or peas. Most of the plants with pods that split into halves are legumes. Another distinguishing characteristic of legumes is their ability to take nitrogen directly from the air through association with bacteria that live on their roots, and to manufacture it into food for plant growth. By this means soils are enriched, soil fertility is maintained, and increased crop production is made possible. Some of the minor legumes used solely for cover crops and soil improvement are not so well known as crops grown for forage or grain, but they deserve much wider recognition and could well be used much more extensively.

Improvement work with legumes other than soybeans, alfalfa, and clovers has been very limited, but the importance of this group of plants justifies giving them serious consideration in any improvement program. They have been the subject of some genetic investigation, which will be discussed later.

BREEDING WORK AND POSSIBILITIES

WHILE the legumes considered in this article occupy a place secondary to such crops as alfalfa and red clover, some have proved of great value in sections in which the other legumes do not thrive. The annual lespedezas, for example, because of their ability to grow on soils of low fertility and too acid for alfalfa and clover, have become the chief forage crops from southern Iowa to the Gulf of Mexico. Without them a profitable agriculture in much of that region would be difficult or impossible.

Likewise the vetches and field peas fill an irreplaceable function in the soil-improvement programs of the Southern States, while the cowpea is a standard crop and the bur-clovers furnish winter grazing and soil improvement for millions of acres. Of the more recently introduced crops the crotalarias fill a place on sandy land not otherwise filled, and there are good reasons for believing that some of these species may become leading forage crops in the South.

The present soil-conservation program will require legumes for a variety of situations, but all must have in common the property of

adaptation to reduced fertility and probably to soil acidity. Among these miscellaneous legumes now little known there may be some that with proper attention to selection will prove precisely suited for one or more such situations.

Astragalus

(*Astragalus* spp.)

The genus *Astragalus* contains a very large number of species, commonly called milk vetches. Most of them are especially adapted to dry and arid conditions. None of the species is of much commercial importance, although several are utilized locally and have forage value. No selection or other improvement work has been attempted in this genus, but the drought-resistant quality of the many species would seem to justify the conclusion that for dry-land and arid regions it is perhaps the most likely group from which to expect a legume of agricultural value.

Beggarweed

(*Meibomia* spp.)

The beggarweed or tick trefoil group is composed of a fairly large number of species, few of which have been brought under cultivation. The Florida beggarweed (*Meibomia purpurea* (Mill.) Vail) is the best known and the only one that is grown commercially in the United States. No attempt at improvement has been undertaken, although some natural selection no doubt has taken place, as the crop is harvested from cultivated stands. To what extent improvement is possible no one can say. The species are variable, however, and, no doubt, would respond readily to selection. One botanical variety, *M. paniculata* var. *pubens* (T. and G.) Vail, that has been grown in experimental plantings has growth habits that give promise of usefulness.

WHILE *the legumes considered in this article occupy a place secondary to such crops as alfalfa and red clover, some have proved of great value in sections in which other legumes do not thrive. The annual lespedezas, for example, grow on acid soils of low fertility, and without them a profitable agriculture in large areas from southern Iowa to the Gulf of Mexico would be difficult or impossible. The vetches and field peas likewise fulfill a valuable function in soil-improvement programs. Among the miscellaneous legumes about which comparatively little is now known, many forms especially suited to thrive in difficult situations could undoubtedly be found by intensive study and developed by systematic breeding.*

Bonavist

(*Dolichos lablab* L.)

The bonavist, which in habits, cultural requirements, and uses is much like the cowpea, has been used in Africa and southern Asia from ancient times, and many varieties are known to exist. Nowhere has improvement of the crop been attempted, although improvement with reference to nematode and wilt resistance and other characteristics no doubt could be effected (fig. 1).

Figure 1.—Bonavist (*Dolichos lablab*) showing general habit of growth.

Bur-Clover

(*Medicago* spp.)

Many species of *Medicago* that never are grown as cultivated crops enter into use for pasturage and are recognized as having very great value for this purpose. However, these have received no attention from the plant breeder. Other species that are grown for soil improvement and occasionally used for hay or seed have received some attention by experimenters. In a few instances selections of distinct forms have been made by practical growers who have increased their supply of seed and distributed it locally. Natural selection resulting from regional climatic differences, however, is rèsponsible for much of the improvement in the medicagos.

In the case of spotted bur-clover (*Medicago arabica* (L.) All.) at least two new forms have appeared in the South in recent years. One of these, Manganese bur-clover, was selected and named by A.

138904°—37——64

Lee Andrews on his place at Lafayette in eastern Alabama. The other, Early Southern bur-clover, was selected and named by A. F. Ruff at Rock Hill, S. C. Both these varieties are earlier maturing than the commercial spotted bur-clover from which they were selected, and make as good a growth, if not better. A variety of bur-clover grown by H. H. Hopson in Coahoma County, Miss., under the name Giant bur-clover seems to be identical with the Early Southern and probably has the same origin. The Manganese bur-clover is somewhat earlier than the Early Southern and matures about 2 weeks ahead of the

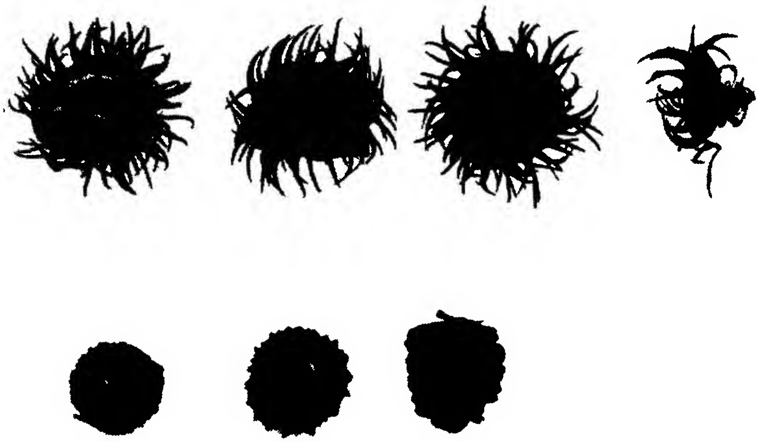

Figure 2.—Coiled seed pods of spiny and spineless forms of spotted bur-clover (*Medicago arabica*). In other species variation in length of spines is not uncommon.

commercial spotted bur-clover. A spineless form of spotted bur-clover has been recognized as a subspecies, but this has never been grown commercially (fig. 2).

California bur-clover (*Medicago hispida* Gaertn.) is very variable and responds to improvement by selection. Where bur-clovers occur spontaneously it is difficult to maintain pure stands of selected forms, and in pastures all that can be hoped for is to increase the relative amount of the improved varieties. Improved selections of bur-clovers were made by the United States Department of Agriculture some years ago and distributed from the United States Plant Introduction Garden at Chico, Calif., but supplies of seed have not been maintained and none are available commercially. The Texas Agricultural Experiment Station has made selections of the California bur-clover and is increasing seed of spineless forms for use in sheep pastures. The many other species are quite variable, like the species just mentioned, and could be readily improved by selection, but so far as is known most of these are in no way superior to the species now used commercially. Thus there seems to be no reason to give them special attention in

preference to the commercial forms. Black medic (*Medicago lupulina* L.) is quite variable and could be improved readily by selection. No work has been reported on the improvement of this plant.

Chickpea

(*Cicer arietinum* L.)

Throughout the western United States attempts have been made to grow the chickpea, which is native to western Asia, but nowhere has commercial production been successfully established. So far as known, no attempt has been made to develop superior varieties adapted to the United States, although it is known that the chickpea is variable and thus presumably could be improved by selection.

Cowpea

(*Vigna sinensis* (Torner) Savi)

A very large number of cowpea varieties are recognized. For the most part these have been developed through several hundred years by natural hybridization and incidental selection rather than by any planned improvement program. Introductions into the United States are recorded in the seventeenth century, but it is within the last century that specific reference is made to named varieties. In the United States in recent years considerable work has been done by experiment stations in the way of bringing existing varieties together for comparative testing. This has resulted in a more extensive use of superior varieties and an elimination of inferior ones. While selection of superior plants has thus been the principal means of improving cowpeas, natural hybridization has played a very important part. Artificial hybridization in recent years has been attempted by a few plant breeders, and at least one outstanding variety has been developed in this way.

A cross between the Groit and Brabham varieties made by workers in the Department of Agriculture resulted in the Victor, characterized by its resistance to wilt and nematodes, which seriously damage most varieties. In the process of continuous growing and natural selection through long periods of time, varieties have changed to suit local conditions with reference to diseases, insects, and climate. Apparently for this reason varieties that have been grown for years in the United States are much more resistant to bean rust than recently introduced varieties, and resistance to wilt and nematode in the Iron, Brabham, Groit, and New Era varieties can be attributed to similar selection. In the case of the Victor, resistance to wilt and nematode has been inherited from its parents, the Brabham and Groit.

The origin of most of the commercial varieties of cowpeas is unknown. The Whippoorwill has been grown under that name since 1840, and the Iron has been known in South Carolina since 1888, but its origin is uncertain, and no information is available as to where the New Era may have come from. From a study of the characters of the Brabham it has been concluded that it is a hybrid between Iron and Whippoorwill, and the Groit is regarded as a hybrid of New Era and Whippoorwill. Improved selections from Brabham and Iron have been made in California and are being grown commercially. Recently a variety of unknown origin was introduced into Florida

and distributed to growers by the State Agricultural Experiment Station, under the name Suwanee. It has given high forage yields and seems to be especially well adapted to Florida conditions.

CROTALARIA

(*Crotalaria* spp.)

Crotalaria, commonly called rattlebox, is one of the newest agricultural crops that has become of commercial importance in the United States within the last 10 years. In India and a few other

Figure 3.—Crotalaria spectabilis, F. C. 18096 (*a*), and the commercial strain from which it was selected (*b*).

tropical regions several species have been in use for a much longer period. Three species are now grown commercially in the United States. These are *Crotalaria spectabilis* Roth, *C. striata* DC., and *C. intermedia* Kotschy. Being variable in plant characters, they lend themselves readily to improvement by selection. Late maturity, which makes the saving of a good seed crop difficult, has been one of the principal objections to crotalaria, and this character was the first in which improvement was attempted. The Department of Agriculture and the North Carolina, South Carolina, Georgia, and Florida Agricultural Experiment Stations working in cooperation have made selections for earliness in all of these species. At Columbia, S. C., an early-maturing variety of *C. spectabilis* has been developed that ripens its seed quite uniformly and 2 weeks or more ahead of the original lot from which it was selected. This is known as F. C. 18096 and in South Carolina has been called locally Carolina crotalaria (fig. 3). Some progress has been made in selecting early varieties

of *C. intermedia* and *C. striata*, but additional improvement is needed before these can be called superior.

Since most of the *Crotalaria* species have been observed only in the wild, it is not possible to say how much improvement may be expected. Up to this time, however, little work has been attempted.

Fenugreek

(*Trigonella foenumgraecum* L.)

Fenugreek (the name means Greek hay) occurs in the Mediterranean region and east as far as India. As grown under cultivation it shows varietal differences that probably are the result of natural regional development rather than artificial selection. So far as known no special improvement work has been done in any country. In the United States fenugreek has succeeded only in California, and there it is grown only occasionally. At the California Agricultural Experiment Station at Davis the continued propagation for years of one of the best introduced strains of fenugreek appears to have resulted in the development of a superior variety well suited to at least that part of the State.

Field Pea

(*Pisum arvense* L.)

The history of the field pea is closely associated with that of the garden pea, since the distinction between the two groups is more one of usage than of botanical characteristics. The more extended use of varieties of field peas, however, has been in comparatively recent times, while the use of the garden pea extends back to earliest history. The development of pea varieties through all these years has been largely the work of the gardener and the commercial seed grower, while the field husbandman has merely grown the varieties apparently best suited to his conditions.

In more recent times a number of experiment stations have made selections from the more promising varieties and introduced them. The experiment stations in Canada and in the United States, particularly in Wisconsin, Colorado, Idaho, and Washington, have been most active in this work. The varieties O. A. C. 121, Wisconsin Perfection, and others represent the results of such work.

The new interest in field pea varieties has been largely in connection with their use as a cover and green-manure crop for the South. The Austrian Winter variety serves well for this purpose, but its susceptibility to disease and its inability to mature a good seed crop under southern conditions has lessened its popularity and called attention to the need for breeding and selection to overcome these difficulties. The Department in cooperation with the Georgia Experiment Station has recently inaugurated a program with such results as the objective. The State experiment stations at Auburn, Ala., and Knoxville, Tenn., have begun similar programs.

By bringing varieties together from every possible source and growing them under southern conditions it is probable that varieties with superior disease resistance and heavy seeding qualities will be found. These can then be used in a breeding program to combine the other desirable qualities needed in a cover and green-manure crop.

Grass Pea

(*Lathyrus sativus* L.)

Lathyrus sativus, commonly known as grass pea, has never become of commercial importance in any part of the United States, although in many places it makes good growth and produces fair seed crops. In India the crop is of some importance, the natives using the seed for food and the plant for forage. A large number of varieties exist, differing in flower and seed color, growth of the plant, and size and shape of the seed. Varieties with large white seeds are superior for human food, while those with strong vegetative growth are preferred for fodder. Varieties of *L. sativus* occurring in India have been studied by Howard and Khan (*11*).[1] While inheritance studies have been carried on with the sweet pea (*L. odoratus* L.), no one has studied *L. sativus* or related species in this way.

Guar

(*Cyamopsis psoraloides* DC.)

Guar, a summer annual, is used in India quite commonly for food for man and beast. Varieties exist, and the plants are more or less variable, but so far as known no special work on improvement has been attempted. In the United States guar has been used in cultural experiments but has not been recognized as having commercial value.

Kidneyvetch

(*Anthyllis vulneraria* L.)

No commercial plantings of kidneyvetch are made in the United States, and so far as known no selection or other improvement work has been attempted in this country. In Wales, selection work with this plant is in progress, but results have not yet been published. In Denmark the improvement of kidneyvetch has been attempted, and strains Tystofte No. 8 and Tystofte No. 28 when compared with commercial kidneyvetch were found to be more productive.

Kudzu-Bean

(*Pueraria thunbergiana* (Sieb. and Zucc.) Benth.)

No work has been done in the improvement of kudzu-bean, but there is no reason to suspect that it would not respond readily to improvement by selection.

Lespedeza

(*Lespedeza* spp.)

The lespedezas or bush clovers as a group are still wild plants. Only one species, *Lespedeza striata* (Thunb.) H. and A., has been long known to agriculture. The others are of such recent introduction that the possibilities of improvement have not been adequately explored.

Agronomically there are two groups of lespedezas. The annual consists of two species, *Lespedeza striata*, or common lespedeza, and *L. stipulacea* Maxim., or Korean lespedeza. The second and much larger group consists of perennial plants, of which one species only, *L. sericea* (Thunb.) Benth., has recently been introduced to agriculture.

---

[1] Italic numbers in parentheses refer to Literature Cited, p. 1018.

As is the case with most wild plants, the lespedezas are more or less variable, plants differing in size of leaflets and height of growth, in habit, and especially in date of maturity.

Lespedeza striata, common lespedeza, was first found in Georgia in 1846, spread rapidly over the lower South, and gradually worked north. The character that made this spread possible was undoubtedly the difference in date of maturity between plants. As the species worked farther north the earliest forms seeded and reproduced themselves. This process went on generation after generation, until now the common lespedeza is established as far north as central Indiana.

The variations in habit of growth were made the basis of selection work by the late S. H. Essary, of the Tennessee Agricultural Experiment Station. He began his study of individual plants in 1912 and found a great variation, especially in the habit of growth. Among the variants was one having an erect habit and great productive capacity, which was segregated and put into experimental plantings in 1921. This was introduced by the Tennessee station as Tennessee 76 and is one of the leading late-maturing varieties.

Another variety with larger leaflets and ranker growth than usual was found by J. B. S. Norton, an explorer of the Department of Agriculture, growing wild near the city of Kobe, Japan, and was introduced as Kobe. It is somewhat earlier in maturity than Tennessee 76 but does not grow so erect except in thick stands. Another variety of common lespedeza, inventoried as no. 81742, was collected by Dorsett and Morse, of the Department, in Japan in 1929 and is the earliest maturing form of *Lespedeza striata*. In habit it is nearly as erect as Tennessee 76.

The possibilities for improvement in this species have not been exhausted, but its natural dependence on high temperatures will probably prohibit pushing the species much farther north than its present limits.

The Korean lespedeza also shows variations, especially in date of maturity. Two extra-early forms have been found growing wild in Manchuria. One of these, no. 65280, has been introduced as Harbin; the other, no. 59379, is a week later and makes a little larger growth than Harbin. Neither variety promises much usefulness, because the plant is low in growth habit and the yield is consequently small. They do, however, show the range of possibilities in the development of earliness. Harbin has matured seed at Winnipeg.

Two varieties, an early Korean, no. 19604, maturing about 2 weeks earlier than standard Korean, and a late form, no. 19601, maturing 2 weeks later than the standard Korean, have been selected at the Department nursery at the Arlington Experiment Farm, Arlington, Va. (fig. 4). The early form, no. 19604, has been released for use in northern Iowa, northern Illinois, and adjacent areas. Its habit of growth and yielding ability are like that of standard Korean, and it differs only in earliness. The late form, which is matting in growth habit, is still under observation.

Here again the possibilities of selection have not been fully explored, and in the future better varieties, or varieties better suited to certain conditions, may be selected.

The group to which *Lespedeza sericea*, the perennial lespedeza, belongs consists of several species differing from one another in

botanical characters and in habit of growth. Certain variations in *L. sericea* itself have been noted. The botanical group consists of *L. sericea*, an erect, rather strict plant with narrow leaflets; *L. inschanica* (Maxim.) Schindler, with larger leaflets and lax habit; *L. latissima* Nakai, a prostrate plant; and *L. juncea*, intermediate in habit between *L. sericea* and *L. latissima*. Variations in *L. sericea* are found in width of leaflets, height of growth, coarseness and number

Figure 4.—Korean lespedeza (*Lespedeza stipulacea*). Selected plants showing different growth habits. The plant on the left (*a*), with horizontal lower branches, makes a low matting growth, while *b* is quite upright.

of stems, and earliness (fig. 5). Of the varieties studied, no. 04730 is early, tall, and coarse, no. 12087 is later, with finer stems, and no. 19284 is from a single plant selection out of no. 04730 and is somewhat more uniform than the parent. These variations are neither important nor significant, but they show that a more intensive study may uncover variations of agricultural significance.

One of the most important fields for selection with *Lespedeza sericea* is that of finding forms with a low tannin content. Studies made show that the tannin content varies among individuals, ranging from about 5 or 6 to 10 or 11 percent. From the standpoint of palatability as well as forage value, it is important that a form with low tannin content be found and introduced. Work with this object is being carried on.

The shrubby species, as *Lespedeza bicolor* Turcz. and its allies, have not been studied intensively enough to determine the range of variation, and it does not seem probable at this time that they will offer great possibilities for agricultural usefulness.

Lotus

(*Lotus* spp.)

Several species of *Lotus* (not to be confused with the water-lily of that name) are recognized as being of some commercial importance in several European countries and in Australia, but in the United

States none is recognized as having special value. Seed of *Lotus corniculatus* L. and *L. uliginosus* Schkuhr, two perennial species that are used for hay and pasturage, is available through the seed trade, but no varieties are listed. So far as known no special improvement of these plants has ever been attempted, although varieties with low cyanophoric glucoside content have been reported. The elimination

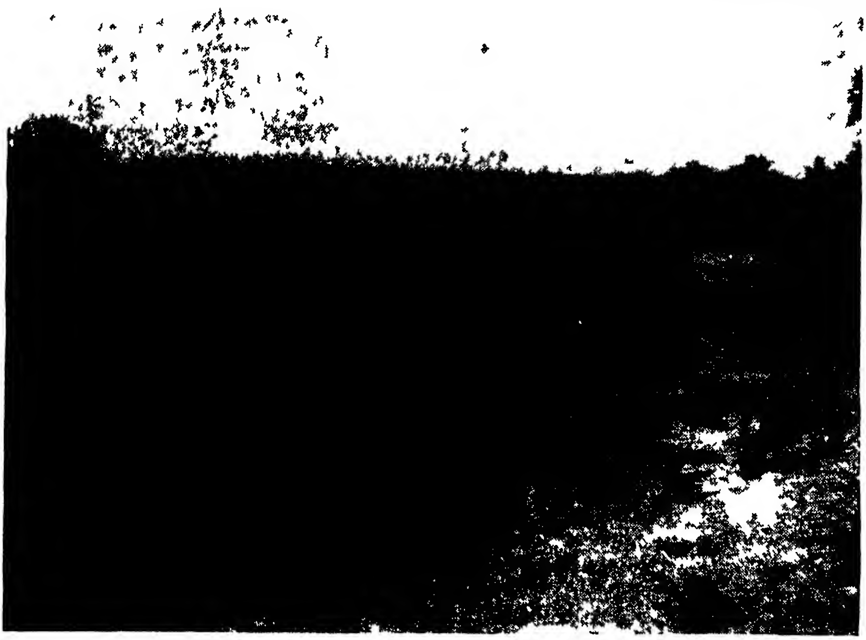

Figure 5.—Lespedeza sericea, showing variation in size and habit of growth. Plants in each row are from seed of a single mother plant

of this glucoside is desirable, since in the course of digestion it is changed to hydrocyanic acid, which is injurious to animals

Lupine

(*Lupinus* spp.)

Several species of *Lupinus* are grown commercially as field crops in European countries, and at least one species is being used in Australia. None, however, has ever been commercialized in the United States, since experimental plantings have indicated that in most places they are not well adapted and cannot be used as economically as legumes now commonly grown.

Varietal improvement in this group of plants has been confined largely to work in European countries, particularly Germany and the Union of Soviet Socialist Republics, where in recent years attempts have been made to produce lupines devoid of alkaloid poisons. Both German and Russian workers report having developed strains with little or no alkaloid, which they call "sweet lupines." The object

has been to produce plants and seed that could be used for both livestock and human consumption without injurious results.

Peanut

(*Arachis hypogaea* L.)

The improvement of the peanut for forage has received little attention. In the United States the experiment stations of Florida and Texas have undertaken hybridization studies, but the results of this work have not yet been published. *Arachis nambyquare* Hoehne and *A. rastiero* A. Cheval. have been used in crossing with the common peanut (*A. hypogaea*), and attempts have been made to introduce other wild species. These offer possibilities but as yet are too little known to justify a statement regarding results.

Pigeonpea

(*Cajanus indicus* Spreng.)

In many tropical countries the pigeonpea is recognized as one of the most valuable legumes. In India a large number of varieties exist and the superior value of some of these is recognized. In the Hawaiian Islands, where the pigeonpea was introduced, improvement of the crop has been undertaken and selection and breeding work have resulted in the production of superior varieties. New Era strain X is recognized in Hawaii as one of the most desirable and much superior to the strains from which it was produced. In the United States varieties have been grown for selection work at several southern stations. The plantings at the Florida Agricultural Experiment Station at Gainesville have been the most extensive. Wide variation in the plants has been observed and early-maturing varieties have been selected, but no variety has been found sufficiently well adapted to justify commercial use. One variety has matured as far north as Washington, D. C., but seed production has been light.

Sainfoin

(*Onobrychis vulgaris* Hill.)

Sainfoin has been grown in France and other European countries for over 300 years. In the United States it has never become of commercial importance, although in experimental trials at a number of experiment stations it has made good growth. A number of botanical varieties are known to exist, but improvement of most of these for agricultural use so far as known has never been attempted. Commercial sainfoin is quite variable and includes both biennial and perennial forms. Improvement by selection in both of these no doubt could be easily effected. The Washington Agricultural Experiment Station at Pullman is making selections of sainfoin with the idea of obtaining better adapted varieties.

Serradella

(*Ornithopus sativus* Brot.)

In central Europe serradella is used on acid sandy soils, but in the United States production or use on a commercial scale has never been successful. Improvement of varieties is reported from Germany, although the amount of work seems to have been very limited.

Sesbania

(*Sesbania macrocarpa* Muhl.)

The seed of sesbania as found in the commercial trade is gathered from wild and volunteer plants and represents the species as it is found growing naturally. The plant grows in wet or moist soils in the Southern States. No attempts at improvement have been made.

Sulla

(*Hedysarum coronarium* L.)

Attempts to grow sulla in the United States have indicated that while it succeeds fairly well in a number of places so far as growth is concerned, it does not appear to have a place in competition with legumes now commonly grown. In several European countries it is grown as a commercial crop and is considered as having superior value for special localities. While varieties are known to exist, few attempts at varietal improvement seem ever to have been undertaken. In New South Wales a special strain was selected for many years and tested on the experimental farms, but for other countries no work is reported.

Velvetbean

(*Stizolobium* spp.)

The Florida velvetbean (*Stizolobium deeringianum* Bort) is one of the leading legume crops in the southeastern United States. It was introduced in Florida previous to 1875 and for many years was confined largely to that State, since it would seldom mature much farther north. Attempts to grow the crop in Georgia and Alabama later resulted in the selection of mutants that required a much shorter season to mature and were well adapted otherwise. In 1906 Clyde Chapman, of Sumner, Ga., observed an early-maturing plant that he selected and grew under the name Hundred Day Speckled. This variety later became known as Georgia and is the earliest maturing commercial variety now grown.

In 1908 R. W. Miller, of Broxton, Ga., selected an early-maturing variety that was grown as Clark's velvetbean, but this proved to be so like the selection made by Chapman that it later was considered identical with the Georgia.

In 1911 a Mr. Blount, of Flomaton, Ala., selected an early-maturing variety, which he called Alabama. This was not quite so early maturing as the Georgia but was sufficiently good to become commercialized and is still being grown.

A variety of velvetbean known as the bush velvetbean (fig. 6) was selected on the farm of Roan Beaseley at Kite, Ga., about 1914. As its name implies, it is a bush or bunch variety, lacking the twining habit of other velvetbean varieties. In work with this variety at the Mississippi branch experiment station at McNeill, H. R. Reed noted a white-seeded variant and made selections of it with the idea of using the white seed character to identify the bush variety. This selection did not prove to be stable as to seed color, and subsequent selection was continued. Now after 10 years a variety seems to have been obtained that reproduces true to color.

At the Florida station a hybrid variety known as Osceola was produced by John Belling, who made a cross between the Florida velvetbean (*Stizolobium deeringianum*) and the Lyon velvetbean (*S. niveum* (Roxb.) Kuntze). This is a vigorous, heavy-yielding variety with a medium season, so that it is adapted as far north as central Georgia.

Figure 6.—Bush velvetbean

The velvetbean offers opportunity for much further improvement, and the importance of the crop suggests that such work could be done with profit.

Vetch

(*Vicia* spp.)

A large number of species of *Vicia* are in general use, all of which go under the general name vetch. The species that are of importance commercially are *Vicia villosa* Roth, *V. sativa* L., and *V. pannonica* Crantz. Others that are occasionally used are *V. atropurpurea* Desf., *V. calcarata* Desf., *V. monantha* Desf., *V. dasycarpa* Ten., and *V. angustifolia* Grufberg. So far as known, vetches are close-pollinated, and seldom, if ever, does crossing take place. All species seem to be variable, but differ somewhat in this respect. Hairy vetch (*V. villosa*) is much more uniform than common vetch (*V. sativa*), and while several species seem to be less variable than hairy vetch, none are so uniform but that improvement can be made by selection.

Common vetch has been grown in the Mediterranean region for centuries, and through regional selection and otherwise a large number of varieties have been developed, differing in seed color and growth

characteristics. Much of the improvement in this crop, no doubt, traces to selections made by local growers, but natural selection due to continued regional production probably also played a part. In later years experiment stations have developed improved varieties for local use, but published statements regarding such work are very meager.

Most of the work in vetch improvement in the United States has been carried on at Corvallis, Oreg., by cooperation between the Department and the Oregon station.

In this region common vetch has been grown for many years, and the commercial strain now grown is the result of natural selection through this long period. The winter temperatures of western Oregon and western Washington represent about the extreme of cold that the most hardy strain of common vetch will endure. Thus the variety that has survived and been developed and increased here in commercial production represents one of the most winter-hardy of the common vetches.

Since other vetches are of very recent introduction commercially, natural selection has played little if any part in the development of varieties.

In the case of both hairy vetch and common vetch the work of the Oregon station, cooperating with the Department, has resulted in improved varieties that already have been or are becoming commercialized. Here a vigorous growing variety of smooth vetch (*V. villosa* var.), lacking the heavy pubescence of hairy vetch, was selected in 1926 by H. A. Schoth and is now grown quite extensively. A good deal of the seed of *V. villosa* imported from central Europe under the name hairy vetch is smooth vetch and resembles the smooth vetch variety grown in Oregon. Of the common vetch (*V. sativa*) selections that have been developed, a white-flowered variety, F. C. 02830, that is somewhat superior in vigor and winter hardiness to commercial Oregon common vetch and was selected by Schoth in 1915, is perhaps outstanding. The white-flower character offers a ready means of identification in the field and will enable the grower to keep his seed pure.

In the Netherlands, Denmark, and other European countries where common vetch is grown, improved varieties adapted to local conditions have been developed, but none of these, so far as they have been tested in the United States, has proved superior to varieties developed in this country.

GENETIC STUDIES IN MISCELLANEOUS LEGUMES[2]

Inheritance studies have been made in few of the so-called miscellaneous forage legumes. From general observation and in some cases from definite experimental demonstrations it is known that a number of legumes are self-pollinated and rarely if ever are cross-fertilized. Whether or not these can be crossed or hybridized has in many cases not been determined.

Studies of several species of *Phaseolus* in India indicate that the urd bean (*P. mungo* L.) and the mung bean (*P. aureus* Roxb.) are

[2] This section is written primarily for students or others professionally interested in breeding or genetics.

usually self-pollinated, although the mode of anthesis in many cases would permit of cross-pollination.

Unpublished observation of legume plantings in the United States indicates that *Crotalaria, Vicia, Lathyrus,* and the annual species of *Medicago* are largely self-pollinated and seldom if ever cross-fertilize. A close study of anthesis in such cases, however, might indicate a means of effecting crossing.

No work on crossing lespedezas has been done. The technical difficulties are of the same order as those presented by the clovers and are due to the fact that the flowers are small and difficult to manipulate. There is another difficulty in addition. The three commonly known species of *Lespedeza*—*L. striata* (Thunb.) H. and A., *L. stipulacea* Maxim., and *L. sericea* (Thunb.) Benth.—have flowers of two kinds, and both kinds occur in the same cluster. One set of flowers bears a corolla and is therefore conspicuous; the other and more numerous kind has closed flowers with reproductive parts complete but with no corolla. These flowers are consequently self-fertile. Although definite data are wanting, the conclusion drawn from observation is that these species are self-fertile. No sign of hybridizing has been observed, though the species have been grown side by side for years. The progeny from the seed of individual plants is always true to the mother plant.

In the case of serradella, which has been reported as self-fertile, plants inbred for four generations did not lose vigor.

While crossing in many legumes seems to be uncommon, there are others that cross readily and are naturally cross-fertilized. Species that have been used in inheritance studies are the cowpea (*Vigna sinensis* (Torner) Savi), chickpea (*Cicer arietinum* L.), adzuki bean (*Phaseolus angularis* (Willd.) Wight), bonavist (*Dolichos lablab* L.), horsebean (*Vicia faba* L.), pigeonpea (*Cajanus indicus* Spreng.), lupine (*Lupinus* spp.), peanut (*Arachis hypogaea* L.), velvetbean (*Stizolobium deeringianum* Bort), and field pea (*Pisum arvense* L.).

Chickpea

(*Cicer arietinum* L.)

While self-pollination is the general rule in *Cicer arietinum*, varietal crosses have been recorded. In 1915 Howard, Howard, and Khan (*10*) reported the growing of selections that split in the F_2 generation, indicating natural crossing. Their observations were not made in sufficient detail, however, for the deduction of the various color factors present.

More recently inheritance studies were made by Khan and Akhtar (*13*) relating to color and number of flowers. In making artificial hybrids it was found that in order to prevent accidental crossing emasculation should be effected the evening of the second day preceding fertilization. The flowers open naturally on bright days between 9 and 10 a. m., and the pollen should be applied at this time. Five crosses were studied and the following results reported (*13, p. 155*):

(1) The flower color depends upon the interaction of several factors.
(2) Blue color depends on a single factor *B*.
(3) Pink color is produced by a factor *P* in the presence of *B*.

(4) In the absence of *B* the flower is white whether *P* is present or absent.
(5) Greenness in the standard is developed in the absence of the factor *W*. Greenness is therefore recessive to nongreen.
(6) Singleness depends upon a factor *S* and is dominant to doubleness.

Cowpea

(*Vigna sinensis* (Torner) Savi)

The cowpea has been recognized as one of the legumes that offer excellent facilities for inheritance studies, and investigations by Spillman and Sando, and in particular by S. C. Harland, have indicated what may be expected by more extended research. In studies made by Spillman and Sando (*16*) flower color was found to be correlated with coloration in the seed coat, joints, peduncles, stipules, and petioles, and complete linkage was observed in certain seed-coat-color factors.

It was determined that the presence of anthocyanin coloration in the stem and leafstalk is due to a single unit factor, dominant to its absence.

In the case of certain seed-coat-color patterns, two factors that are inherited independently were found to influence the color pattern, resulting in the expected 9:3::3:1 ratio.

Seventeen Mendelizing factors of cowpeas were definitely identified. These factors with the characteristic effect they produce are as follows:

A. Seed pod curved after the manner of the alfalfa seed pod.
B. Brown seed coat.
D. Dense speckling, characteristic of the New Era variety.
E. Narrow eye.
F. Very fine and dense speckling, giving rise to blue seed coat.
G. Dotting; converts Holstein spots into numerous small ones.
H. Holstein type of seed-coat spotting.
I. Eye with indefinite margin.
L. Longitudinal furrowing of the surface of the seed.
N. Presence of anthocyanin pigment factor.
P. Purple seed coat.
R. Red seed coat. (This is the general factor for color, the absence of which determines white seed coat, white flowers, and absence of pigment in vegetative parts.)
S. Black spotting on certain types of seed coat.
T. Less dense speckling, characteristic of the Taylor variety.
U. Buff, or clay-colored, seed coat.
W. Whippoorwill type of seed-coat spotting.
X. Taylor inhibitor cancels (crosses out) the effect of *T*.

The eight factors *B*, *F*, *N*, *P*, *R*, *TF*, *U*, and *X*, either singly or in combination, give rise to the ten distinguishable seed-coat colors, purple, black, dull black, blue, coffee, maroon, buff, red, pink, and white. The factors *P*, *B*, *D*, *T*, and *F* and probably *S* belong to a linked group. The factors *D*, *T*, and *F* restrict the distribution of color pigments in the seed coat. Three independent eye factors *I*, *H*, and *E*, either singly or in combination, give rise to the five distinct types of eyes, Watson, Holstein, small eye, narrow eye, and very small eye.

Indications were found that when all of the pigment factors are absent, including factor *R*, there is a tendency for the seeds to be small, weak, or abortive.

The flower color has been found to be correlated with the coloration in the seed coat, joints, peduncles, stipules, and petioles (*16, pp. 282–283*).

Experiments reported by Haigh and Lochrie (*6*) indicate a progressive variation with age of a simple Mendelian ratio in the cowpea. The results in the F_2 cultures from successive days of flowering showed an orderly variation in the simple Mendelian 3:1 ratio, an

excess of recessives in the first 9 days being compensated for by an excess of dominants as the plants grew older. No cause for this phenomenon was discovered.

Hofmann (*9*), in experiments at the University of Illinois, found that crosses made in the greenhouse between California Blackeye and Blue Goose show definite evidence of hybrid vigor.

Bonavist

(*Dolichos lablab* L.)

In studying *Dolichos lablab*, Harland (*8*) found that dehiscence of the anthers takes place at least 1 and sometimes 2 days before the flowers open. Studies in inheritance showed that in the case of determinate and indeterminate growth the segregating ratio in the F_2 generation was 3 : 1, with complete dominance of the indeterminate factor.

Two factors were found to influence color, each being transmitted independently, resulting in the expected 9 : 7 ratio. One of these factors has no effect except in the presence of the other, when it converts white flower into purple, and brown seed into black, and causes pigmentation of the nodal region.

Lupine

(*Lupinus* spp.)

Burlingame (*2*) reports studies of *Lupinus* species with reference to variation and inheritance. His findings show that races with dark-blue and pink flowers breed true and that races with striped white flowers are heterozygous for a single factor, which in the homozygous condition produces white flowers. Light-blue flowers are due to a single dominant factor, indistinguishable in the homozygous and heterozygous condition.

Dark seed coats are linked with dark-blue flower color, but probably due to separate factors.

The factors for light-blue and striped-white flowers are both allelomorphic to that for dark-blue and not improbably constitute a system of multiple allelomorphs.

Mutations are frequent, some are already known to be dominant, and others appear to be in the nature of additions of new characters and factors and so progressive in the sense of de Vries (*2, p. 447*).

Hallqvist (*7*) studied seven different types of flower color and five types of seed color in *Lupinus angustifolius* L. His conclusions were as follows (*7, p. 344*):

One fundamental colour factor has been demonstrated (pure red). A synthesis of blue colour has been obtained from crosses between bluish red and violet flower colours. One "dilution" factor has been found to be present.

Pleiotropic correlation has been demonstrated between certain flower and seed colours.

Three flower colour factors have been found to form a linkage group. The linkage between two of the factors is very close, if not complete. The other linkage value represents a crossover percentage of about 22%.

Greb (*5*), in studying *Lupinus albus* L., found that there are at least two genetically different rootlet types in this species. These differ in rate of rootlet elongation in young seedlings and in time of development of the root hairs. The ratio in the F_2 was 2:1, which suggested that the homozygous nonhairy might be lethal.

Adzuki Bean

(*Phaseolus angularis* (Willd.) Wight)

Kakizaki (*12*), in a study of crosses between Miyako and Donsu varieties of adzuki bean, found that reddish purple in the stems, black spotting on red seed coats, and blackish brown in ripe pods were dominant over their recessive allelomorphs, green stems, unspotted seed, and brown pods. From the segregating ratios in the F_2 it was concluded that color of stem was due to the interaction of two factors, while the black spotting of the seed coat and color of ripe pods were influenced by only one factor pair.

Colored stems are completely correlated with black-spotted seed coats, and colorless (green) stems with unspotted seed coats.

The factor *P* for reddish-purple color of stems and its recessive allelomorph *p* (green stems) are very closely linked with *S*, a factor for black-spotting of seed-coats, and its recessive allelomorph *s*, respectively, and hardly any crossing over occurs between them.

The *I* factor, which intensifies the purple color of the stem, and its recessive allelomorph *i* are also very closely linked with the *B* factor, which produces a blackish-brown color of the ripe pods, and *b*, its recessive allelomorph, and this linkage is also very close, so that crossing over hardly ever occurs between them.

The *P*-*S* linkage group is independent of the *I*-*B* linkage group.

Presence of *S* in a homozygous condition produces more intense spotting of the seed coats than when it is present in a heterozygous condition (*12, p. 177*).

Horsebean

(*Vicia faba* L.)

The horsebean is known to cross readily but has been used comparatively little in inheritance studies. Darlington (*3*) studied variegation and albinism and found that variegation is a heterozygous type of which albino and normal are the homozygous types. Sirks (*15*) in a study of quantitative inheritance in *Vicia faba* presented evidence to indicate that quantitative factors do exist.

Velvetbean

(*Stizolobium* spp.)

Several species of *Stizolobium* have been hybridized. Inheritance studies made at the Florida Agricultural Experiment Station a number of years ago were reported in the annual reports of that station for 1910, 1912, 1913, and 1915. Species that have been hybridized are *S. deeringianum* Bort × *S. pachylobium* Piper and Tracy, *S. deeringianum* × *S. niveum*, and *S. deeringianum* × *S. hasjoo*.

The inheritance studies are concerned mostly with the cross *S. deeringianum* × *S. niveum*, which are the species of most economic significance. In these crosses Belling (*1*) found that color in wings and standard, length of seed, curve in pods, and open and closed pods were influenced by a single factor pair, and size of pod and length of pubescence on pod by two or more factors, while mottling was due to three independent factors. Correlations were established between lateness of flowering and number of flowers in a raceme and between length of pod and seed.

138904°—37——65

PIGEONPEA

(*Cajanus indicus* Spreng.)

Inheritance studies with the pigeonpea carried on at the Hawaiian Agricultural Experiment Station have been reported by Krauss (*14, p. 13*). According to his findings—

* * * red flower standards are dominant over yellow; blotched or speckled seed dominate over solid colored, and maroon-blotched pods are dominant over solid light-tinted pods. Pubescent pods are dominant over glabrous; large, flat pods are dominant over small round pods, and large seeds over small seeds. Four and five seeded pods are dominant over 3 and 4 seeded pods. Round seeds, slightly flattened, dominate over all others of widely different shapes, including spherical, oval, flattened, and irregular. The axillary flowers and pods dominate over terminal inflorescence. In stature blended inheritance is observable, very dwarf varieties when crossed with very tall varieties produce an intermediate type, and two varieties when crossed almost invariably produce a type that is taller and more vigorous than either parent. Crossing an annual type on a perennial type appears to produce perennial forms. This behavior has been found to remain constant, practically complete dominance for some well-defined differentiating unit characters being the rule.

When red dorsal standard sorts were crossed with red types, it was noticed that the solid red changed to red lacing, and when extremely tall and dwarfed forms were crossed, the first generation was of intermediate height. Wherever dominance is apparent the second generation shows fairly definite Mendelian segregation as well as definite linkage between some characters. Dihybrid crosses appear to adhere rather closely to the 9:3::3·1 ratio.

Studies in *Cajanus indicus* relating the inheritance of color in the flower and seed coat have been reported by Dave (*4*). In most cases one factor pair controlled color inheritance, but in others two independently inherited factors were operative, in agreement with the general results obtained by Kraus. Complete linkage was noted between orange-yellow flowers and purplish-black seed, yellow flowers and back of standard with purple veins, and base diffused purple and green pods; and purple color at the back of the standard was closely linked with maroon color of the pod.

BREEDING MISCELLANEOUS GRASSES[1]

H. N. VINALL,[2] Senior Agronomist;
M. A. HEIN, Agronomist, Division of Forage Crops and Diseases, Bureau of Plant Industry

THE grass family, known by botanists as the Gramineae, is the most important and widely distributed of all plants. Grasses are found from the Tropics to the Arctic Zone, and in deserts and swamps. To this group belong some of the most important cultivated crops such as corn, wheat, oats, rye, barley, rice, sugarcane, and the sorghums and millets.

Grass breeding really began in a remote time with the development of these crops from various species of wild grasses. This breeding, however, had for its purpose an increased production of food grain rather than any improvement in forage value. Pastoral agriculture was founded on the utilization of grasslands for grazing domesticated animals; and primitive peoples still migrate, with their flocks, in search of grass which provides the entire sustenance of these animals. It is only within the last 30 years that any serious effort has been made to increase the forage production of grasses.

In different parts of the world natural selection took place under the influence of climate, and thus we find the original grasslands of each country characterized by certain genera and species, which are native or indigenous there. As civilization developed and intercourse between nations became easy, the native grasses of each country were introduced and domesticated in countries having similar climates, so that grasslands are now less distinctive from a national viewpoint than formerly. However, there still remain more or less well-defined centers of development for each of the important grasses, and these centers are important as sources of breeding material.

GERM-PLASM SOURCES FOR VARIOUS GRASSES

GROUPS of related grasses have become concentrated in certain parts of the world as a result of their reactions to climatic conditions. It is in such regions that these genera are found in the greatest abundance, and here also the widest variation may be expected in habit of growth within the species. These development centers have been outlined broadly in figure 1, which may be considered as a graphic illustration of grass adaptations and the chief grass resources of the world, with the natural migration channels of these grasses indicated, of course, without any attempt to present details. The most important genera

[1] The purpose of this article is to bring together as far as possible the available information as to the breeding in progress and that contemplated with all grasses of agricultural importance with the exception of timothy, sugarcane, and the cereal grasses such as corn, sorghum, rice, wheat, rye, oats, and barley. As considerable breeding work has been done with timothy, it is discussed in a separate article.

[2] Died Feb. 22, 1937.

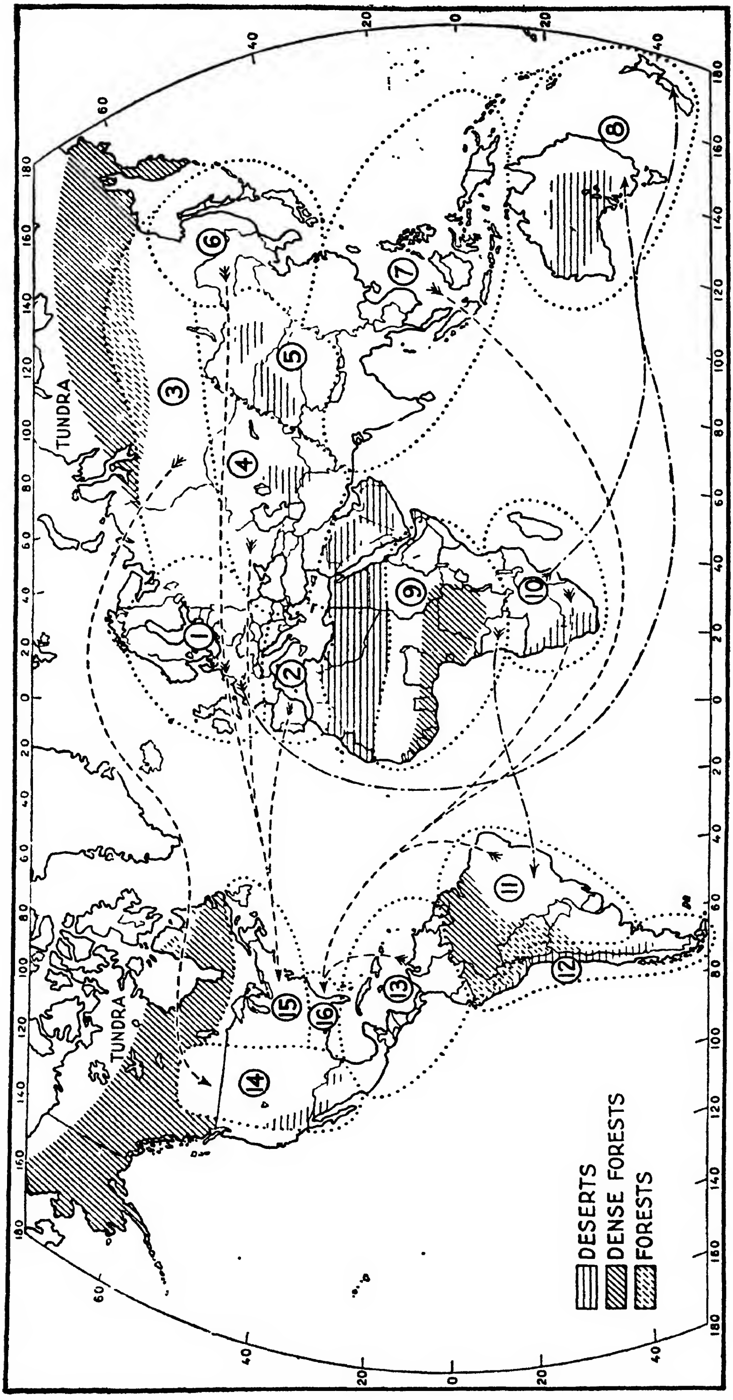

Figure 1.—Development centers of various important grasses.

138904°—37——66

and species in each of the 16 regions are listed in table 1 (in the appendix). The boundaries or limits of these regions are obviously not exact, and wide variations occur within certain regions because of mountain ranges and other physiographic features that affect vegetation.

Region 1 includes most of western Europe where the annual precipitation is 20 inches or more and the temperatures are mild. Practically all of the so-called "tame" grasses now grown in southeastern Canada and the humid part of the United States north of the Cotton Belt are native in region 1 and were introduced from there by early settlers in North America. This region is rich in species and varieties of timothy, bluegrass, orchard grass, ryegrass, redtop, bentgrass, oatgrass, and fescue. Other grasses abundant in this region, but of little or no agricultural value, are velvet grass (*Holcus lanatus*),[3] matgrass (*Nardus stricta*), and the other moorland grass (*Molinia caerulea*). These constitute the principal grass cover of wet heaths and moorlands throughout this region.

Region 2, the Mediterranean region of Europe and Africa, characterized by low rainfall and rather poor soils, is the native home of the annual species of *Avena* (wild oats), bromes, and fescues. Most of the winter annual grasses now growing in the foothills of southern Cali-

[3] The authorities for the botanical names used in this article are given in table 5 of the appendix.

COMPARED *with the work in several other countries, very little has been done in the United States in breeding any of the grasses except timothy. Orchard grass, bluegrass, redtop, bromegrass, bentgrass, Bermuda grass, carpet grass, and all other grasses ordinarily used in seeding pastures and lawns are mixed populations consisting of many strains that vary in such important characteristics as date of maturity, disease resistance, leafiness, number and vigor of stolons and rhizomes, and viability and abundance of seed. Because of these wide variations, there is a great opportunity for improvement by simple selection processes, and probably still greater possibilities in hybridization. The widely differing uses of grass, however, necessitate a close scrutiny and thorough examination of the variants from the standpoint of each possible use. Moreover, improved strains developed by British or other foreign workers are not likely to represent the best for our own country, since maximum values in plant breeding are attained only by aiming for close adaptation to local conditions. In the development of improved grasses, we shall have to solve our own problems by a systematic attack based on regional differences.*

fornia are of Mediterranean origin. In addition red fescue, canary grass, and Harding grass originated in region 2. The esparto or alfa grass used in the manufacture of fine paper grows naturally in northern Africa. Grasses that are abundant in this region but of little value include many species of both *Aristida* and *Stipa*.

Region 3 includes the eastern or low-rainfall section of the Union of Soviet Socialist Republics and practically all of Siberia. Here, where the average rainfall is less than 20 inches and the winters are very severe, a group of extremely hardy and drought-resistant grasses has developed, including the crested wheatgrass which has proved so valuable on the northern Great Plains of the United States. On the dry, cold steppes are many species and varieties of wheatgrass (*Agropyron*), wild-rye (*Elymus*), reedgrass (*Calamagrostis*), and "chee" or "tshee" grass (*Stipa*). The small fescues such as the sheep fescue are present but not so characteristic of this region as the Agropyrons.

Region 4, including southeastern Union of Soviet Socialist Republics, western China, and that ancient cradle of the human race, Asia Minor, Persia, and Afghanistan, is peculiarly important as the native home of several cereal grasses. All of this region is very dry and a considerable part is actual desert. While not so important from a forage standpoint, the native grasses of this region include what are believed to be the progenitors of wheat, emmer, einkorn, and rye. Numerous species of wheat (*Triticum*), rye (*Secale*), and their near relatives the goatgrasses (*Aegilops* and *Haynaldia*) are found here. The wild barleys (*Hordeum* spp.) are common, and bulbous bluegrass (*Poa bulbosa*) is almost everywhere. Meadow foxtail, sweet vernalgrass, red fescue, and Johnson grass are other important grasses found in region 4.

Region 5 includes Tibet, the western provinces of China, and eastern Mongolia. This is a region of high mountain ranges, cold, dry plateaus, and deserts. On account of its inaccessibility less is known about the grasses of this region than of any other part of the world. The grasses that have developed here would assuredly be drought-resistant and able to withstand other climatic extremes. At least four species of bluegrass and as many fescues have been reported from this region, along with several species of wheatgrass and wild-rye. Needlegrass (*Stipa* spp.) and sedges (*Carex* spp.) are widely distributed.

Region 6 includes eastern Siberia, Manchuria, northeastern China, Chosen, and Japan. Although attention has chiefly been given to the many soybean varieties in this region, it is also important as the home of most of our cultivated millets and that group of sorghums known as kaoliang. Foxtail millets, broomcorn millet (proso), and Japanese millet are all widely distributed and show a great variety of forms in this region. The Japanese lawngrass (*Zoysia japonica*) and Manila grass (*Zoysia matrella*), both of which appear valuable in the United States, are at home here. Among the less important grasses are many species of *Arundinella*, *Calamagrostis*, *Ischaemum*, and *Panicum*.

Region 7, including southeastern China, most of India, Burma, the Malay Peninsula, and adjacent islands, is largely tropical and has a heavy rainfall except in northern India. Such important cultivated crops originated in this region as sugarcane, rice, and bamboo; and also the forage grasses, Bermuda grass, Angleton grass, and centipede

grass. There are many other species and varieties of *Andropogon*, *Cynodon*, *Eleusine*, *Oryza*, *Panicum*, *Paspalum*, *Saccharum*, and *Sorghum* that have not yet proved of value under cultivation but may be of some importance from a breeding standpoint. Cogon grass, said to be a useful pasture grass in China and the Philippine Islands, is of doubtful value in the United States on account of its aggressive rootstocks.

Region 8, including Australia, New Zealand, and Tasmania, has a very distinctive vegetation, and many of the native grasses of this region are found nowhere else in the world except in small experimental plantings. The interior of Australia is very dry, almost desertlike. Along the coast where rainfall conditions are favorable the pastures and meadows are composed almost entirely of grasses and legumes introduced from Europe. In the drier portions native grasses supply most of the forage, and the most important of these are perhaps Mitchell grass, Wallaby grass, kangaroo grass, red grass (*Themeda* sp.), Flinders grass, and tussock grass. On the sand ridges in the semidesert area spinifex (*Triodia* spp.) is very abundant. Common Mitchell grass, curly Mitchell grass, and Wallaby grass have all been introduced into the United States, but they seem to be of little value here. The tussock grass of New Zealand (*Poa flabellata*) appears to be a very desirable grass, but so far all attempts to introduce it have failed. So much of Australia is desertlike that many grasses such as the annual bromes, fescues, Avenas, and Hordeums, which are not considered desirable in the United States, are appreciated there.

Region 9 consists of the equatorial part of Africa, some of which is occupied by dense forest. In parts where the rainfall is not too heavy, grasses abound in the open places of the timbered areas and in exclusively grass-covered lands or savannas replete with wild game animals. Here are found numerous species of *Sorghum*, *Pennisetum*, *Panicum*, *Hyparrhenia*, *Andropogon*, *Ehrharta*, and *Themeda*. Molasses grass and jaragua grass originated here, but are now more important in South America. In the highlands of Ethiopia are found many Hordeums (barley relatives). Sudan grass originated near Khartum, and other varieties of grass sorghum occur in profusion in this region. Pearl millet is native here also and originally was an important food crop of the inhabitants.

Region 10 is composed of that part of Africa south of 10° S. latitude and the adjacent island of Madagascar. The annual rainfall varies from about 40 inches in the northern part to actual desert conditions in Bechuanaland and southwestern Africa. The rains come largely during the summer months (winter in the Northern Hemisphere), and in this period they are fairly adequate except in the desert regions of Bechuanaland and along the West Coast. Temperatures are rather high except in a very limited mountain section in eastern South Africa. Plants that have developed under these conditions in Africa are well adapted to the Cotton Belt of the United States. Practically all of our cultivated varieties of sorghum originated in this region, and from there came Rhodes grass, Natal grass, and woolly fingergrass. Many species of *Chloris*, *Cynodon*, *Digitaria*, *Ehrharta*, *Hyparrhenia*, and *Themeda* contribute forage for their domestic and wild animals. Grasses that are abundant but of little value include the *Aristida* and *Trichopteryx* species, especially the latter.

Region 11 comprises most of Brazil, eastern Bolivia, Paraguay, Uruguay, and the northeastern part of Argentina. In this part of South America the rainfall is heavy (30 to 70 inches) and the temperatures are subtropical to tropical. Here we find an immense area of open parklike grasslands, including the campos of Brazil and the pampas of Uruguay and Argentina. The basin of the Amazon, with a rainfall of over 80 inches annually, is a dense, junglelike forest of little importance from a grass standpoint. Notwithstanding the extent of the grasslands in South America, few if any of the native grasses have shown any forage value in the United States or in their homeland. The superior forage grasses of South America were almost without exception introduced from tropical Africa, the native pampas grass being used chiefly as an ornamental because it is unpalatable. The molasses, jaragua, Guinea, and Para grasses all appear to have been introduced many years ago and are now widely distributed in region 11. They provide a large proportion of the pasturage for livestock, which is one of the main sources of revenue in this region.

Region 12 comprises Chile and the western or Andean sections of Argentina, Bolivia, and Peru as far north as the Gulf of Guayaquil. Except for southern Chile and Patagonia, this is a region of high altitudes and low rainfall. Although important as the native land of the potato and other Solanaceae, it does not appear promising as a source of forage grasses. *Axonopus scoparius*, a relative of carpet grass called "cachi" in Bolivia, is said to be a good pasture grass. This is found on the moist meadows of the eastern slope of the Andes. The forage in the high mountain valleys and plateaus is derived mostly from species of *Festuca*, *Poa*, *Calamagrostis*, and *Muhlenbergia*. Grasses that are abundant but have little agricultural value comprise numerous species of *Eragrostis*, *Stipa*, *Trisetum*, and *Piptochaetium*. The last-named genus is said to be encountered everywhere in this region, although it is uncommon in other parts of the world.

Region 13 includes southern Mexico, all of Central America and the West Indies, and Colombia, Venezuela, and Guiana in South America. This region, surrounding the Caribbean Sea and the Gulf of Mexico, is largely in the Tropics, but differences in altitude give it an extremely varied climate. It is also the home of the early Mayan civilization and the source of several of our most important food plants, including corn. In the Orinoco Basin of South America are the llanos, broad savannas or grasslands similar to the campos of Brazil. Several very useful forage grasses have been obtained from region 13, where they appear to be indigenous. The best known of these are teosinte, gamagrass, Bahia grass, St. Augustine grass, Guatemala grass, carpet grass, and wildrice. This region also abounds in species of *Trisetum*, *Setaria*, and *Andropogon*, most of which are of little or no value agriculturally. Sourgrass (*Trichachne insularis*) is very common but worthless.

Region 14 in western North America comprises a broad expanse of rugged mountains, dry plains, and plateaus extending from the Peace River section of Canada to southern Mexico. In all this region the rainfall is very limited, varying from actual desert conditions to 20 inches annually, while the temperatures range from very hot in Mexico and Arizona to very cold in northern United States and

Canada. The flora is rich in native grasses except for the desert areas, where the dominant vegetation consists of woody shrubs and cacti. Among the native grasses that contribute most to the sustenance of livestock are a great variety of wheatgrasses, bluestems or beardgrass, gramas, buffalo grass, sandgrass (*Calamovilfa* sp.), wildryes, fescues, bluegrasses, mesquite grasses (*Hilaria* sp.), and the Sacaton or dropseed grasses. Grasses that are common but of no particular value include the needlegrass (*Aristida* sp.), spear grass (*Stipa* sp.), and squirreltail grasses (*Sitanion* spp.). Foreign grasses that have proved adapted in this region include crested wheatgrass, awnless bromegrass, bulbous bluegrass, and Sudan grass.

Region 15, consisting of southeastern Canada and the northeastern United States, was originally occupied almost exclusively by hardwood and coniferous forests. Naturally, valuable native grasses are scarce except in the western part of the Corn Belt, which was from early days an open prairie carpeted with big bluestem and little bluestem. Both of these are excellent forage grasses. The rainfall in this region is usually adequate, and as the country was settled by people from Europe, the land when cleared of timber was seeded to introduced grasses from region 1. At the present time most of the pastures and meadows are occupied by these European grasses, which have proved admirably adapted to the climatic conditions here. Foxtail millet and Japanese millet, introduced from Europe but natives of Asia, are also grown rather extensively. Reed canary grass, big bluestem and little bluestem are about the only native grasses that have proved important. Other native grasses of minor importance are noted in table 1, because they may be of some value from a breeding standpoint.

Region 16 is that part of the Eastern United States south of the 60° isotherm. This is the original Cotton Belt, and while limited in area, it has been set apart from region 15 because of its marked difference in grass flora. This region was also originally a forest, and when the timber was cleared off by settlers European grasses proved unadapted, but more tropical grasses from Asia, Africa, and Central America have occupied the cleared lands where the soil is sufficiently fertile for these introduced grasses to compete with the omnipresent native broomsedge and other Andropogons. The most important of the introduced grasses are Bermuda, carpet, Dallis, and Johnson grasses, and they provide the bulk of the pasturage and hay in the region. Napiergrass, Japanese cane, and pearl millet also thrive here, but will not be discussed further at this time, since the situation in regard to grasses in the United States is presented in the appended detailed maps. The native grasses, some of which may offer possibilities in breeding, are listed in table 1. Texas bluegrass is one of these already used in crosses with Kentucky bluegrass.

CLIMATIC ADAPTATION OF PRINCIPAL FORAGE GRASSES OF THE UNITED STATES

The effective improvement of grasses by breeding requires an understanding of their inherent climatic relationships. In the United States this relationship is best expressed by dividing the country into six

regions as illustrated in figure 2. This generalized picture of a situation that has developed naturally under the influence of prevailing climatic factors provides a basis for the organization of grass breeding in this country. The introduction of other foreign grasses in the future may conceivably change the situation, especially in the Southwest. At this time, however, the opportunities for success in breeding appear to lie in working with those grasses that have met the require-

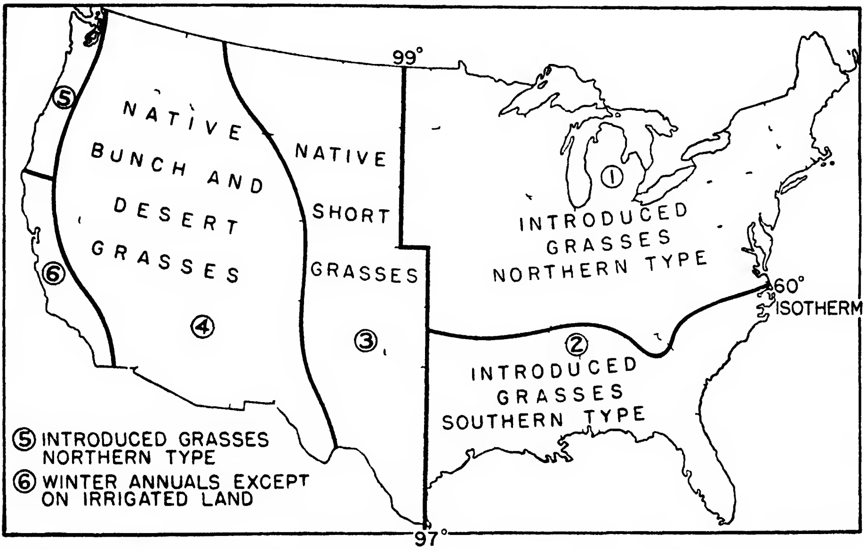

Figure 2.—Grasslands of the United States, showing the dominant type of grasses in each as determined by the climate.

ments of man and have been most productive during the past century. The most outstanding of these are discussed briefly.

In considering the distribution maps it must be understood that the limits indicated are not exact. Beyond the boundaries where a particular grass is really important it will be found less and less frequently struggling to survive under increasingly unfavorable conditions which results in an overlapping of adjacent distribution areas.

Kentucky Bluegrass, Canada Bluegrass, and Timothy

Kentucky bluegrass, Canada bluegrass, and timothy were introduced from Europe by the early settlers, and as the land was cleared of forest they spread over practically all of the humid part of the United States north of the 60° isotherm, as indicated in figure 3. In addition to the areas shown, these grasses are abundant in region 5 of figure 2, which is also humid. None of them is sufficiently drought-resistant to be grown successfully in arid or semiarid sections except under irrigation. These grasses have become the leading hay and pasture grasses of the United States and the adjacent sections of Canada. They proved so well adapted to climatic conditions here

that they now occupy much more extensive areas in North America than they do in Europe.

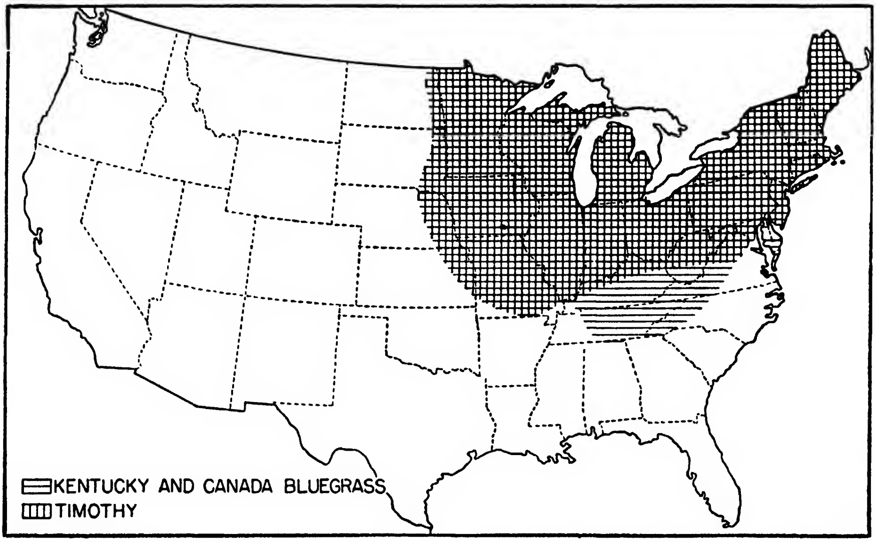

Figure 3.—Sections of the United States where Kentucky bluegrass and Canada bluegrass are well adapted and of primary importance.

Redtop and the Bentgrasses

Although redtop and the bentgrasses (species of *Agrostis*) are not so important agriculturally as are Kentucky bluegrass and timothy, redtop is valuable for both hay and pasture on wet or acid soils, and

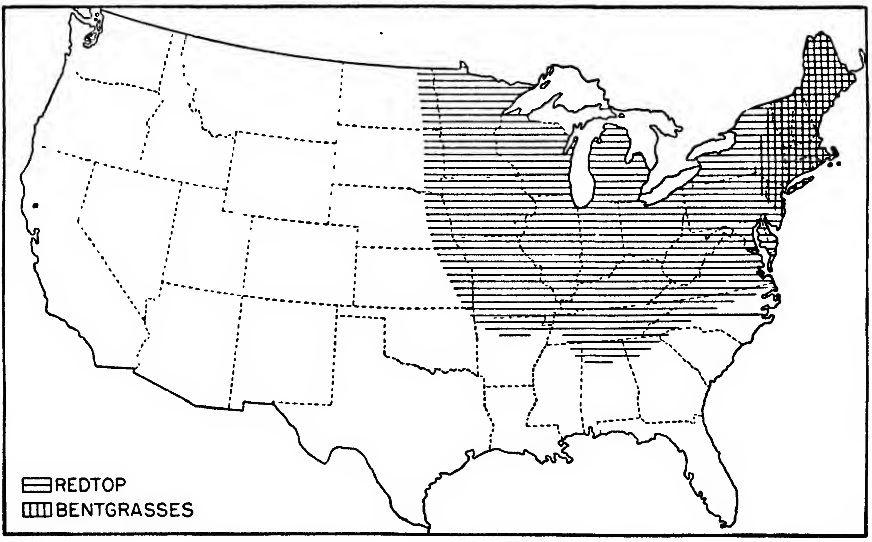

Figure 4.—Sections of the United States where redtop and the bentgrasses are well adapted and of primary importance.

the bentgrasses, because of their fine turf, are used extensively on lawns and golf courses. The sections where these grasses are of major importance are shown in figure 4, but they thrive equally as well in region 5 of figure 2, and the use of the bentgrasses for fine turf is common throughout the whole redtop region. Redtop is most highly regarded in Illinois, where most of the seed is produced. It seems better suited to the poorly drained, rather unproductive clay soils of that section than any other grass.

Orchard Grass and Tall Oatgrass

The approximate range of distribution of orchard grass and tall oatgrass is shown in figure 5. Of these two introduced grasses, orchard grass is the more common and undoubtedly the more valu-

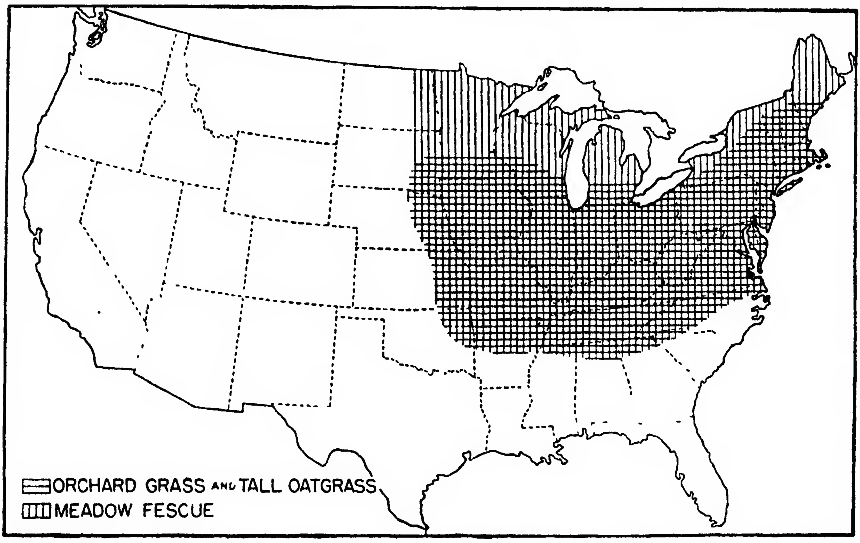

Figure 5.—Sections of the United States where orchard grass and tall oatgrass are well adapted and of primary importance.

able because of its longevity and its value in pasture mixtures. It is more tolerant of shade than bluegrass and produces better on poor soils. The results obtained in the improvement of orchard grass in Europe and Australia lead to the belief that much may be accomplished with it here. One of the obvious points of weakness in tall oatgrass is seed shattering which has already been overcome by selective breeding.

Bermuda, Johnson, and Dallis Grasses

Bermuda, Johnson, and Dallis grasses together with carpet grass are the principal hay and pasture grasses of the Cotton Belt. All of them were introduced at a comparatively early date and have spread naturally over most of these States. Although Bermuda grass and Johnson grass are found more or less frequently north of the limits indicated in figure 6, they are sensitive to low temperatures and grow

only during the frost-free period; hence they are unimportant outside of the section indicated in figure 6 except in the irrigated sections of southern California, Arizona, and New Mexico. In these States both are abundant, but Johnson grass especially is considered a weed and Bermuda grass is a doubtful asset. Both grasses invade irrigated

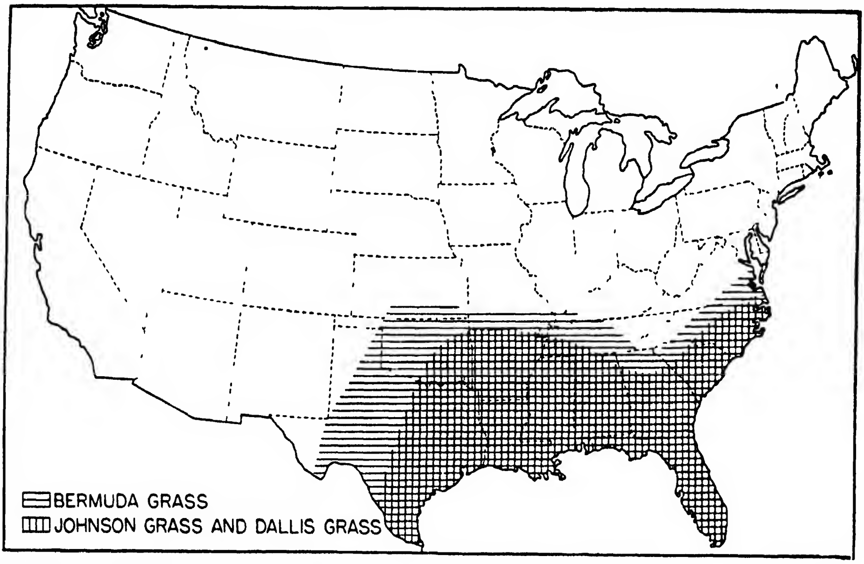

Figure 6.—Sections of the United States where Bermuda, Johnson, and Dallis grasses are well adapted and of primary importance.

cultivated lands and are difficult to control because of their aggressiveness. Dallis grass, however, is gradually coming to be recognized as a valuable constituent of pasture mixtures on irrigated lands in these States.

Carpet, Napier, Bahia, and Para Grasses

Successively more tropical and less winter-hardy, carpet, Napier, Bahia, and Para grasses are confined almost entirely to sections of the United States indicated in figure 7 and to extreme southern parts of California and Arizona. Carpet grass is much more common than the other three and next to Bermuda grass is foremost in pasture improvement. Napier grass, because of its large, coarse growth, may be used effectively as a soiling or silage crop in addition to its value as a supplemental pasture.

Awnless Bromegrass and Crested Wheatgrass

Awnless bromegrass and crested wheatgrass, unlike the grasses just discussed, are extremely winter-hardy, and both are very drought-resistant. Both were introduced from Europe and have been found most useful in the northern parts of the Great Plains and of the intermountain region (fig. 8). Bromegrass, however, is proving valuable

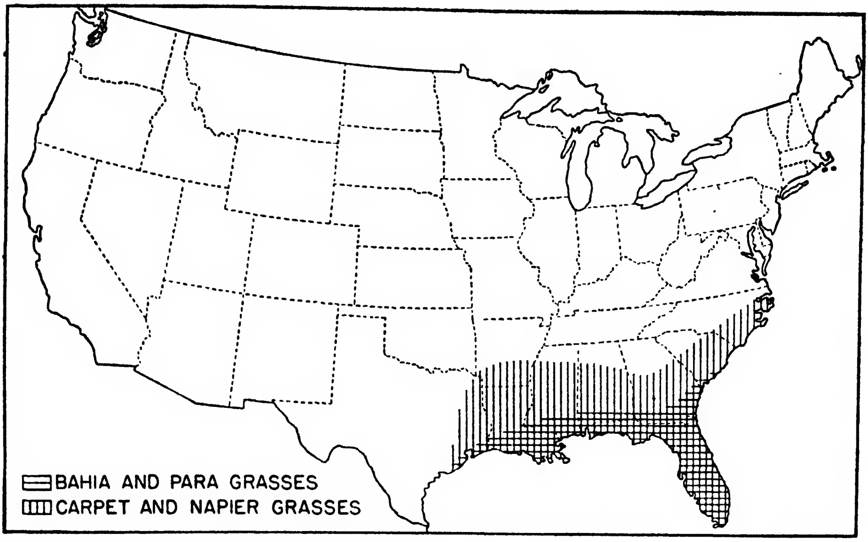

Figure 7.—Sections of the United States where carpet, Napier, Bahia, and Para grasses are well adapted and of primary importance.

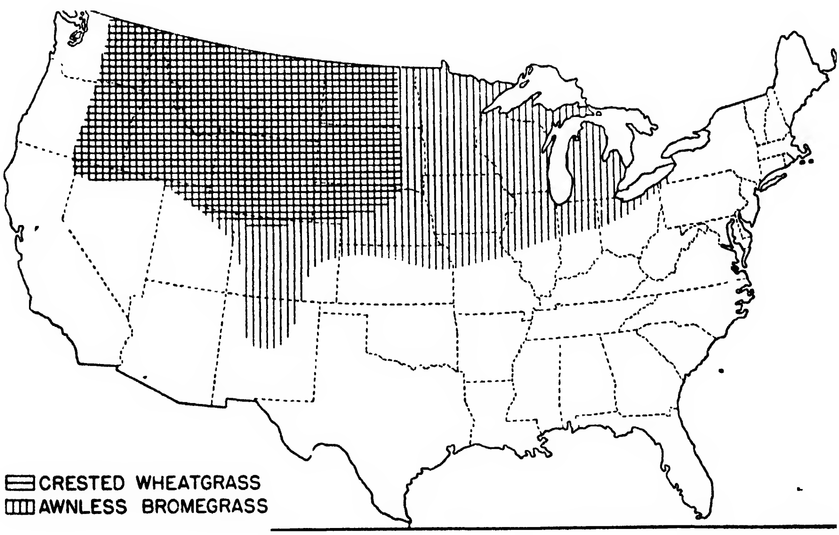

Figure 8.—Sections of the United States where awnless bromegrass and crested wheatgrass are well adapted and of primary importance.

in the North Central States in pastures and meadows, especially in mixtures with alfalfa. The chief objection to it, the difficulty encountered in eradicating it, may be overcome by selective breeding. Grazing animals are very fond of both crested wheatgrass and bromegrass.

Native Short Grasses and Prairie Grasses

Buffalo grass, the gramas, mesquite grasses, bluestems, and wheatgrasses supply a very large part of the pasturage and wild hay produced in the Great Plains. The distribution areas of all of these except the wheatgrasses are indicated in figure 9. Much of this region is semiarid, and in order to grow successfully here grasses must be able to endure periods of severe drought. All of these with the exception of big bluestem are preeminently drought-resistant, and the chief object in breeding will be improvement in productiveness of

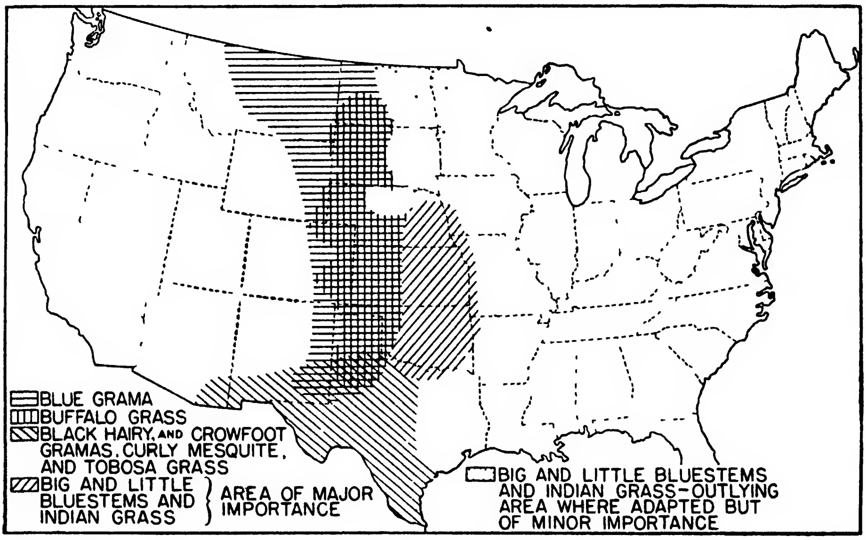

Figure 9.—Sections of the United States where native short grasses and prairie grasses are well adapted and of primary importance.

forage and viable seed. The actual distribution of each grass is considerably wider than is indicated on the map, which outlines the areas where each grass is of major importance and where their breeding is warranted. Big bluestem and little bluestem are adapted quite well to the outlying stippled area but are of minor importance there because most of the land is now under cultivation and introduced grasses are more productive. These two bluestems are found in small isolated colonies as far south as the Gulf coast. Indian grass is found growing in combination with the bluestems but rarely constitutes over 5 percent of the herbage.

Slender and Western Wheatgrasses

Western wheatgrass is found growing naturally all over the Great Plains except the extreme southern part. In the depressions where the soil is heavier, western wheatgrass often occupies the land to the virtual exclusion of all other grasses. Its foliage is rather harsh but palatable and very nutritious especially when immature. Slender wheatgrass is more widely distributed than western wheatgrass, although it does not extend so far south in the Great Plains as the

latter, and being a bunch grass it seldom occupies any large area to the exclusion of other grasses. The regions where these two native grasses are of importance are outlined in figure 10. Both are valuable for

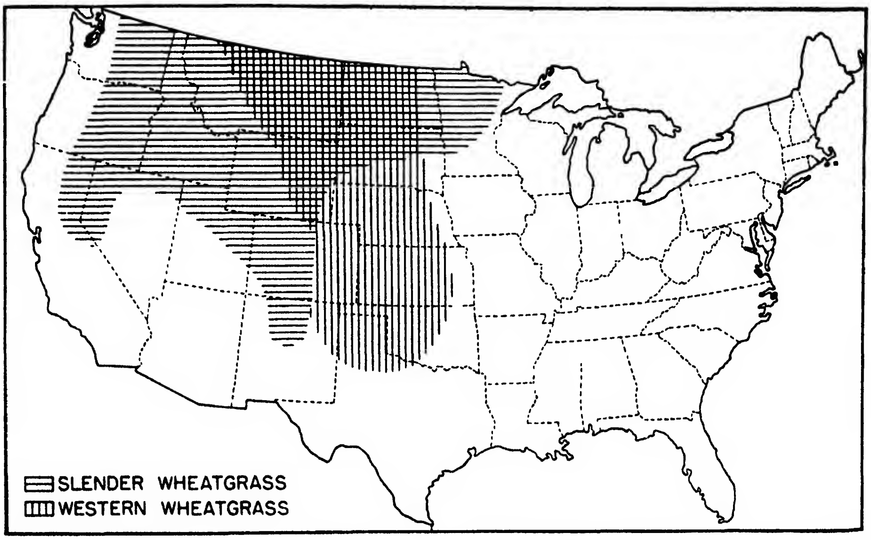

Figure 10.—Sections of the United States where slender wheatgrass and western wheatgrass are well adapted and of primary importance.

hay as well as pasturage, and less difficulty is found in obtaining viable seed of these wheatgrasses than of the other native grasses just discussed.

Sudan, Reed Canary, and Other Grasses

The species that have been discussed include nearly all of the grasses of recognized importance in the United States except Sudan grass and reed canary grass. Sudan grass, an annual, has been found useful as an emergency hay crop and for summer pasture in all parts of the United States, although best suited to conditions in the middle and southern Great Plains. Reed canary grass is valuable on wet lands anywhere north of the 60° isotherm. Breeding activities will no doubt be most productive with these grasses, but there are many others that should not be ignored, since in them are found useful characters that may be transferred to the more important species by hybridization.

WHY THE BREEDING OF GRASS IS WORTH WHILE

Approximately 60 percent (*32*) [4] [5] of the total land area of the United States is grazed at least part of the year, and a major portion of the feed obtained by grazing animals is provided by grasses. It is estimated that in 1919 the grazing lands supplied about 49 percent (*25*) and in 1929 about 41 percent (*33*) of the total feed consumed by all

---

[4] Italic numbers in parentheses refer to Literature Cited, p. 1074.

[5] Acreage of pasture on farms is given for 1934. The National Resources Board also furnished data on grazing land (*33*, *pt. 2*, *table 2*, *p. 109*). The 1930 acreage figures for grazing land not in farms were adjusted by O. E. Baker for 1934.

classes of farm animals. If the 11,798,065 tons of hay from grasses other than timothy be included, approximately 43 percent of the sustenance of our farm livestock must be credited to miscellaneous grasses.

In addition to the farm animals there are in the United States over 1 million herbivorous game animals (*31*), including deer, elk, and antelope. Deer and elk are the most numerous, and they subsist largely by browsing on trees and woody shrubs, but 10 to 15 percent of the food of this group consists of grasses.[6] The grasses are also important in providing food and cover for wild fowl.

Results obtained by soil erosion experiment stations [7] indicate that on various soil types on slopes varying from 4 to 16 percent the losses of soil by erosion are from 650 to 4,600 times greater where the land is devoted to clean-cultivated crops as corn and cotton than on lands with a perennial-grass cover. Besides the reduction of direct losses through soil erosion and run-off, there is an additional benefit derived from a grass cover in the conservation of soil fertility, chiefly nitrogen and organic matter. It has been estimated that there is an average annual loss of 60 pounds of nitrogen per acre from cultivated soils. Hopkins (*8, p. 559*), of Illinois, found 4,000 pounds of nitrogen per acre in the surface soil of land that had grown corn for 16 years, as compared with 4,914 pounds per acre in the soil of adjoining pasture land. A determination of organic matter by the combustion method showed in the soil of old pastures 6.12 percent, new pastures 4.16 percent, and cultivated soil 2.44 percent (*37*).

Grass in lawns is the foundation of all landscape effects for private houses and public buildings. It has been estimated that over $100,000,000 is spent annually in the United States on private lawns and at least $10,000,000 for turf establishment and maintenance in cemeteries. To this must be added about $65,000,000 spent annually in providing the required turf on golf courses, athletic fields, and playgrounds, and $16,000,000 in providing a ground cover on airports, road shoulders, and railway embankments.[8]

An increase in the acreage of grasses and legumes has been definitely adopted as a national policy because grasslands not only conserve the soil but also contribute to a better balanced agriculture. This places a larger emphasis on the work of the breeder.

POSSIBILITIES AND PROBLEMS IN BREEDING GRASSES

In the United States breeding of grasses has received little attention with the exception of timothy. Orchard grass, bluegrass, redtop, bromegrass, bentgrass, Bermuda grass, carpet grass, and all other grasses ordinarily used in seeding pastures and lawns are mixed populations consisting of many strains varying in such important characteristics as date of maturity, disease resistance, leafiness (fig. 11), number, and vigor of the stolons and rhizomes, and viability and abundance of the seed—to name only a few of the many variations. There is,

[7] The data are taken from unpublished reports or summaries of results from the various stations indicated: Guthrie, Okla., Soil Conservation Service Circ. L–1121 (1936); Temple, Tex., Soil Conservation Service Circ. L–1134 (1936); Hays, Kans., Soil Conservation Service Circ. L–1134 (1936); La Crosse, Wis., Soil Conservation Service Circ. L–1122 (1936).

[8] These estimates of expenditures were supplied by John Monteith, Jr., collaborator, Division of Forage Crops and Diseases, Bureau of Plant Industry, U. S. Department of Agriculture.

therefore, a great opportunity for improvement by simple selection processes. The uses made of these grasses are varied as compared with those of cotton, tobacco, sugarcane, or even corn. This broad field of usefulness increases the opportunity, but it also implies a closer scrutiny and more thorough examination of the variants because a strain that may be of no value for hay purposes might be exactly the kind needed for pastures or lawns.

It is now rather generally acknowledged that the maximum values in plant breeding are attained only by breeding plants adapted to local conditions. Improved strains are not ordinarily found superior under

Figure 11.—Two selected strains of Kentucky bluegrass, showing the variations in leaf width found in individual plants of commercial cultures.

all conditions of soil and climate. There is therefore little reason to believe that the improved strains of grasses developed by British or other foreign workers will represent the best attainable here in the United States. Plant-breeding work with cereals has shown also that there are different strains of certain disease organisms, such as smut, and that a grain variety that is almost wholly immune to the ordinary smut may be susceptible to other strains of this disease. The same condition will probably prevail with reference to the diseases of forage grasses, which implies additional restrictions and necessitates better controlled tests in breeding.

Opportunities for the accomplishment of practical results in the improvement of forage and fine turf grasses appear most promising in the following respects:

1. Yield and viability of seed.
2. Disease resistance.
3. Ability to compete successfully with other plants.
4. Increased vigor and ability to renew growth quickly after defoliation.
5. Longevity, drought resistance, and winter hardiness.
6. Tolerance to wet or saline soils.
7. Palatability and nutritive value of herbage.
8. Quality, durability, and uniformity of texture in turf.

Increasing Yield and Viability of Grass Seed

Many valuable grasses are notably shy seed producers. This is especially true of our native grasses, but it also applies to many of the introduced grasses. The failure to produce viable seed in sufficient quantity to supply the demand is a great handicap and often prevents an otherwise valuable grass from being grown on an extensive scale; it prohibits a wide use of native grasses in regrassing abandoned farm land in the Western States; for example, the gramas, buffalo grass, big bluestem and little bluestem, wheatgrass, and several other species would be seeded on millions of acres of these lands if good, germinable seed were available in commercial quantities. The same thing is true of many of the promising introduced grasses. Woolly fingergrass from South Africa gives indication of being an outstanding pasture grass for the poor upland soil of the Southeastern States, but it produces little or no seed. The Japanese lawngrass (*Zoysia japonica*) appears to be exactly the kind of grass needed for sodding airports and athletic fields. It forms a tough, long-lived turf, which would endure rough usage and be more or less permanent. Here again seed production is negligible. Good seed of Dallis grass, Bahia grass, and centipede grass is scarce, and the use of these valuable pasture and lawngrasses is therefore limited.

Production of Disease-Resistant Strains

While diseases are not usually so destructive to the forage grasses as the rusts and smuts of cereal crops, there are several that present a definite handicap to the effective use of these grasses in certain localities. Sudan grass, immensely valuable in dry regions, is almost worthless in the humid portion of the United States from Washington, D. C., south to Florida, because of the ravages of foliage diseases. Ergot is the chief factor limiting the production of Dallis grass seed. A leaf-spot disease causes widespread damage to Kentucky bluegrass in pastures and lawns. Grass diseases are most feared, however, in the growing of fine turf on golf courses and lawns. Under certain conditions diseases like brown patch are the greatest menace to the fine turf grasses, especially bentgrass as it is grown and handled on the putting greens of golf courses and on lawns. Control of diseases of fine turf is possible through the application of fungicides, but the development of resistant strains or varieties is preferable. In the case of pasture and meadow grasses, the use of fungicides is not practical, and breeding for disease resistance is the only logical means of overcoming the difficulty.

Regulating Aggressiveness by Breeding

Most of our cultivated cash crops are grown in pure stands and occupy the land for only 1 year. Aggressiveness or ability to compete with weeds and other plants is not, therefore, a factor of any importance in these crops. With perennial grasses, however, the ability to retain possession of the soil to the exclusion of weeds and less desirable grasses is a characteristic of major importance in permanent pastures. In breeding grasses aggressiveness is a character that must be regulated. If it is too pronounced the grass becomes difficult to eradicate;

this is true of quackgrass and Bermuda grass. Another disadvantage of pronounced aggressiveness is the difficulty of growing legumes in combination with such grasses. In pastures and hay meadows also, a mixture of grasses and legumes is desirable not only because of the higher nutritive value of the mixtures but also from the standpoint of benefiting the soil. Carpet grass and centipede grass under favorable soil and climatic conditions produce so close a turf as to drive out all the clovers and lespedezas that may have been seeded with them. Bromegrass in the Dakotas and southern Canada has been condemned by some because of its tendency to become sod-bound and because it reappears in a field that has been plowed for the production of a cash crop. Thus in some cases breeding methods must be used to reduce aggressiveness and in others to increase it.

Increased Vigor and Quick Renewal of Growth After Defoliation

The ability to renew growth quickly after defoliation is important. Grasses are of low value in pastures or on ranges unless they are able within a reasonable time to replace by new growth the herbage removed by the grazing animal. Our best hay plants, such as alfalfa, are high producers because, after cutting and removing one crop of hay, new shoots appear immediately and grow as rapidly as the original stems, thus providing from two to eight cuttings a year. Among the grasses Sudan grass is a conspicuous example of a hay and pasture plant that comes back quickly after being cut or grazed. The extent and rapidity of growth in all plants is of course limited by soil and climatic conditions. Without a productive soil and adequate moisture supply either through rains or irrigation, continued luxuriant growth throughout the growth season is impossible. Fundamental differences however occur in the growth habits of plants that determine their behavior when clipped or grazed. Grasses that do not continually produce new growing points low down near the surface or underneath the surface of the soil are useless for lawns or golf courses because the turf becomes stubbly after it is clipped a few times. Hay plants that do not have a succession of buds at the crown capable of producing new shoots seldom produce more than one hay crop each season. The variation in these essential growth habits within a single species is marked and presents a good opportunity for improvement by selection processes.

Persistence or Longevity Fundamental in Pasture Grasses

Longevity under grazing conditions may be less important in the future than it has been in the past because of the present tendency to appreciate and demand high production in pastures. However, there will always be a large percentage of livestock producers who are willing to accept mediocre production from pastures and ranges in return for the assurance that this production level will continue indefinitely and reseeding will not be necessary. In some localities, like the semiarid regions, where the establishment of a satisfactory grass cover is difficult or highly uncertain, permanency may be the controlling factor in choosing a grass. Several factors such as drought resistance and

winter hardiness have an important bearing on the longevity of a grass. In breeding, therefore, longevity must be considered as a complex of several factors rather than a single one.

Drought resistance in plants has been the subject of much study in the arid and semiarid regions. It is not due to a simple Mendelian factor inherited as a unit character. Breeding for increased drought resistance will require a thorough understanding of the elements in plant composition and structure that enable certain plants to persist and produce better than others under low rainfall conditions.

Tolerance to Wet or Saline Soils

In the United States considerable areas of wet lands occur. Some of these overflow at more or less regular intervals; other areas have a high water table or are continually saturated by the seepage of drainage water from the land above them. In irrigated areas benchland ditches often produce seepage areas in the bottom lands below them, and such areas are frequently both wet and saline (alkaline). Poorly drained lands in arid sections are almost invariably unproductive because salts accumulate in the surface layer through evaporation.

Certain species of grass are known to be adapted to wet soils, and other species are especially tolerant of soil salinity. In both cases, however, these grasses are usually of low palatability and often of low nutritive value. A very real need undoubtedly exists for improvement of these grasses in palatability and nutritive value as well as for the development of strains with increased tolerance for the abnormal quantity of water or salts that such soils contain.

Increasing Palatability or Nutritive Value Difficult

Grasses adequate as forage for farm animals must be both palatable and nutritious. To increase either the palatability or nutritive value of a grass is perhaps the most difficult of all the breeding problems. The qualities that make a grass palatable are little understood, and the variations in nutritive value as indicated by chemical composition are slight within any one species. There is, therefore, little encouragement to attempt an improvement in these fields except by hybridization.

Quality, Durability, and Uniformity in Turf Grasses

Considerable success has already been achieved in selecting strains of bentgrasses that meet the special needs of the golfing public. For the putting greens of golf courses both fine texture and uniformity are required (fig. 12); otherwise the path of the putted ball will be uncertain. Disease resistance, longevity, and aggressiveness are factors of great importance on both golf courses and lawns in order that the turf may be permanent and free of weeds and weedy grasses.

On athletic fields and playgrounds, and especially on airports, durability is the first consideration. A satisfactory turf for such purposes must be able to withstand the tearing and gouging of cleated or spiked shoes and the terrific impact of the landing gear on airplanes. To do this the grass must be deep-rooted and tough and also able to cover quickly gashes made in this way with spreading stolons or rhizomes.

CURRENT BREEDING WORK, ITS OBJECTIVES AND RESULTS

Selective Breeding of Grasses in the United States and Canada

Replies to questionnaires on grass breeding submitted to various agricultural institutions reveal the fact that selection for improvement is under way with a large number of grasses other than timothy. Limited and more or less desultory activities in this field have been in progress for 16 years or more, but organized and intensive grass-breeding activities, for the most part, have been inaugurated within the last 5 years. The various grasses included in the current selective breeding programs of State and Federal institutions in the United States and Canada are listed in table 2. It is apparent that a considerable number of workers are now concerned in developing superior pasture and turf grasses. The results accomplished by selective breeding in foreign countries other than Canada are not discussed in

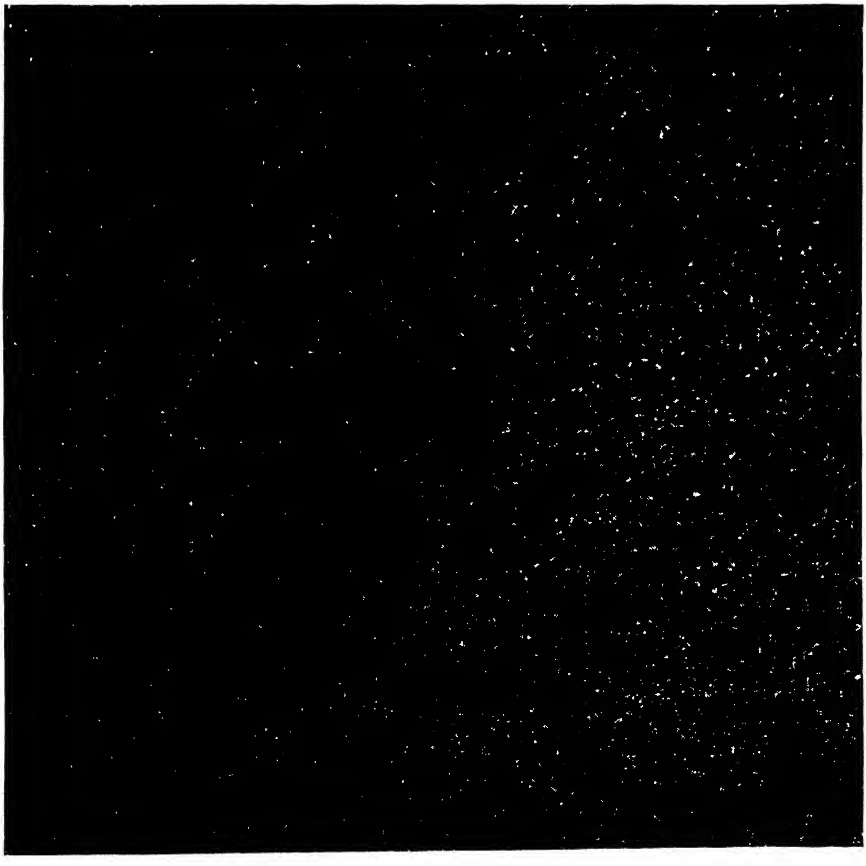

Figure 12.—A turf plot of Metropolitan bentgrass illustrating the fine texture and uniformity required for the putting greens of golf courses.

detail because of the limitations of space and the fragmentary information obtained in response to the questionnaires. We have also to consider the fact that very few of the improved strains of grasses developed in Europe, Australia, or New Zealand have shown outstanding value in the United States. In Canada, however, the species under investigation are the same as those in the United States

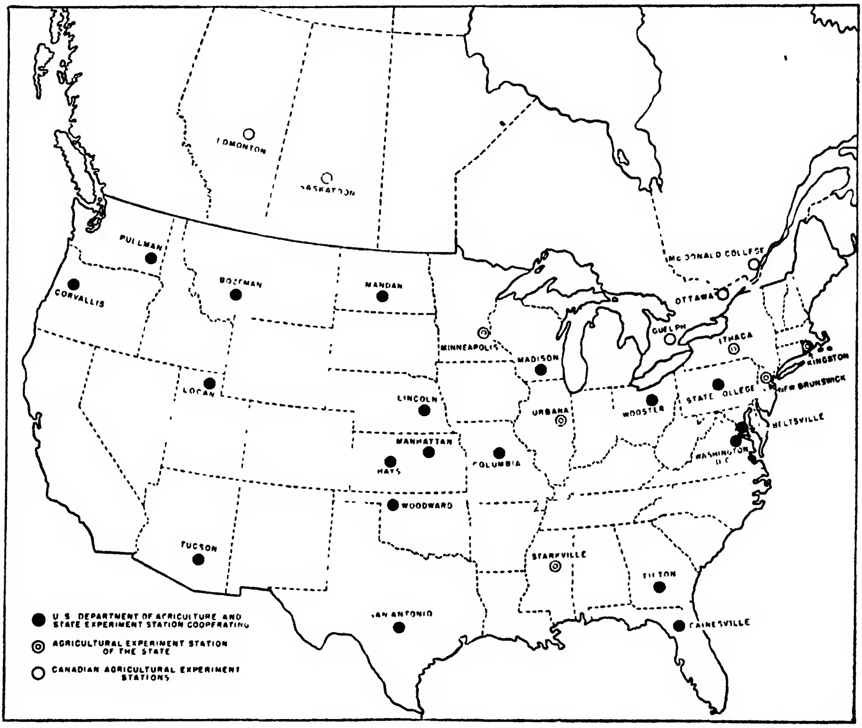

Figure 13.—Locations of experiment stations in the United States and Canada where organized grass-breeding work is in progress.

and climatic conditions are similar to those in our Northern States, hence results there should be helpful to our plant breeders. The locations of experiment stations in the United States and Canada where organized grass-breeding work is in progress are shown on the map in figure 13.

Improved or Elite Strains Developed by Selection

In the United States very few improved strains have yet been introduced into cultivation, but notable progress has been made, especially in the fine-turf grasses. The new strains already introduced, or soon to be ready for introduction, include:

Washington and Metropolitan bent grass: These two strains of creeping bent grass developed by the green section of the United States Golf Association have replaced other grasses on a large percentage of the putting greens of golf courses throughout the country.

The fact that these turf grasses, when used on putting greens, are usually propagated vegetatively makes it easy to keep the strains pure and preserve their identity.

Velvet bent grass, strain F. C. 14276: This has shown marked superiority over the ordinary strain of velvet bent grass in vigor, disease resistance, and quality of turf.

Promising turf strains of *Poa pratensis* and *P. trivialis* have also been developed by the green section of the United States Golf Association, but these are not yet ready for distribution.

H. A. Schoth, of the United States Department of Agriculture, cooperating with the Oregon Agricultural Experiment Station at Corvallis, Oreg., has several improved strains ready for distribution.

Highland Reed canary grass: This is definitely superior on upland soils; it is a heavy seed producer, and the seed shatters less freely than that of the ordinary strain. Seed of this improved strain is now being produced and marketed commercially.

Tall fescue, strain F. C. 29366: This has softer or less harsh leaves than the ordinary tall fescue and in general improved quality of foliage and better seeding habits. Seed production of this tall fescue will be on a commercial basis in 1937.

Tall oatgrass, strain F. C. 29367: The fault of seed-shattering characteristic of this species has been remedied almost completely. In this strain the seed increase is just in the initial stages, so that it is not ready for commercial distribution.

Bahia grass, strain F. C. 19774: A selection made in 1929 by F. H. Hull, associate agronomist, Florida Agricultural Experiment Station, Gainesville, Fla., on the basis of stigma color has proved definitely more resistant to the helminthosporium leaf disease than the ordinary strain. This selection has been compared with the common strains of Bahia grass by George E. Ritchey, of the United States Department of Agriculture, at the Florida station. Arrangements are being made to increase the seed of it in Arizona as a source of commercial seed production.

Tift Bermuda grass: A vigorous, fine-stemmed strain selected by J. L. Stephens, of the United States Department of Agriculture, at the Georgia Coastal Plain Experiment Station, Tifton, Ga. This strain is much more productive as a hay plant than the common Bermuda grass. In 1936, when 400 pounds per acre of complete fertilizer were applied, 2 tons per acre of fine quality hay were obtained in two cuttings. In the past it has been propagated vegetatively, since Bermuda grass does not produce viable seed in Georgia, at least in any quantity.

Reed canary grass, Iowa 503: This was selected by H. D. Hughes and F. D. Wilkins, agronomists at the Iowa Agricultural Experiment Station, from the progeny of seed sent to them by an Iowa farmer in 1918. The strain produces high yields of both hay and seed and appears valuable also in pastures because it makes a rather dense turf and remains green late in the fall. It was distributed to farmers in 1930 under the name Iowa Phalaris.

In Canada, where agricultural workers have devoted more attention to breeding problems, a considerable number of improved forage and

turf strains have been developed and are now in commercial production. Among those reported by Canadian workers are the following:

Grazier slender wheatgrass: A leafy uniform strain that produces a high yield of pasturage and hay. Developed by G. P. McRostie and L. E. Kirk at the Central Experimental Farm, Ottawa, Ontario.

L. E. Kirk, before his removal to Ottawa, and T. M. Stevenson, working at the Dominion Forage Crops Laboratory, Saskatoon, Saskatchewan, developed four elite strains or varieties, namely:

Figure 14.—O. McConkey, associate professor, Department of Field Husbandry, Ontario Agricultural College, Guelph, Ontario, Canada, who, with L. E. Kirk, of Ottawa, has pioneered in grass-breeding investigations in Canada.

Mecca slender wheatgrass: A high-yielding hay variety.

Fairway crested wheatgrass: A rather dwarf, fine-stemmed, leafy strain that usually produces lower yields of hay than ordinary crested wheatgrass but is superior to the latter for use on lawns and on the fairways of golf courses. Already the Fairway strain has a wide use in the western parts of the United States and Canada.

Superior bromegrass: This was developed by Kirk from material collected by J. Bracken prior to 1921. It is now definitely established as a high-yielding hay and pasture variety.

Parkland bromegrass: Characterized by a reduced rhizome development that makes it to all intents and purposes a noncreeping variety. Parkland bromegrass does not become sodbound so quickly as ordinary bromegrass and is less difficult to eradicate when grown in rotation with cultivated crops.

Fyra slender wheatgrass: This was developed by M. O. Malte and G. H. Cutter at the University of Alberta, Edmonton, Alberta, as an improved hay variety.

Avon orchard grass: Developed by workers in the Agronomy Department of MacDonald College at Quebec, this strain had its origin in foundation stock introduced by L. S. Klinck, 1911–14. Selfed lines were isolated by L. A. Waitzinger, G. P. McRostie, and A. MacTaggart in the period 1914–30, and J. N. Bird in subsequent years has combined the most promising of these genotypes to form the strain called Avon. The Avon is decidedly more winter-hardy and therefore longer lived and produces larger yields of hay and aftermath than commercial orchard grass. Increased seed production of the Avon is in progress at MacDonald College.

In addition to the named strains herein credited to Canadian breeders, O. McConkey (fig. 14) and his associates at the Ontario Agricultural College, Guelph, report (Y. B. Q.)[9] that 23 improved strains of grasses are being increased for more extended trials and distribution at Guelph. These include the species listed for Guelph in table 1.

[9] This abbreviation will be used in the following pages to indicate that the information was received in reply to the Yearbook questionnaire, sent out in the cooperative survey of plant and animal improvement.

Reservoirs of Plant Material for Selection

The most important sources of material for selection are, of course, the ranges, pastures, and meadows where grasses have been established for a good many years. From this primary source and from foreign lands the United States Department of Agriculture in cooperation with State experiment stations has brought together for

Figure 15.- Grass nursery maintained by the Bureau of Plant Industry and the Soil Conservation Service of the United States Department of Agriculture at the Northern Great Plains Field Station, Mandan, N. Dak. Side-oats grama in the middle foreground.

comparison in grass nurseries extensive collections of native and introduced species. Seed of all the more important native grasses was collected by the Soil Conservation Service in 1935 and 1936 throughout the arid and semiarid Western States. Seed or propagating material of foreign species has been obtained through the Division of Plant Exploration and Introduction of the Bureau of Plant Industry for many years, and these and the native species are available to plant breeders in nurseries (fig. 15) maintained at field stations of the United States Department of Agriculture and at State experiment stations and substations where cooperation with the United States Department of Agriculture exists. Such cooperation is indicated in table 1.

Selective Breeding in Foreign Countries Other Than Canada

Breeding work with grasses has been developed much more in the British Isles, New Zealand, Australia, Sweden, Germany, and Denmark than in the United States.

The Imperial Bureau of Plant Genetics, Aberystwyth, Wales, has made the greatest contribution in the work on herbage grasses, under the direction of R. G. Stapledon. The technique for producing and distributing improved strains of grasses that has been developed

by Stapledon and his associates, especially T. J. Jenkin (fig. 16), should be very helpful in formulating a program for similar work in the United States. It is described fully in a publication of that bureau (*11*).

The results achieved in the British Isles and New Zealand also provide proof of the practical value of a comprehensive grass-breeding program. Levy (*18*) agrostologist, New Zealand Department of Agriculture, reports progress in the use of improved strains of perennial ryegrass as follows: "The North Island is using over 95 percent certified (seed) and it is difficult to dispose of uncertified at any price."

Figure 16.—T. J. Jenkin, who is associated with R. G. Stapledon at the Welsh Plant Breeding Station and has made many important contributions to the science and art of grass breeding. He is responsible for the breeding of all grasses except orchard grass and for the development of a breeding technique.

While the work at the Welsh Plant Breeding Station and in New Zealand is perhaps most outstanding, excellent breeding work has long been under way at the Northumberland County Agricultural Experiment Station at Cockle Park near Newcastle, England; at the Scottish Plant Breeding Station near Edinburgh, Scotland, and in South Africa and Australia. F. Nilsson and A. Muntzing, of the Seed Control Station, Swedish Seed Association, Svalöf, Sweden; H. Weller, Weihenstephan near Munich, Germany; and H. N. Frandsen, Stoftegaard, Denmark, are also making valuable contributions in grass improvement and breeding technique.

The map in figure 17 gives the locations of foreign grass-breeding stations.

Progress in Hybridization of Grasses

Improvement by selection within a species or variety is usually the first step in a breeding program. In every crop, however, the plant breeder ultimately resorts to hybridization as a means of inducing greater variation and also in order to combine in one plant the desirable characters found in different species or genera of plants. The question of how soon hybridization should become a part of a breeding program is not an easy one to answer. Many believe crossing of species and genera should not be undertaken until the possibilities of improvement by selection have been virtually exhausted and approximately pure lines have been obtained for use as parents of the cross. Several potent reasons exist for earlier use of this effective method of plant improvement: (1) To wait until the possibilities of selection

are exhausted would delay hybridization benefits almost indefinitely; (2) strains developed by hybridization usually show more marked difference from the ordinary strain than do selections and are therefore easier to identify and keep pure in commercial trade channels; and

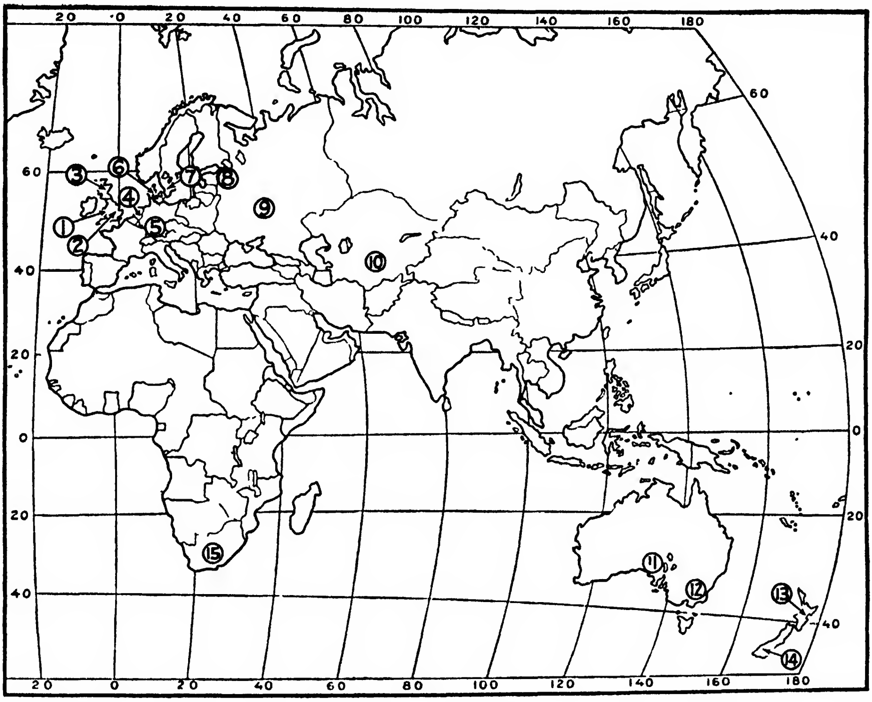

Figure 17.—Locations of the principal grass-breeding stations in the Eastern Hemisphere: 1, Welsh Plant Breeding Station, Aberystwyth, Wales; 2, Northumberland County Agricultural Experiment Station at Cockle Park, near Newcastle, England; 3, Scottish Plant Breeding Station, near Edinburgh, Scotland; 4, Rijksstation voor Plantenveredeling, Ghent, Belgium; 5, Landessaatzuchtanstalt, Weihenstephan, near Munich, Germany; 6, Danish Plant Breeding Station, Stoftegaard, Denmark; 7, Seed Control Station, Swedish Seed Association, Svalöf, Sweden; 8, Institute of Plant Industry, Leningrad, Union of Soviet Socialist Republics; 9, Institute for Fodder Crops, Moscow, Union of Soviet Socialist Republics; 10, Central Asia Scientific Research Institute of Plant Protection, Tashként, Union of Soviet Socialist Republics; 11, Waite Agricultural Research Institute, Adelaide, Australia; 12, Commonwealth Council for Scientific and Industrial Research, Canberra, Australia; 13, Plant Research Station, Department of Agriculture, Palmerston North, New Zealand; 14, Canterbury Agricultural College, Lincoln, Canterbury, New Zealand; 15, Prinshof Pasture Research Station, Pretoria, South Africa.

(3) the intelligent combining of desirable traits, such as disease-resistance, with good forage characters, is often possible by crossing.

Breeders have successfully crossed many species of grasses and in several instances have been able to combine closely allied genera. For the information of present and future workers in this field the hybrids between species are listed in table 3 and the hybrids between

genera in table 4 in the appendix. It will be noted that a large proportion of these hybrids are the products of foreign workers, Russian plant breeders having been especially active in this field. A number of the hybrids are combinations of the relatives of wheat and rye.

Figure 18.—*Triticum-Agropyron* hybrid produced by W. J. Sando, United States Department of Agriculture, showing the hybrid vigor attained in the first generation. From left to right, *Agropyron elongatum*, hybrid, *Triticum aestivum*.

Some of these, especially the *Triticum-Agropyron* hybrids, appear to have marked forage value (fig. 18). Sando, of the United States Department of Agriculture, and Armstrong, of the Canadian Department of Agriculture, who have had an opportunity to observe such hybrids, are convinced that many of the segregates of these crosses

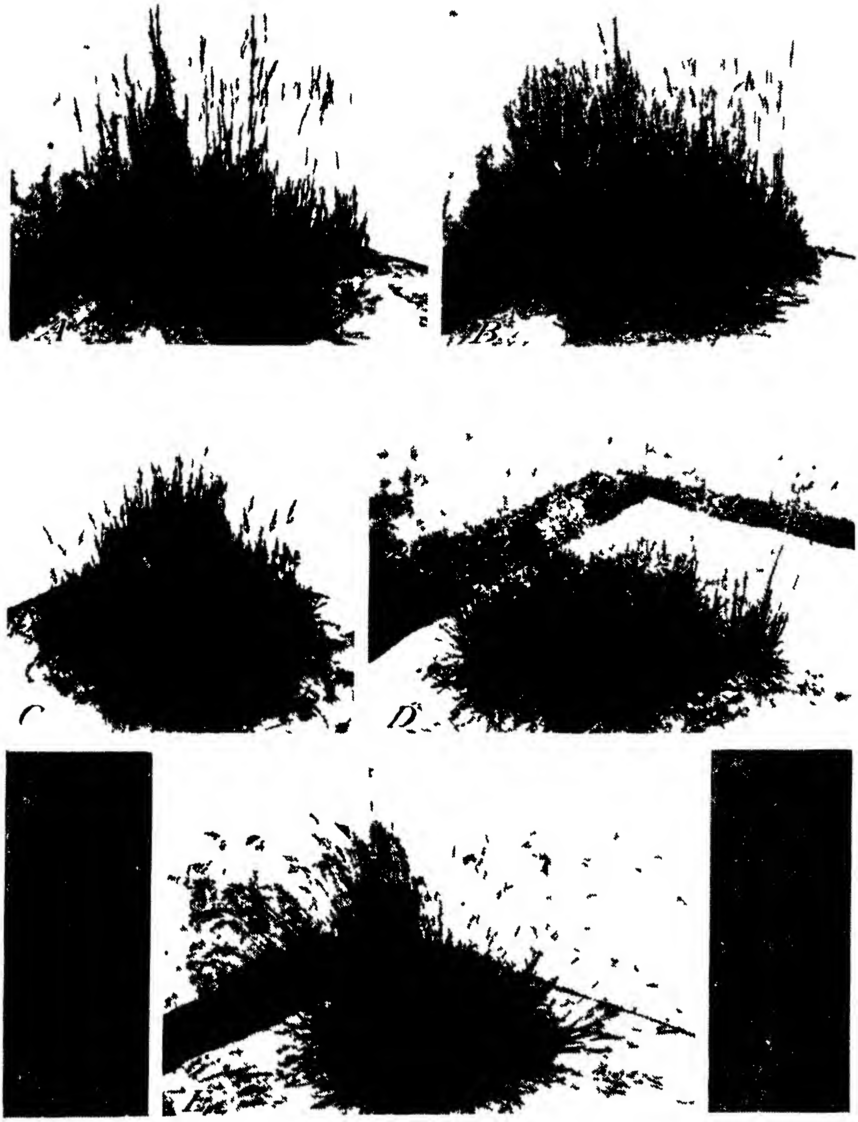

Figure 19.—A few of the variants found in the first-generation hybrid of a cross *Poa arachnifera* × *pratensis* *A*, Texas bluegrass type; *B*, *C*, and *D*, intermediate types, *C*, being one of the less desirable; *E*, Kentucky bluegrass type.

will have great value from a forage standpoint. Armstrong (*1*) states in his report: "Their [the Russian plant breeders] chief aim has been the creation of new forms of perennial wheat. For Canadian conditions the possibilities of obtaining new forms of forage crops by this method appear more attractive." Arrangements are now being made by the United States Department of Agriculture to study the forage value of Sando's crosses.

Jenkin, of the Welsh Plant Breeding Station, has successfully crossed the two genera *Festuca* and *Lolium* and has also made many hybrids among the species within these genera. Brief notes on the progeny characters of these hybrids will be found in tables 3 and 4. No new strain of superior value has resulted from these crosses to date, and Jenkin reports that more immediate improvement in forage

Figure 20.—Single plants representing the various types found in the first generation of a cross *Poa arachnifera* × *pratensis*. These plants were grown on the United States Department of Agriculture grounds in 1909 from seed of crosses made by George W. Oliver the previous year.

value can be attained through selection within a species than in the progeny of the crosses he has made.

This evidence of the futility of hybridization methods cannot be accepted as final, however. In many instances repeated backcrossing has been found necessary to produce the desired types. Muntzing, of the Swedish Seed Association, found in the progeny of a backcross (*Dactylis glomerata*×*aschersoniana*×*glomerata*) individuals more vigorous than *D. glomerata*. Texas bluegrass (*Poa arachnifera*) is dioecious, having the male and female spikelets on different plants. Using the pistillate plants as the female parent, E. Marion Brown, of the United States Department of Agriculture, made crosses of this species and Kentucky bluegrass at Columbia, Mo. He reports wide variation (fig. 19) in the first-generation plants, including individuals more resistant to heat and drought and more productive than Kentucky bluegrass. This cross was made first in 1908 by the late George W. Oliver. Oliver also found an unusual degree of variation (fig. 20) in the first-generation hybrid of this cross, but there was little interest in grass breeding at that time and nothing came of it. These results, in addition to the observed forage value of the *Triticum-Agropyron* hybrids, encourage further hybridization efforts.

GRASS GENETICS AND HYBRIDIZATION TECHNIQUE [10]

To ACHIEVE the utmost possible success in breeding within any group of crop plants, a thorough understanding of the genetics of the plant species is necessary. It is a fact that a large number of the improved varieties that find their way into commercial channels are produced by the selection of existing variants or by breeders who consciously combine the desirable qualities of several varieties or species by crossing or hybridizing them without having any definite knowledge of the manner in which the desired character is inherited. The genetic analysis of any species of plants or animals is extremely slow work, and many of the results obtained have no practical application. Individuals who accomplish most in the realm of pure genetics are not likely to be concerned overmuch as to whether new and improved crop varieties result directly from their research. Practical plant breeders are, however, impatient of delay and usually proceed without knowing quite what to expect in the progeny of a hybrid but fully convinced that something good will be found in the segregates if the parents of the cross have been intelligently chosen. With the grasses as with corn and wheat the more or less unscientific breeding operations have preceded the genetic investigation. Henceforth the two phases of breeding will no doubt progress to-

Figure 21.—*Phalaris truncata*, a foreign relative of the reed canary grass having a spikelike panicle. Note the progress of blooming from apex to base. Panicle on left began to bloom 2 days earlier than that on the right.

[10] The following section is intended primarily for students and others professionally interested in genetics or breeding.

gether. As specially trained groups of geneticists become interested in the study of forage grasses, the fund of basic information regarding their genetic constitution will increase rapidly. At present it is most inadequate. We do, however, have some knowledge of certain characteristics of our more important grasses that are useful in genetic studies. These will be discussed briefly.

Figure 22.—**Flowering panicle of Kentucky blue grass, illustrating the loose, open type of inflorescence found in many grasses.**

Flowering Habits of Grasses

The inflorescence or flower-bearing organ of grasses may be a compact spikelike panicle as in canary grass or a more or less loose panicle as in orchard grass or bluegrass (figs. 21 and 22). Regardless of the type of inflorescence, flowering begins near the apex of the inflorescence and progresses more or less regularly toward the base. In the spikelet the reverse is true; the basal florets open first, followed in regular order by those above. Through the courtesy of Mrs. Agnes Chase, of the Division of Plant Exploration and Introduction, Bureau of Plant Industry, the essential floral organs, the floral envelope, and the arrangement of florets in the spikelet are shown in figure 23.

Grasses flower, that is, extrude their stamens and liberate pollen, most abun-

dantly in the early morning. This is an almost universal rule (*3*), although the period of flowering may be delayed and prolonged by cloudy atmospheric conditions. For several grasses at least there is apparently a secondary, less intensive anthesis period in the afternoon. Fruwirth (*5*), who from 1906 to 1915 conducted some important and rather extensive studies of anthesis and pollination in grasses, reports a secondary blooming period in the afternoon that lasted only 1 or 2 hours. This work was conducted at Hohenheim and Waldhof, near Amstettin, Germany. Sando[11] found in *Agropyron elongatum* the maximum anthesis between 6 and 8 a. m., but there

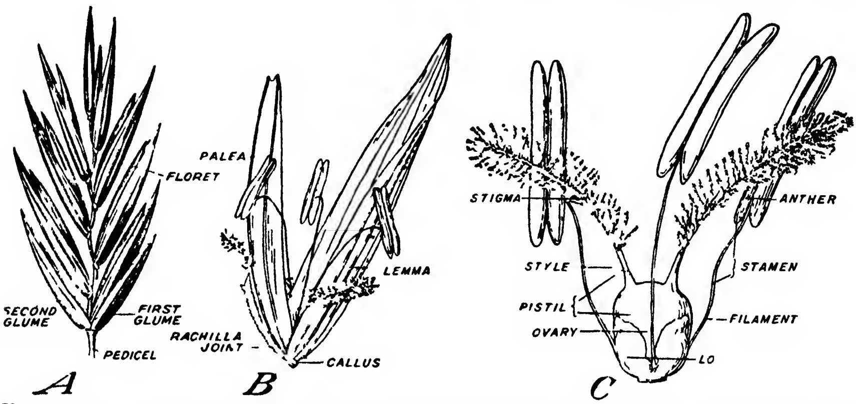

Figure 23.—A grass inflorescence is composed of spikelets, florets, and flowers: *A*, Generalized spikelet indicating the alternate arrangement of florets on the rachis and relative positions of the glumes; *B*, grass floret opened as at blooming time, showing how the lemma and palea are forced open by the lodicules; *C*, typical grass flower showing the essential floral organs necessary in fertilization.

was another period of activity between 3 and 4 p. m. "No blooming occurred between 8 a. m., and 3 p. m." Sando also reports that blooming is most active when the sun is shining and the temperature 70° F. or above. No blooming was ever observed at temperatures below 52°. He believes the delay or reduction in anthesis caused by a cloudy sky is due more to the lowering of temperatures than to increased humidity.

The views of Sando respecting the effect of humidity are confirmed by the studies of Stephens and Quinby (*29*) on sorghum (*Sorghum vulgare*). They concluded, "Relative humidity apparently did not influence the time of blooming." Since sorghum is a grass, it is interesting to note that under field conditions at Chillicothe, Tex., the rate of blooming in the sorghums was highest shortly after midnight rather than in the early morning as Sando found for his *Agropyron* and *Triticum* species growing in the greenhouse. Although the hour of maximum blooming activity in sorghum varied with varieties, Stephens and Quinby state, "A relatively small proportion of flowers opened before 10 p. m. or after 8 a. m., but there were no hours in which flowers were never found opening." By placing plants in a dark room during the day and exposing them to artificial light at

[11] Personal correspondence, 1936.

night the natural rhythm of blooming was reversed in 36 hours. It would appear, therefore, that light conditions are a most important factor in governing the time of blooming. They found, however, that lowering the temperature reduced the rate of blooming.

Fruwirth (*5*) agrees with Stephens and Quinby regarding the effect of humidity but not as to light. In an experiment with ryegrass and orchard grass in which he placed a box lined with black paper over the plants to exclude all light rays, he found that the plants bloomed in spite of the lack of light. He concluded from this experiment in which the heat was sufficient but light was lacking, that the latter seemed to be unnecessary for blooming. There is one criticism to be made of this experiment in that Fruwirth did not alternate darkness and light but left the box in place day and night. Recent investigations have emphasized the importance of the relative proportion of daylight and darkness in the reproduction processes of plant development.

Wolfe (*38*) in his studies of orchard grass at Blacksburg, Va., observed 76.9 percent of the flowers blooming from sunrise to noon, 6.6 percent from noon to sunset, and only 0.3 percent from sunset to midnight. The maximum blooming occurred from 8 to 9 a. m.

Jenkin (*9*) in 1921 observed for several grasses the time on "very fine days" when anthers were exserted under cool greenhouse conditions. These results show that the greater part of the blooming takes place in the forenoon. His recorded observations were as follows:

Lolium perenne.—Blooming period 9 a. m. to 11 a. m.; maximum 9:15 to 9:30 a. m.

Festuca rubra.—Blooming period 9:45 a. m. to 2:30 p. m.; maximum 12 to 1 p. m.

Alopecurus pratensis.—Blooming period 6 to 7:45 a. m.; maximum 6:30 to 7:30 a. m.

Phalaris arundinacea.—Blooming period 5 to 10:15 a. m.; maximum 6 to 6:30 a. m.

The author does not state in what month these observations were made. He does say, however, that in the open "these species apparently flower rather earlier while in dull weather in the greenhouse anther exsertion may be considerably delayed and * * * may be very poor for several days." Jenkin found that orchard grass, tall oatgrass, and timothy, unlike the perennial ryegrass and red fescue, begin blooming early in the morning.

Self-Fertility in Grasses and its Relation to Effect of Inbreeding

The fertility of many important grass species has been summarized in great detail by Beddows (*3*), of the Welsh Plant Breeding Station, who made a thorough review of the literature on this subject. He found that as a general rule the annual grasses were "highly self-fertile", but the perennials showed a high degree of self-sterility. Exceptions occurred however, in both cases, and in certain species there was a marked variation in respect to this character within the species. Nilsson (*21*), of Sweden, made a detailed study of fertility and the effect of inbreeding in meadow fescue, orchard grass, and timothy. As would be expected, the effect of close fertilization or

inbreeding varies in different species according to whether they are naturally cross-fertilized or self-fertilized. The situation regarding these characters as they affect a few of our more important grasses will be found useful in breeding by either selection or hybridization methods.

Orchard grass or cocksfoot (*Dactylis glomerata*): Stapledon (*27*) found *D. glomerata* normally setting much more seed when cross-fertilized than when self-fertilized, but containing "representative plants which are highly self-fertile." These results have been confirmed by breeders in the United States and Canada. Stapledon says, "There is every reason to suppose that completely self-fertile, single plant lines could be isolated." Regarding loss of vigor from inbreeding he concludes that on the average selfed plants are about half as vigorous as plants produced by crossing. He found, however, certain "robust" plants that showed little loss in vigor when selfed for five generations. There is, therefore, an opportunity to use inbreeding methods on this species to purify lines.

Perennial ryegrass (*Lolium perenne*): Jenkin (*10*) and Gregor (*7*) report a low degree of self-fertility in *L. perenne*, but great variation between plants in this respect. Some plants were completely male-sterile while others were comparatively self-fertile, so that Jenkin (*10*) concludes "breeding for self-fertility would not be a difficult matter" in perennial ryegrass. Beddows (*3*) reports 3.6 times as much seed produced in open-fertilized as in close-fertilized plants.

Loss of vegetative vigor resulting from continued inbreeding of unselected perennial ryegrass plants is extreme. Jenkin (*11*) reports an average loss of vigor approximating 63 percent when plants were selfed or fertilized with pollen from other plants of the same line. He concludes, "In perennial ryegrass loss of vigor from selfing is extreme, and consequently the results from other forms of inbreeding will also be relatively pronounced." Wenholz and Whittet, of Australia (Y. B. Q.), confirm Jenkin's results and have discontinued the practice (selfing) in breeding perennial ryegrass.

Italian ryegrass (*Lolium multiflorum*): The conditions regarding self-fertility and loss of vegetative vigor are about the same in Italian as in perennial ryegrass.

Crested wheatgrass (*Agropyron cristatum*): White (Y. B. Q.), of Saskatchewan, reports that sterility is very marked in caged or bagged plants, although this evidence of self-sterility is not conclusive. He found also a large decrease of vegetative vigor in close-fertilized plants, which indicates a low degree of self-fertility.

Slender wheatgrass (*Agropyron pauciflorum*): Malte (*19*), of the Central Experimental Farm, Ottawa, Ontario, Canada, reported in 1921 that *A. pauciflorum* (*A. tenerum* Vasey) was self-fertile, and White (Y. B. Q.) found this species almost completely self-fertile and showing no loss in vegetative vigor from continued selfing. This condition presents a strange contrast to the behavior of *A. cristatum*. Beddows (*3*), of Wales, agrees with White, finding both *A. repens* and *A. pauciflorum* highly self-fertile.

Bentgrass (*Agrostis* spp.): North (Y. B. Q.), formerly of Rhode Island, reported *A. alba* (redtop) somewhat more self-fertile than *A. tenuis* (colonial bent), *A. canina* (velvet bent), or *A. palustris*

138904°—37——68

Huds. (creeping bent). All of the *Agrostis* species showed a tendency toward loss of vigor from continued selfing although only a few generations were obtained.

Smooth bromegrass (*Bromus inermis*): White (Y. B. Q.) reports self-sterility "fairly marked" in bromegrass, but adds that there is a wide variation between plants. If this variation exists it would admit of the development of reasonably self-fertile strains. Beddows' (*3*) results show a very high degree of self-sterility in *B. inermis*, but very little in *B. catharticus* (*B. unioloides*) and other annual bromes. White also reports a marked and progressive loss in vegetative vigor from selfing for four or five generations. This loss of vigor from selfing is confirmed by McConkey (Y. B. Q.), of the Ontario Agricultural College.

Reed or tall fescue (*Festuca elatior* var. *arundinacea*): Beddows (*3*) found 5.1 times as many seeds developing in open-pollinated as in close-pollinated inflorescences. Govaert (Y. B. Q.), of the Rijksstation voor Plantenveredeling, Ghent, Belgium, reports a wide variation between individual plants, some being almost completely self-fertile.

Meadow fescue (*Festuca elatior* var. *pratensis*): According to Beddows (*3*), the meadow fescue is more self-sterile than the tall fescue. Open-pollinated panicles gave 22.3 times as many seed as the close-fertilized ones. As in the tall fescue, however, Govaert (Y. B. Q.), of Belgium, found a wide variation in individual plants, the number of seeds on different plants varying from an average of less than 1 to 409 per inflorescence. There would seem, therefore, to be an opportunity here to select self-fertile strains. G. Nilsson-Leissner (Y. B. Q.), at the Swedish Seed Association, Svalöf, Sweden, found cases of complete self-sterility in meadow fescue and a marked loss of vigor after repeated selfing.

Red fescue (*Festuca rubra*): Beddows (Y. B. Q.) found the self-fertility in red fescue about as low as in tall fescue, selfed plants producing about one-fifth as much seed as those open-pollinated. G. Nilsson-Leissner (Y. B. Q.), of Svalöf, found cases of complete self-sterility and a marked loss of vigor caused by selfing, as he had in meadow fescue.

Canada bluegrass (*Poa compressa*): McConkey (Y. B. Q.), of the Ontario Agricultural College, reports this species largely self-fertile. Under such conditions there is probably very little decrease in vegetative vigor caused by selfing.

Kentucky bluegrass (*Poa pratensis*): A considerable number of plant breeders and cytologists have studied this important grass and found it unusually interesting from two angles—there is a wide variation in the number of chromosomes, and seed is produced, to a considerable extent at least, apomictically. Musser (Y. B. Q.), of Pennsylvania, Brown (Y. B. Q.), of Missouri, and others report no self-sterility in Kentucky bluegrass and no apparent loss of vigor from selfing.

Sudan grass (*Sorghum vulgare* var. *sudanense*): Sudan grass, a close relative of the cultivated sorghums, is self-fertile. Robertson (Y. B. Q.), of Colorado, reports no apparent loss of vigor after three generations of selfing. Wenholz (*36, p. 33*), of New South Wales, reports loss of vigor in some lines under continued inbreeding.

Fruwirth (*5*) reports a method of overcoming the handicap of self-sterility in the perennial grasses that may be of great value to plant breeders. He divided the clump or tuft that had developed from a single seed and grew these parts of the same plant to maturity in separate pots or boxes. When these individual plants were isolated as a group and allowed to bloom freely and interpollinate each other, considerable viable seed was produced. There were, however, some cases where this method was not successful. With "French ryegrass" no seed was obtained, and Fruwirth concluded that these plants were completely self-sterile.

Self-Sterility in Hybrids

Self-sterility, or more properly male-sterility, in the F_1 of interspecific and intergeneric grass hybrids is quite common (table 4). In many cases there is variation in the degree of sterility among individuals, but in most cases backcrossing is required to produce seed. The number of self-fertile segregates increases with repeated backcrossing, which is an accepted procedure among breeders who are laboring to produce new varieties of value in practical agriculture. In some cases polyploidy is induced and increased vigor obtained by crossing the hybrid with a third species.

Verushkine (*35*) reports that in general the fertility of the hybrids of *Triticum* and *Agropyron* exceed considerably the fertility of the rye-wheat hybrids, and that it is somewhat higher than the fertility of *Aegilops* × *Triticum* hybrids. He classifies the *Triticum* × *Agropyron* hybrids into the following groups in respect to the fertility of the first generation:

1. *T. vulgare* [12] × *A. elongatum.*
2. *T. durum* × *A. intermedium* and *A. trichophorum.*
3. *T. vulgare* [12] × *A. intermedium* and *A. trichophorum.*
4. *T. durum* × *A. elongatum.*

No trouble is experienced in the first group in obtaining self-fertilized seed, but in the fourth group "among hundreds of plants" Verushkine and his associates found none self-fertile.

Successful crosses of the two genera *Festuca* and *Lolium* are reported by T. J. Jenkin (see footnotes 1 and 3, table 4), of the Welsh Plant Breeding Station. In many cases although seed set, none of it germinated. In other cases F_1 plants were established, but these were male-sterile. They were, however, in many cases used successfully as the pistillate parent in backcrosses on one of the parent species.

Chromosome Complex of Grasses

The basic chromosome number for grasses is usually seven. There are, of course, exceptions, like that of the *Sorghum* species, where the basic number is five. Cytologists have already determined the chromosome number in a large proportion of the grass species, and their summarized records are available to the plant breeder in several publications. The most extensive lists of chromosome numbers in grasses are those of Avdulow (*2*), Gaiser (*6*), and Tischler (*30*). In order to make such data available to breeders in the United States, a condensed list of reported chromosome numbers in grasses is given in table 5.

[12] Synonym for *T aestivum.*

No thorough investigation of the chromosome behavior during meiosis has been made for any of the forage grasses. A limited amount of information is available, however, regarding valence, lagging, etc., of the chromosomes of certain grasses. Wide differences in the chromosome numbers of individuals of certain species have been reported. These chromosome irregularities naturally affect the behavior of hybrids and in some cases are useful factors in maintaining the purity of selected strains. Thus in breeding orchard grass (*Dactylis glomerata*) the Ontario Agricultural College (*23*) found the leafy pasture strain had 14 chromosomes while the common commercial strain had 28 chromosomes. Therefore the two strains do not cross readily; each remains pure or distinct.

The pasture strain of orchard grass developed by selection in Ontario has 14 chromosomes, the same number as the so-called wild species *Dactylis aschersoniana*, according to Müntzing (*20*) of the Swedish Seed Association. Müntzing found natural crosses of *D. glomerata* and *D. aschersoniana* near Svalof, although it was found very difficult to make this cross artificially. He found 21 chromosomes in the natural hybrid, and when this triploid was backcrossed on *D. glomerata* the F_1 had 35 chromosomes. These pentaploids were more vigorous than ordinary orchard grass, and in their progeny individuals were found having 38, 39, and even 41 chromosomes. Peto (*24*), at the University of Alberta, in his very detailed cytological studies of the *Agropyron* species, reported 14 and 28 chromosome forms of *A. cristatum* and 21 and 28 chromosome forms of *A. pauciflorum*.

Randolph (Y. B. Q.), cytologist, Division of Cereal Crops and Diseases, Bureau of Plant Industry, at Cornell University, found in Kentucky bluegrass (*Poa pratensis*) individuals having 48, 50, 54, 68, and 72 somatic chromosomes. The most common number reported for *P. pratensis* is 56. Practically all cytologists who have worked with this species have noted wide variations. Since 7 is the basic chromosome number in most grasses, if this condition is a tendency toward polyploidy the differences should be various multiples of 7. Randolph's results previously mentioned and those of Rancken (*26*) may be explained on the basis that these indicated variations from exact multiples of 7 are the result of the cytologists' failure to distinguish between whole chromosomes and fragments. These "supernumerary chromosome fragments" Rancken reports are present in *Poa pratensis*, *Dactylis glomerata*, *Festuca elatior* var. *pratensis*, and *Alopecurus pratensis*. Chromosome fragments, Rancken believes, may possibly act as phylogenetic factors.

A peculiar chromosome relationship found in *Phalaris* species is reported by Jenkin and Sethi (*15*). *P. arundinacea* and *P. tuberosa* both have 28 somatic chromosomes showing 14 bivalents in the heterotypic metaphase. The basic number in these species is obviously 7, but in *P. canariensis* the basic number is reported as 6. *P. arundinacea* and *P. tuberosa* were successfully crossed and the F_1 had 28 chromosomes, 12 bivalent and 4 univalent. Other instances of apparent aberrant chromosome conditions are recorded by cytologists, but those mentioned are sufficient to indicate the nature of such abnormalities in forage grasses.

The production of polyploidy or doubling of the chromosome number by means of species crosses is illustrated by the work of Nilsson (*21*), Undrom, Sweden, who reports as follows: "From the hybrid *F.* [*Festuca*] *arundinacea* × *F. gigantea*, which is highly sterile, 2 progeny plants were obtained. F_1 had the same somatic chromosome number (42) as the parents, but the progeny plants differed very much, one having the somatic number 84." This doubling of the chromosomes is explained to have originated by accidental intercrossing of the F_1 hybrid and a third species, *F. elatior* var. *pratensis*. Such an explanation is said to be in harmony with the morphological characters. The author claims this has resulted in "a new polyploid type intermediate between the parents and highly fertile in comparison with F_1."

Compatibility a Factor in Hybridization

As hydridization investigations progress it is apparent that there are different degrees of compatibility not only between species but also between varieties and even strains. Thus Armstrong (*1*), when using *Agropyron glaucum* as the pollen parent, was 32.2 to 34.6 percent successful with *Triticum durum* and *T. dicoccum*, respectively, as the pistillate parents and only 6.5 to 11.7 percent successful with three varieties of *T. aestivum* as the pistillate parent. Strain no. 820 of *A. elongatum* crosses on emmer (*T. dicoccum*) resulted in 38.7 percent success, while strain no. 1083 crossed with emmer gave only 1.5 percent success.

Most workers have found a high degree of compatibility between *Triticum aestivum* and *Agropyron elongatum* and between *T. durum* or *T. dicoccum* and *A. intermedium*. *A. trichophorum* and *A. junceum* are also said to cross readily with wheat, but no one has been able to cross wheat with *A. repens*, and Sando[13] reports failure in his attempts to cross wheat and *A. smithii*. Armstrong (*1*) and other Canadian workers have failed in their attempts to use as the pollen parent *A. desertorum*, *A. dasystachyum*, *A. caninum*, *A. imbricatum*, *A. repens*, *A. cristatum*, or *A. richardsoni* in crosses on *T. durum*, *T. dicoccum*, or *T. aestivum*. These unsuccessful attempts to combine the indicated species of *Agropyron* with the *Triticum* species, while not conclusive, are evidence of incompatibility not apparent from morphological characters customarily used in botanical classifications. The examples given of differences between species of *Agropyron* and *Triticum* will serve to illustrate what the breeder may expect to encounter in other genera.

Technique of Hybridization

Jenkin, of the Welsh Plant Breeding Station, has, no doubt, studied this question to a greater extent than any other investigator. His recommendations (*9*) as to the best methods of crossing grasses are given in a bulletin published in 1924, and a later résumé (*11*) of the subject was published in 1931.

Geneticists usually agree that hand-crossing is the only method to follow if dependable results are to be obtained, and this is emphasized by Jenkin. He sets forth several rules to be observed in the work of hybridization:

---

[13] Personal correspondence, 1936.

1. No inflorescence of a species used for crossing should be allowed to flower unprotected in the greenhouse. This is to avoid free pollen floating about.

2. All ventilators should be closed an hour or more before starting operations, to prevent drafts and allow free pollen to settle and avoid scattering pollen that is being collected for use in crossing.

3. Soft brushes should be used in applying pollen.

4. On both the pistillate and the pollen parent inflorescences should not be exposed any longer than absolutely necessary.

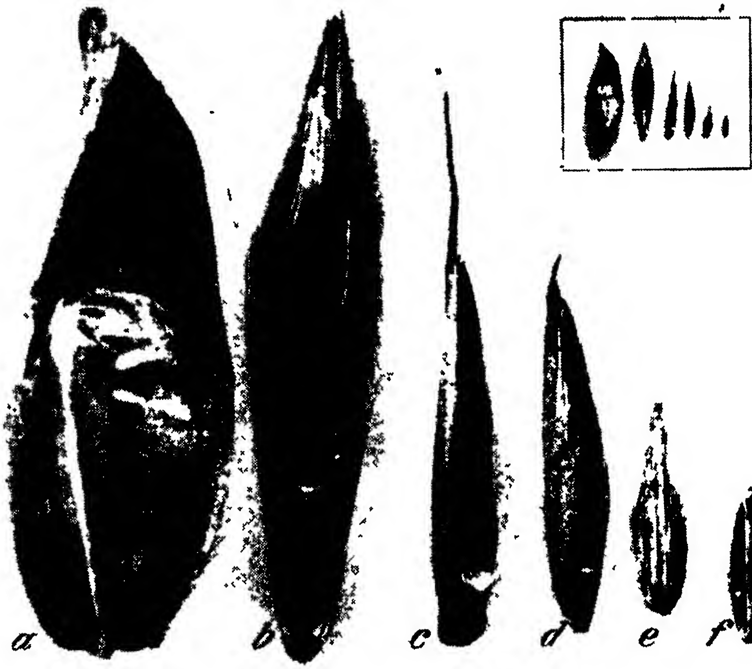

Figure 24.—Comparative size of florets of various grasses in comparison with the wheat floret: *a*, Wheat; *b*, smooth bromegrass; *c*, crested wheatgrass; *d*, orchard grass; *e*, woolly fingergrass; *f*, Kentucky bluegrass. × 9. Upper right natural size.

5. Each brush should be sterilized after being used, and a sufficient number of brushes should be available so that no brush will be used more than once a day.

Emasculation Methods and Equipment

Emasculation of all flowers left on the pistillate parent to be pollinated is necessary except when that parent is known to be completely male-sterile. This operation must perforce be performed before full bloom occurs, but it is most easily accomplished just prior to this stage of development. In sorghums the flowers may be successfully emasculated by immersing the inflorescence in hot water for a short time. This method, discovered by Stephens and Quinby (*28*), may perhaps be equally effective on the smaller grasses, but until the exact temperatures required to kill the pollen on these grasses without

injuring the stigmas are determined, most breeders will continue to use the more tedious hand-emasculation method.

The process of hand emasculation in grasses is very difficult owing to the small size of the individual florets (fig. 24). While Jenkin suggests emasculating with the naked eye or with the assistance of only a small hand lens, most breeders find magnifying instruments necessary or at least very helpful. Instruments for this purpose should be capable of use without being held in the hand, since both hands must be free to manipulate the flowers. Magnifying glasses provided with a contrivance to hold them in position on the operator's head are preferred by some. Others find binocular microscopes attached to a horizontal arm on a vertical stand of the proper height most satisfactory for this work (fig. 25). When the lenses are adjusted to a long focus there is little interference with the movements of the hands and the delicate emasculation operations may be carried out with more assurance than without such equipment. The use of a binocular in hybridization work with grasses was suggested in 1934 by De Villiers (*4*), research officer, Division of Plant Industry, Pretoria, South Africa. Much of his work was with the *Digitaria* species, or woolly fingergrasses, which have extremely small flower parts (fig. 24). Emasculation of such grass flowers without magnifying instruments is well-nigh impossible.

Figure 25.—A binocular microscope with horizontal arm adjustment as used in the emasculation of woolly fingergrass for cross-pollination in the greenhouse.

The technique that Sando (Y. B. Q.) developed in the hybridization of *Triticum* and *Agropyron* species is applicable to other grasses. The necessary operations are described as follows: In preparing a plant for hybridization, several upper and lower spikelets of the inflorescence are excised with a small scissors before blooming. Likewise all but the two lower florets of the remaining spikelets are removed. Emasculation of these flowers is then effected with slender tweezers and the inflorescence enclosed in a glassine bag. Several days later,

when the stigmas reach the stage of receptivity, the glassine bag is removed and pollinations are made, after which the bag is again replaced to remain until maturity.

In the transfer of pollen the most successful results have been accomplished by holding a sheet of clean paper beneath the blooming flowers and slightly shaking them to cause the anthers to expel their pollen. This pollen is then placed in a convenient ring receptacle

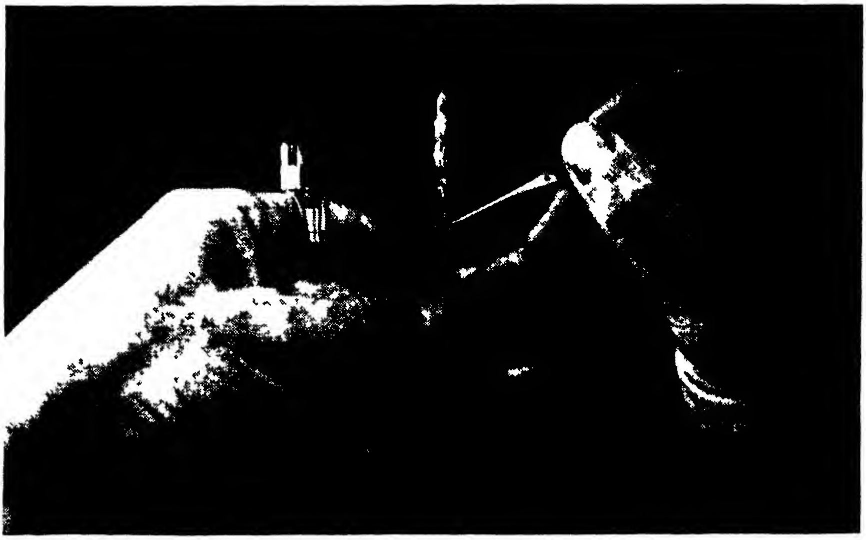

Figure 26.—A handy pollen carrier devised by W. J. Sando, United States Department of Agriculture, consisting of an adjustable ring in which are inserted capsules that may be readily removed and discarded after the pollination process is completed.

(fig. 26), described in a previous publication (*17*). From this receptacle it is transferred with a pair of tweezers or otherwise to the stigmas of the flowers previously emasculated. The period of pollen production Sando finds can be extended considerably by the following practice: Holding a culm just below the inflorescence with the left hand, the head is stroked upward vigorously several times with the thumb and forefinger of the right hand. This induces the flowers to extrude their anthers, provided the temperature is favorable. Such artificial stimulation is most readily accomplished previous to the active blooming periods rather than later. High humidity or rainfall causes the pollen to form a conglomerate mass through the absorption of moisture from the atmosphere. Such pollen is nonfunctional and therefore useless in hybridization.

Collecting the Pollen and Pollinating

It will be noted in the previous discussion that Sando applies the pollen with tweezers while Jenkin prefers to use a soft brush. In collecting the pollen also Jenkin merely shakes the bagged heads until all the pollen grains are detached from the anthers and then pours the pollen out of the bag on a sheet of paper previously creased so

that it can be folded easily to collect the pollen in the middle of the sheet.

The time of day when anthesis takes place in various grasses has been discussed under flowering habits. When two species or two genera are being crossed, difficulty is sometimes encountered because the pollen parent does not reach the blooming stage at the same date as the pistillate parent. Some adjustment of the blooming period in most grasses may be effected by subjecting one or both parents to an artificial regulation of the day length. Sando (Y. B. Q) used this method successfully to bring his *Agropyron elongatum* plants into bloom at the time his wheat plants were ready to cross-pollinate.

The length of time pollen grains will remain viable depends altogether on the conditions in which they are kept. When properly stored they have been known to remain viable several days, but the safest procedure is to apply the pollen immediately after it is gathered. More latitude exists in respect to the receptivity of the stigmas. Stephens and Quinby (*29*) report for sorghums that "stigmas were receptive at least 48 hours before the flowers bloomed and from 8 to 16 days after blooming." Jenkin (*9*) reports for *Lolium perenne* that the stigmas were receptive in one case 13 days after emergence, but none were found receptive on the fifteenth day. It is apparent therefore that considerable time may elapse before pollen need be applied to the stigmas.

While Jenkin advises repeated application of pollen, his data show as good results from two applications as from four or six. It would seem, therefore, that if the pollen is in good condition and is properly and thoroughly applied, one replication is sufficient.

Isolation Methods and Materials

When hybridization is being conducted in a greenhouse, ordinary glassine or waxed paper bags have proved satisfactory for isolating the inflorescences of parent plants. For field operations, however, Jenkin (*11*) found the glassine bags, as used in the greenhouse, useless, and ordinary parchment paper bags equally unreliable. Cloth bags woven in seamless pillowcase form and held in place by specially constructed frames proved most satisfactory. Extensive tests were made of various cotton fabrics, and it was found that many of these did not fully prevent the passage of pollen grains. However, Jenkin found a satisfactory standard fabric, the specifications of which are: Threads per inch—warp 68, weft 65; count—warp 2/32's, weft 16's.

Cages are also used in the field to prevent unintended pollination, and special ventilated rigid boxes which may be adjusted over a single culm have been constructed and used by some breeders. The latter, however, are too expensive for extensive use. All experienced breeders agree that unless great care is used in bagging, the results of otherwise careful work may be vitiated by unfavorable conditions within the bag. Failure of bagged heads to produce seed is in many cases caused by these unfavorable conditions rather than by incompatibility of the parents.

Inheritance of Characters

Only a very limited amount of data is available on this subject. Those who have studied *Triticum-Agropyron* hybrids agree that the perennial nature of the *Agropyron* parent is dominant in the F_1 hybrid. The proportion of perennials quite naturally decreases rapidly in succeeding generations of backcrosses on the annual *Triticum* species. According to Verushkine (*35*), only 43 to 66 percent of the second generation plants are perennials. He remarks that the F_2 affords a wide segregation of characters and includes for the most part intermediate types.

Armstrong (*1*), of the Central Experimental Farm, Ottawa, Canada, agrees with Verushkine in general as to the dominance of the perennial character in the *Triticum-Agropyron* hybrids. He names several other *Agropyron* characters that are dominant, but finds a condition of intermediacy in respect to quantitative characters such as spike density, glume width, and leaf width and scabrousness. When awned wheats were used as the pistillate parent and *A. glaucum* as the pollen parent, the hybrids were awn-tipped, an intermediate condition. When *A. elongatum* was used as the pollen parent the hybrids were awnless in most cases. Both species of *Agropyron* are awnless.

The presence in *Lolium multiflorum* of a root substance that causes a fluorescence on filter paper when examined under ultraviolet light has been used to distinguish this species from *L. perenne*. Woodforde (*39*), of the Tasmanian Department of Agriculture, reports that this character is inherited as a simple Mendelian dominant dependent on a single factor. However, he found no genetic linkage between fluorescence and awned flowering glumes, a distinguishing character of *L. multiflorum*.

Jenkin (*12*), of the Welsh Plant Breeding Station, in a study of bulbous tall oatgrass, found in the F_1 of a cross of the nonbulbous and bulbous forms an intermediate condition in respect to bulb development, although all F_1 plants were definitely bulbous. In the F_2 and F_3 there was an apparent segregation for bulb development, which was hard to analyze, since a great majority of the plants were more or less bulbous. He concludes that more than one pair of factors is concerned in bulb development, and that the same is true of the hairiness of stem nodes, another distinguishing character of bulbous tall oatgrass. The value of this research lies in the fact that the bulbous form behaves as a weed in cereal fields under certain conditions, while the nonbulbous form does not.

TABLE 1.—*Development centers of important grasses useful in breeding* [1]

Region	Grasses [2]: Common name	Grasses [2]: Scientific name
(1) Europe, except the Mediterranean region and the eastern or dry portion of the Union of Socialist Soviet Republics.	Redtop	*Agrostis alba.*
	Bentgrass	*Agrostis* spp.
	Beachgrass	*Ammophila areanaria.*
	Tall oatgrass	*Arrhenatherum elatius.*
	Awnless bromegrass	*Bromus inermis.*
		Dactylis aschersoniana.
	Cocksfoot or orchard grass	*D. glomerata.*
	Reed or tall fescue	*Festuca elatior* var. *arundinacea.*
	Meadow fescue	*F. elatior* var. *pratensis.*
	Italian ryegrass	*Lolium multiflorum.*
	Perennial ryegrass	*L. perenne.*
	Mountain timothy	*Phleum alpinum.*
		P. boehmeri.
	Timothy	*P. pratense.*
	Mountain bluegrass	*Poa alpina.*
	Annual bluegrass	*P. annua.*
	Canada bluegrass	*P. compressa.*
	Kentucky bluegrass	*P. pratensis.*
	Rough-stalked bluegrass	*P. trivialis.*
	Cordgrass	*Spartina townsendii.*
(2) Mediterranean region of Europe and Africa.	Giant reed	*Arundo donax.*
	Wild oats (annuals)	*Avena barbata, A. fatua, A. sterilis, A. strigosa.*
	Bromes (annuals; cheat or chess)	*Bromus arvensis, B. mollis, B. secalinus, B. sterilis.*
	Red fescue	*Festuca rubra.*
	Canary grass	*Phalaris canariensis.*
	Harding grass	*P. tuberosa.*
	Esparto grass	*Stipa tenacissima.*
(3) Eastern Union of Socialist Soviet Republics and Siberia.	Wheatgrasses	*Agropyron caninum, A. cristatum, A. ehongatum, A. intermedium, A. trichophorum.*
	Reedgrasses	*Calamagrostis* spp.
	Wild-rye	*Elymus* spp.
	Sheep fescue	*Festuca ovina.*
	Ricegrasses	*Oryzopsis* spp.
	Chee grass	*Stipa splendens.*
(4) Southern Union of Soviet Socialist Republics, Turkistan, Sinkiang (China), Turkey, Palestine, and Afghanistan.	Goatgrasses	*Aegilops crassa, A. cylindrica, A. ovata, A. squarrosa, A. triuncialis.*
	Meadow foxtail	*Alopecurus pratensis.*
	Sweet vernal grass	*Anthoxanthum odoratum.*
	Wild oats	*Avena barbata, A. fatua, A. sterilis, A. strigosa.*
	Red fescue	*Festuca rubra.*
	Barley relatives	*Hordeum species.*
	Bulbous bluegrass	*Poa bulbosa.*
	Rye	*Secale cereale.*
	Johnson grass	*Sorghum halepense.*
	Wheat relatives	*Triticum* spp.
(5) Tibet, western provinces of China, and eastern Mongolia.	Wheatgrasses	*Agropyron* spp.
	Wild-ryes	*Elymus* spp.
	Fescues	*Festuca* spp.
	Bluegrasses	*Poa alpina, P. attenuata, P. nemoralis, P. tibetica.*
	Needlegrasses	*Stipa* spp
(6) Eastern Siberia, Manchuria, northeastern China, Chosen, and Japan.		*Arundinella* spp.
	Manchu reedgrass	*Calamagrostis epigeios.*
	Jungle rice	*Echinochloa colona.*
	Japanese millet	*E. crus-galli.*
	Broomcorn millet	*Panicum miliaceum.*
	Foxtail millet	*Setaria italica.*
	Bristlegrasses	*Setaria* spp.
	Japanese lawngrass	*Zoysia japonica.*
	Manila lawngrass	*Z. matrella.*
	Sorghums	*Sorghum vulgare.*

[1] Numbers of regions correspond to those in fig. 1.

[2] In naming the grasses characteristic of a region no attempt has been made to restrict them to native species, since in certain areas the introduced species are more abundant and more important than the native ones. Some grasses, omitted because of their apparent lack of usefulness, are more widely distributed and more characteristic of a region than are any of the species named. It should be understood also that in most cases other species of the genera listed occur in the region.

TABLE 1.—*Development centers of important grasses useful in breeding*—Continued

Region	Grasses	
	Common name	Scientific name
(7) India, southeastern China, Burma, Malay Peninsula, Sumatra, Java, Borneo, New Guinea, Taiwan.	Angleton grass	*Andropogon annulatus.*
	Dwarf bamboo	*Bambusa nana.*
	Bamboo	*B. vulgaris.*
	"Doob" (Bermuda) grass	*Cynodon dactylon.*
	Finger millets	*Eleusine coracana.*
	Centipede grass	*Eremochloa ophiuroides.*
	Cogon grass	*Imperata cylindrica.*
	Ricegrass	*Oryza sativa.*
	Kutki millet	*Panicum psilopodium.*
	Koda millet	*Paspalum scrobiculatum.*
	Edible bamboo	*Phyllostachys edulis.*
	Sugarcane relatives	*Saccharum* spp.
	Sorghums	*Sorghum vulgare.*
(8) Australia, New Zealand, and Tasmania.	Native grasses (grown in dry areas):	
	Mitchell grass	*Astrebla pectinata.*
	Curly Mitchell grass	*A. triticoides*
	Wallaby grass	*Danthonia semiannularis.*
	Flinders grass	*Iseilema membranacea.*
	Australian tussock grass	*Poa caespitosa.*
	New Zealand tussock grass	*P. flabellata.*
	Silvery sandgrass	*Spinifex hirsuta.*
	Kangaroo grass	*Themeda* spp.
	Spinifex	*Triodia* spp.
	Introduced grasses (grown where rainfall is adequate).	
	Rhodes grass	*Chloris gayana.*
	Orchard grass	*Dactylis glomerata.*
	Meadow fescue	*Festuca pratensis.*
	Italian ryegrass	*Lolium multiflorum.*
	Perennial ryegrass	*L. perenne.*
	Dallis grass	*Paspalum dilatatum.*
(9) Equatorial Africa	Bluestem relatives	*Andropogon* spp.
	Brachiarias	*Brachiaria* spp.
	Teff	*Eragrostis abyssinica.*
	Carib grass	*Eriochloa polystachya.*
	Wild barleys	*Hordeum* spp.
		Hyparrhenia spp.
	Guinea grass	*Panicum maximum.*
	Para grass	*P. purpurascens.*
	Bentham grass	*Pennisetum benthami.*
	Kikuyu grass	*P. clandestinum.*
	Pearl or cattail millet	*P. glaucum.*
	Merker grass	*P. merkeri.*
	Napier or elephant grass	*P. purpureum.*
	Sorghums	*Sorghum vulgare.*
	Grass sorghums	*S. vulgare* vars.
	"Rooi gras" or red grass	*Themeda triandra.*
	Herringbone grass	*Urochloa pullulans.*
(10) Africa south of 10° south latitude, which includes southern Angola and Tanganyika, all of Nyassaland, Mozambique, Rhodesia, Bechuanaland, South Africa, and Madagascar.	Rhodes grass	*Chloris gayana.*
	"Kweek" (Bermuda) grass	*Cynodon dactylon.*
	Red kweek grass	*C. hirsutus.*
	Woolly fingergrass	*Digitaria eriantha stolonifera.*
	Other fingergrasses	*Digitaria* spp.
		Ehrharta calycina.
		Hyparrhenia spp.
	Sorghums	*Sorghum vulgare.*
	Grass sorghums	*S. vulgare* vars.
	"Rooi gras" or red grass	*Themeda triandra.*
	Natal grass	*Tricholena rosea.*
(11) Brazil, eastern Bolivia, Paraguay, Uruguay, and northeastern Argentina.	Carpet grass	*Axonopus compressus.*
	Pampas grass	*Cortaderia selloana.*
	Jaragua grass	*Hyparrhenia rufa.*
	Molasses grass	*Melinis minutiflora.*
	Rice	*Oryza sativa.*
	Guinea grass	*Panicum maximum.*
	Bahia grass	*Paspalum notatum.*
(12) Andean region of Peru, Bolivia, Chile, and Argentina.	"Maicillo" or "cachi"	*Axonopus scoparius.*
	Reedgrasses	*Calamagrostis* spp.
	Fescues	*Festuca* spp.
	Muhly grass	*Muhlenbergia* spp.
	Bluegrasses	*Poa* spp.
(13) Southern Mexico, Central America, northwestern South America, and the West Indies.	Giant reed	*Arundo donax.*
	Carpet grass	*Axonopus compressus.*
	"Malojilla" or Carib grass	*Eriochloa polystachya.*
	Teosinte	*Euchlaena mexicana.*

TABLE 1.—*Development centers of important grasses useful in breeding*—Continued

Region	Grasses: Common name	Grasses: Scientific name
	Mexican teosinte	*E. perennis.*
	Wild rice	*Oryza latifolia.*
	Guinea grass	*Panicum maximum.*
	Para grass	*P. purpurascens.*
	Bahia grass	*Paspalum notatum.*
	St. Augustine grass	*Stenotaphrum secundatum.*
	Eastern gamagrass	*Tripsacum dactyloides.*
	Long-leaved gamagrass	*T. latifolium.*
	Guatemala grass	*T. laxum.*
	Corn (maize)	*Zea mays.*
(14) Great Plains and intermountain regions of North America.	Native grasses:	
	Thickspike wheatgrass	*Agropyron dasystachyum.*
	Slender wheatgrass	*A. pauciflorum.*
	Streambank wheatgrass	*A. riparium.*
	Bluestem (western wheatgrass).	*A. smithii.*
	Bluebunch wheatgrass	*A. spicatum.*
	Bearded wheatgrass	*A. subsecundum.*
	Big bluestem	*Andropogon furcatus.*
	Turkeyfoot	*A. hallii.*
	Silver beardgrass	*A. saccharoides.*
	Little bluestem	*A. scoparius.*
	Six-weeks grama	*Bouteloua barbata.*
	Crowfoot grama	*B. chrondrosioides.*
	Side-oats grama	*B. curtipendula.*
	Black grama	*B. eriopoda.*
	Hairy grama	*B. hirsuta.*
	Rothrock grama	*B. rothrockii.*
	California bromegrass	*Bromus carinatus.*
	Buffalo grass	*Buchloë dactyloides.*
	Pine grass	*Calamagrostis rubescens.*
	Long-leaved sandgrass	*Calamovilfa longifolia.*
	Canada wild-rye	*Elymus canadensis.*
	Giant wild-rye	*E. condensatus.*
	Beardless wild-rye	*E. triticoides.*
	Virginia wild-rye	*E. virginicus.*
	Bluebunch fescue	*Festuca idahoensis.*
	Six-weeks fescue	*F. octoflora.*
	Sheep fescue	*F. ovina.*
	Red fescue	*F. rubra.*
	Greenleaf fescue	*F. viridula.*
	Curly mesquite	*Hilaria belangeri.*
	Galleta grass	*H. jamesii.*
	Junegrass	*Koeleria cristata.*
	Switchgrass	*Panicum virgatum.*
	Canby bluegrass	*Poa canbyii (P. laevigata).*
	Nevada bluegrass	*P. nevadensis.*
	Sandberg bluegrass	*P. secunda (P. sandbergii).*
	Nuttall alkali-grass	*Puccinellia nuttalliana.*
	Blowout grass	*Redfieldia flexuosa.*
	Indian grass	*Sorghastrum nutans.*
	Alkali sacaton	*Sporobolus airoides.*
	Sand dropseed	*S. cryptandrus.*
	Sacaton	*S. wrightii.*
	Long-awned spear grass	*Stipa comata.*
	Introduced grasses:	
	Crested wheatgrass	*Agropyron cristatum.*
	Awnless bromegrass	*Bromus inermis.*
	Bulbous bluegrass	*Poa bulbosa.*
	Sudan grass	*Sorghum vulgare* var. *sudanense.*
(15) Southeastern Canada and northeastern United States.	Native grasses:	
	Quackgrass	*Agropyron repens.*
	American beachgrass	*Ammophila breviligulata.*
	Big bluestem	*Andropogon furcatus.*
	Little bluestem	*A. scoparius.*
	Bluejoint	*Calamagrostis canadensis.*
	Virginia wild-rye	*Elymus virginicus.*
	American mannagrass	*Glyceria grandis.*
	Switchgrass	*Panicum virgatum.*
	Reed canary grass	*Phalaris arundinacea.*
	Smooth cordgrass	*Spartina alterniflora.*
	Big cordgrass	*S. cynosuroides.*
	Saltmeadow cordgrass	*S. patens.*
	Prairie cordgrass	*S. pectinata.*
	Eastern gamagrass	*Tripsacum dactyloides.*
	Wild rice	*Zizania aquatica.*

TABLE 1.—*Development centers of important grasses useful in breeding*—Continued

Region	Grasses: Common name	Grasses: Scientific name
(16) Southeastern United States.	Introduced grasses (see also list for region 1):	
	Japanese millet	*Echinochloa crus-galli* var. *frumentacea*.
	Foxtail millet	*Setaria italica*.
	Native grasses:	
	Southern cane	*Arundinaria gigantea*.
	Small cane	*A. tecta*.
	Virginia wild-rye	*Elymus virginicus*.
	Texas bluegrass	*Poa arachnifera*.
	Smooth cordgrass	*Spartina alterniflora*.
	Big cordgrass	*S. cynosuroides*.
	Saltmeadow cordgrass	*S. patens*.
	Southern cordgrass	*S. spartinae*.
	Eastern gamagrass	*Tripsacum dactyloides*.
	Southern wild rice	*Zizaniopsis miliacea*.
	Introduced grasses:	
	Carpet grass	*Axonopus compressus*.
	Rescue grass	*Bromus catharticus*.
	Bermuda grass	*Cynodon dactylon*.
	Centipede grass	*Eremochloa ophiuroides*.
	Para grass	*Panicum purpurascens*.
	Dallis grass	*Paspalum dilatatum*.
	Bahia grass	*P. notatum*.
	Vasey grass	*P. urvillei*.
	Pearl millet	*Pennisetum glaucum*.
	Napier grass	*P. purpureum*.
	Japanese cane	*Saccharum chinense*.
	Johnson grass	*Sorghum halepense*
	Natal grass	*Tricholaena rosea*.

TABLE 2.—*Objectives and progress in the selective breeding of grasses as reported by workers in the United States and Canada*

Location [1]	Individual workers	Genera and species	Period work under way	Objectives	Success attained
UNITED STATES					
Arizona:					
Tucson*	E. W. Hardies	*Bouteloua curtipendula, B. eriopoda, B. gracilis, Hilaria belangeri, H. jamesii, H. mutica, H. rigida, Muhlenbergia porteri, Oryzopsis coerulescens, O. hymenoides, O. miliacea, Setaria macrostachya.*	1936 (continued)	Increased seed and forage production, longevity, and drought resistance.	
California:					
Davis	L. G. Goar	*Sorghum vulgare* var. *sudanense.*	5 years	Increased hay and pasture production	Much.
Colorado:					
Colorado Springs*	E. W. Hardies	*Agropyron smithii*	1936 (continued)	Increased seed and forage production, longevity, and drought resistance.	Many promising variants found.
Fort Collins	Alvin Kezer	*Bromus inermis*	1910–14	Increased yield of forage	
	D. W. Robertson and Otto Coleman.	*Sorghum vulgare* var. *sudanense.*	1934 (continued)	(a) Yield and uniformity of seed; (b) reduced hydrochloric acid content.	(a) Much.
Florida:					
Gainesville*	G. E. Ritchey and W. E. Stokes.	*Axonopus compressus*	10 years	(a) Increased pasturage value; (b) reduced stolon development.	(a) Much; (b) little.
		Axonopus furcatus	do	Increased pasturage value	Much.
		Cynodon spp.		do	Medium to much.
		Digitaria spp.	1933 (continued)	Increased seed production and pasturage value.	Medium.
		Eremochloa ophiuroides	1931 (continued)	Increased seed production, pasturage, and lawn value.	Much.
		Melinis minutiflora	1933 (continued)	(a) Increased pasturage value, (b) early seed production; (c) winter hardiness.	(a) Much, (b) and (c) little.
	G. E. Ritchey and F. H. Hull.	*Paspalum notatum*	do	Increased pasturage value and disease resistance.	Much.
	G. E. Ritchey and W. E. Stokes.	*Pennisetum purpureum*	1934 (continued)	Increased pasturage and silage value and resistance to leaf spot.	Do.
Georgia:					
Tifton* (Coastal Plain Experiment Station).	J. L. Stephens and G. W. Burton.	*Cynodon dactylon*	1929 (continued)	Increased hay and pasture production and winter hardiness.	Medium.
		Cynodon spp.	1936 (continued)	Increased seed production, palatability, and winter hardiness.	
		Digitaria spp.		Increased viable seed production, better turf, and winter hardiness.	
		Panicum antidotale		Production of nonshattering seed heads	

[1] Except where otherwise noted, the work is conducted at the State Agricultural Experiment Station. An asterisk (*) indicates cooperation between the U. S. Department of Agriculture and the State agricultural experiment station.

Table 2.—*Objectives and progress in the selective breeding of grasses as reported by workers in the United States and Canada*—Continued

Location	Individual workers	Genera and species	Period work under way	Objectives	Success attained
UNITED STATES—continued					
Georgia—Continued Tifton [a] (Coastal Plain Experiment Station)	J. L. Stephens and G. W. Burton	*Panicum purpurascens*		Winter hardiness and earliness	
		Paspalum dilatatum		Increased production of viable seed, leafiness, and disease resistance	
		Paspalum notatum		do	
		Pennisetum purpureum		Increased forage value and resistance to helminthosporium eye spot	
		Sorghum vulgare var. *sudanense*		Resistance to foliage diseases	
Iowa Ames	H. D. Hughes and F. S. Wilkins	*Phalaris arundinacea*	1921-32	Increased seed and forage, disease resistance, leafiness, and density of turf	Much
Illinois Urbana	O. T. Bonnett	*Agrostis alba*	1934 (continued)	Increased yield of forage, disease resistance, and winter hardiness	
		Poa pratensis	do	Increased yield of forage, resistance to leaf rust and mildew, and winter hardiness	
Kansas Hays [a] (Fort Hays Branch of Kansas Agricultural Experiment Station)	D. A. Savage, H. E. Runyon, and R. E. Solomon	*Agropyron pungens, A. semicostatum, A. smithii*	do	In general the objective for all grasses is to develop drought-resistant grasses suitable for reseeding and resodding on different soil types in the central and southern Great Plains and to improve their forage value	Many promising variants found
		Andropogon furcatus, A. hallii, A. scoparius, Bouteloua gracilis, B. hirsuta	do	Special attention given to increased seed production and viability	
		Buchloe dactyloides	do	Special attention given to increased seed production and viability and rapidity of vegetative spread	
		Bromus inermis	do	Especially to develop a type that will endure high temperatures	
		Elymus virginicus	do	Especially to improve forage quality	
		Sorghastrum nutans	do	Special attention given to increased seed production and viability	
Manhattan [a]	A. E. Aldous	*Andropogon furcatus, A. scoparius*	1928 (continued)	Increased seed and forage values and drought resistance	
		Bromus inermis	1930 (continued)	do	
Kentucky [a] Lexington	F. N. Fergus	*Arrhenatherum elatius*	1931 (continued)	Comparing local strain with commercial	
		Dactylis glomerata	10 years	Increased forage production	
		Festuca elatior	1931 (continued)	Comparing local strain with commercial	
		Poa pratensis	7 years	Increased forage production, disease resistance, and turf density	

Maryland					
Beltsville (National Agricultural Research Center)	H. N. Vinall and M. A. Hein	*Dactylis glomerata*	1932 (continued)	Pasture and hay types, leafiness and late maturing	Medium
		Lolium multiflorum	1930 (continued)	Late maturing and rust resistance	Do
		Lolium perenne	do	Rust resistance and summer forage production	Little
		Poa compressa	1934 (continued)	Leafiness and increased density of turf	Medium
		Poa pratensis	do	Summer forage production	Do
College Park	J. E. Metzger and G. F. Eppley	*Festuca rubra*	5 years	Increased seed production and fine turf value	Do
Michigan					
Augusta* (W. K. Kellogg Demonstration Farm)	A. B. Dorrance	*Cynodon dactylon*	1930–36	Winter hardiness	Do
		Poa pratensis	1934–36	Summer forage production and leafiness	Do
Mississippi					
State College	H. W. Bennett	*Cynodon, Digitaria, Lolium* and *Paspalum* spp.	1936 (continued	Increased seed production and forage value	
Missouri					
Columbia*	E. M. Brown	*Dactylis glomerata*	1935 (continued)	Increased pasturage production and leafiness	
		Poa pratensis	1932 (continued)	Increased pasturage production, drought and heat resistance, dense turf	Medium
Montana					
Bozeman*	L. P. Reitz	*Festuca rubra*	1930–35	Increased seed and forage production	
		Lolium perenne	1930–35	do	
		Sorghum vulgare var. *sudanense*	1930–35	do	
		Various native grasses	1936 (continued)	do	
Havre* (Northern Montana Branch Station)	M. A. Bell	*Agropyron cristatum*	1925	do	Do
		Agropyron inerme	1934	do	
		Agropyron smithii	1934	do	
Moccasin* (Judith Basin Branch Station)	N. F. Woodward, H. E. Tower and J. E. Norton	*Agropyron cristatum*	1924–26, 1929–34, 1935 (continued)	do	Do
Nebraska					
Lincoln*	L. C. Newell, A. L. Frolik and F. D. Keim	*Agropyron cristatum, A. smithii, Andropogon furcatus, A. scoparius, Bouteloua gracilis, B. curtipendula, Bromus inermis, Buchloe dactyloides, Dactylis glomerata, Panicum virgatum, Phalaris arundinacea, Sorghastrum nutans*	1936 (continued)	Increased seed and forage production, drought and disease resistance, palatability, and longevity	
New Jersey					
New Brunswick	H. B. Sprague	*Agrostis canina*	1929 (continued)	Increased seed, resistance to *Pythium* and brown patch and turf quality	Much
		Festuca rubra	1931 (continued)	Increased seed, resistance to *Pythium* and creeping habit	Medium
New York					
Ithaca	D. B. Johnstone-Wallace and C. H. Myers	*Dactylis glomerata*	do	Improved pasture types	Much

TABLE 2.—*Objectives and progress in the selective breeding of grasses as reported by workers in the United States and Canada*—Continued

Location	Individual workers	Genera and species	Period work under way	Objectives	Success attained
UNITED STATES—continued					
North Dakota:					
Dickinson* (substation)	Leroy Moomaw	*Agropyron cristatum*	1928–35	Increased seed and forage production	Medium.
Mandan* (United States Northern Great Plains Field Station).[2]	George A. Rogler	do	1936 (continued)	In general the objectives for all grasses at Mandan are increased seed and forage production, viability of seed, forage palatability, drought and disease resistance, and seedling vigor.	
		Agropyron smithii	do	Rapid spreading of rhizomes, and early foliage emergence.	
		Andropogon furcatus, A. hallii, A. scoparius.	do	Early foliage emergence	
		Bouteloua curtipendula	do	Early foliage emergence and cold resistance	
		Bouteloua gracilis	do	Early foliage emergence	
		Bromus inermis	do		
		Bromus marginatus	do	Cold resistance	
		Buchloë dactyloides	do	Early foliage, dense turf, tall seed stalks, rapid spreading.	
		Elymus canadensis	do		
		Elymus junceus	do	Nonshattering of seed	
		Oryzopsis hymenoides	do		
		Panicum virgatum	do	Early foliage emergence	
		Phalaris arundinacea	do	Nonshattering of seed	
Oklahoma:					
Woodward* (United States Southern Great Plains Field Station).	D. A. Savage, H. E. Runyon, and R. E. Solomon.	*Agropyron repens* var. *pungens, A. smithii, Andropogon furcatus, A. hallii, A. saccharoides, A. scoparius, Bouteloua chondrosioides, B. curtipendula, B. eriopoda, B. hirsuta, Buchloë dactyloides, Calamovilfa longifolia, Elymus virginicus, Panicum virgatum, Redfieldia flexuosa, Sorghastrum nutans, Zoysia japonica.*	do	To develop drought-resistant grasses suitable for reseeding and resodding on different soil types in the central and southern Great Plains and to improve their forage value.	
Stillwater	W. B. Gernert	*Bromus inermis*	Recent years	Increased forage production	
		Buchloë dactyloides	do	do	Much.
		Phalaris arundinacea	do	do	
		Sorghum vulgare var. *sudan-*	do	do	

Oregon:					
Corvallis*	H. A. Schoth and H. H. Rampton.	*Agrostis oregonensis*	1935 (continued)	Improved turf and seed production [3]	Medium.
		Agrostis palustris	do	Deeper root system and ability to withstand brackish overflow.	Do.
		Agrostis sp.	1928 (continued)	Improved forage, turf, and seed production	Do.
		Alopecurus pratensis	1934 (continued)	Increased forage, uniform seed maturity, and less shattering.	Much.
		Arrhenatherum elatius	1932 (continued)	Increased foliage and less seed shattering	Do.
		Brachypodium pinnatum	1928 (continued)	More tender foliage	Little.
		Bromus inermis	1922 (continued)	Reduced rhizome development and early growth.	Medium.
		Dactylis glomerata	1928 (continued)	Improved forage and turf-forming pasture types.	
		Festuca elatior var. *arundinacea*.	1920 (continued)	More tender foliage and less seed shattering	Do.
		Lolium multiflorum	1930 (continued)	Longevity and rust resistance	Do.
		Lolium perenne	do	Longevity, rust resistance, and more seed first year.	Do.
		Phalaris arundinacea	1920 (continued)	Wider adaptation as to soil and increased seed production; especially less shattering.	Much.
		Phalaris tuberosa var. *stenoptera*.	1930 (continued)	Longevity, less seed shattering, and winter hardiness.	
Pennsylvania:					
State College	H. B. Musser	*Agrostis canina*	1929–35	Fine turf	Do.
		Agrostis palustris	1929–35	do	Medium.
		Poa pratensis	1932 (continued)	Improvement in pasture value and fine-turf quality.	Do.
Rhode Island:					
Kingston	T. E. Odland and H. F. A. North.	*Agrostis alba*	1930–34	Purifying lines	Much.
		Agrostis canina	1931–35	(a) Purifying lines, (b) resistance to dollar spot, seed production, fine turf.	Do.
		Agrostis palustris	1930–34	Resistance to brown patch, dollar spot, and snow mold; and fine turf.	Medium.
		Agrostis tenuis	1930 (continued)	(a) Resistance to brown patch, (b) fine turf, (c) purifying lines.	(c) Much.
Texas:					
San Antonio [2]	Gerald O. Mott	*Andropogon furcatus*, *A. hallii*, *A. saccharoides*, *A. scoparius*, *Bouteloua curtipendula*, *B. gracilis*, *B. hirsuta*, *Panicum virgatum*, *Sorghastrum nutans*.	1934 (continued)	Increased production and viability of seed, forage value, longevity, and drought resistance.	
Spur (Texas Substation no. 7).	R. E Dickson	*Buchloë dactyloides*	Few years	Selection and increased yields of forage and seed.	Much.

[2] Bureau of Plant Industry and Soil Conservation Service cooperating.
[3] In addition to objectives stated, general consideration is given in all species at Corvallis to increasing the quantity and quality of forage and resistance to insects and diseases.

Table 2.—*Objectives and progress in the selective breeding of grasses as reported by workers in the United States and Canada*—Continued

Location	Individual workers	Genera and species	Period work under way	Objectives	Success attained
UNITED STATES—continued					
Utah					
Logan*	Wesley Keller and Dean F McAlister	*Agropyron cristatum A pauciflorum, A smithii, Bromus inermis Elymus canadensis E condensatus, Festuca idahoensis, Oryzopsis hymenoides, Poa bulbosa P nevadensis, Sporobolus airoides Stipa comata*	1936 (continued)	All species are selected for increased forage production drought resistance, palatability, and a greater capacity for survival and reproduction under moderately heavy grazing	
Virginia					
Arlington (Arlington Experiment Farm, U S Department of Agriculture)	Staff of U S Golf Association, Green Section	*Agrostis canina*	1920 (continued)	Dense turf uniform texture, and resistance to diseases, trampling, and close clipping	Do
		Agrostis palustris	do	do	Do
		Festuca rubra	1931 (continued)	Dense turf uniform texture and resistance to diseases rapid spread, and close clipping	Little
		Poa pratensis	do	Dense turf uniform texture, and resistance to disease, drought and close clipping	Do
		Poa trivialis	do	Dense turf and resistance to diseases and trampling	Medium
Blacksburg	T K Wolfe and N A Pettinger	*Dactylis glomerata*	1920–36	Increased forage value	Much
Washington					
Pullman	A L Hafenrichter and V B Hawk	*Agropyron cristatum A pauciflorum*	1935 (continued)	Increased seed and forage production	Little
Pullman*	D C Smith and G W Fischer	*Agropyron cristatum*	1936 (continued)	Sustained seed yields, increased palatability and resistance to smut	
		Agropyron inerme	do	Leafiness and improved seeding habits	
		Agropyron pauciflorum	do	Resistance to drought and diseases	
		Arrhenatherum elatius	do	Increased palatability and leafiness, improved seeding habits, and smut resistance	
		Bromus inermis	do	Drought resistance and improved seed production	
		Bromus marginatus	do	Smoothness of foliage and smut resistance	
		Dactylis glomerata	do	Drought and cold resistance and improved seed production	
		Elymus canadensis	do	Obtaining awnless and finer stemmed types	
		Festuca elatior	do	Increased palatability and better seeding habits	
		Phalaris arundinacea	do	Drought resistance, winter hardiness and seed production	
Wisconsin					
Madison*	O S Aamodt, F W Tinney, and H L Ahlgren	*Bromus inermis*	1935 (continued)	Increased forage production, resistance to leaf spot, and reduced rhizomes	Medium to much
		Dactylis glomerata	1936 (continued)	Increased forage production with longer vegetative period and drought resistance	

		Poa pratensis	do	Increased forage production resistance to mildew and drought resistance	
Wyoming					
Cheyenne (Cheyenne Horticultural Field Station U S Department of Agriculture)	H M Benedict	*Agropyron cristatum*	do	( )	
		Agropyron pauciflorum	do	Emphasis on longevity	
		Agropyron smithii	do		
		Agropyron spicatum	do		
		Bouteloua curtipendula	do		
		Bouteloua gracilis	do		
		Bromus inermis	do	Reduced rhizome development	
		Bromus marginatus	do		
		Buchloe dactyloides	do		
		Elymus condensatus	do	Emphasis on palatability	
		Stipa comata	do	Reduced awn development	
Hawaii					
Honolulu	C P Wilsie	*Bromus catharticus*	1934 (continued)	Increased forage and seed production and resistance to smut	
		Digitaria milanjiana D pentzii	1935 (continued)	Increased pasturage development of uniform pasture type	
		Pennisetum purpureum	1933 (continued)	Increased forage leafiness and palatability	
		Sorghum vulgare var sudanense	1933 34	Increased forage, leafiness, and resistance to smut	
CANADA					
Alberta					
Edmonton (University of Alberta)	M O Malte and G H Cutler	*Agropyron pauciflorum*	Several years	Improved hay type	Medium
Ontario					
Guelph (Ontario Agricultural College)	O McConkey	*Agropyron cristatum*	7 years	Increased seed production, forage yield, and (a) leafiness	(a) Much
		Agrostis alba	10 years	Increased seed production, disease resistance, pasturage (a) leafiness, and (b) winter hardiness	(a) and (b) Medium
		Bromus inermis	4 years	Increased seed production, disease resistance, pasturage, and (a) leafiness	(a) Medium
		Dactylis glomerata	10 years	Pasture and pasture hay type winter hardiness, and leafiness	Much
		Festuca elatior	10 years	Increased seed production, disease resistance, forage production, (a) leafiness, and (b) winter hardiness	(a) and (b) Much
		Festuca rubra	6 years	Increased seed production, disease resistance, and turf and pasture value	Medium
		Lolium perenne	10 years	Increased seed and forage, disease resistance, and winter hardiness	Medium hardiness
		Phalaris arundinacea	6 years	Increased seed, disease resistance, pasture value leafiness	Medium
		Poa compressa	10 years	Same also winter hardiness	Much
		P pratensis	10 years	do	Medium

[4] The objectives listed for Washington are the ones to be emphasized in each instance In general the objectives for all species are increased seed and forage yields, greater palatability, and resistance to drought, heat, and disease

[5] All species at Cheyenne are being selected for increased early growth, seed production, winter hardiness, palatability, longevity, and drought and disease resistance Additional or special objectives are indicated

TABLE 2.—*Objectives and progress in the selective breeding of grasses as reported by workers in the United States and Canada*—Continued

Location	Individual workers	Genera and species	Period work under way	Objectives	Success attained
CANADA—continued					
Ottawa (Central Experimental Farm).	L. E. Kirk and R. McVicar.	*Agropyron pauciflorum*	1913–29	Increased forage production, uniformity, fineness and abundance of leaves.	Much.
		Dactylis glomerata	1912 (continued)	Winter hardiness	Do.
		Festuca elatior	1918 (continued)	(a) Increased forage production, (b) uniformity in type suitable for hay and pasture.	(a) Little, (b) medium.
		Poa pratensis	1919 (continued)	(a) Increased forage production, (b) mildew resistance, (c) upright habit of growth, and also spreading habit of growth.	(a) Unestimated, (b) much, (c) much.
Quebec:					
Quebec (Macdonald College).	L. S. Klinck, L. A. Waitzinger, G. P. McRostie, A. MacTaggart, and J. N. Bird.	*Dactylis glomerata*	1911–33	Increased hay and aftermath, winter hardiness, and longevity.	Medium.
Saskatchewan	L. E. Kirk and T. M. Stevenson.	*Agropyron cristatum*	1915 (continued)	Increased hay and pasturage	Much.
Saskatoon (Dominion Forage Crops Laboratory).	L. E. Kirk	*Agropyron pauciflorum*	1922–29	Increased hay	Medium.
	T. M. Stevenson and W. J. White.	do	1933 (continued)	Longevity	
	J. Bracken	*Bromus inermis*	?–1921	Increased hay and pasture	Medium.
	L. E. Kirk and T. M. Stevenson.	do	1923 (continued)	Increased hay and pasture, reduced rhizome development, leafiness, and fineness of stem.	Much.

TABLE 3 — *Nature and characteristics of interspecific hybrids previously reported*

Parents of cross and chromosome numbers (2n)	By whom made	Institution	Date of cross	Characteristics of progeny
Dactylis glomerata 28 × *D aschersoniana* 14	Muntzing (20)	Swedish Seed Association Seed Control Laboratory Svalof Sweden	1931 35	The F_1 chromosome number was 21 the male sterile and female partially sterile when backcrossed on the *D glomerata* produced well developed plants that were self fertile more vigorous than the *D glomerata*, and had ± 35 chromosomes
Festuca arundinacea 42 × *F gigantea* 42	Nilsson (22)	Swedish Seed Association Seed Control Laboratory Undrom Sweden	1934	Chromosome number of the F_1 was 42, but F_1 progeny plants differed very much, one having a chromosome number of 84
Do	Jenkin (14)	Welsh Plant Breeding Station Aberystwyth Wales	1930	F_1 sterile pollen not liberated but in many cases the F_1 plants can be used as female parents for backcrossing some more readily than others
F pratensis 14 × *F arundinacea* 42	Nilsson Leissner	Swedish Seed Association		Cross reported successful, but no description of progeny was given
Do	Jenkin (13)[1]	Welsh Plant Breeding Station Aberystwyth Wales	1924 1928	F_1 sterile pollen not liberated but in many cases the F_1 plants can be used as female parents for backcrossing some more readily than others
F pratensis 14 × *F gigantea* 42	do	do	1930	Do
F pratensis 14 × *F rubra* 42	do	do	1922 1928 1930 1931	10 percent of pollinated flowers produced seeds but none of these germinated
F rubra 42 × *F ovina* 14	do	do	1930	F_1 sterile pollination very incomplete but in many cases the F_1 plants can be used as female parents for backcrossing, some more readily than others
Lolium perenne 14 × *L multiflorum* 14	Woodforde (29)	Department of Agriculture Tasmania Australia		The F_2 segregated in a ratio of 3 4 1 for seedling fluorescence a characteristic of *L multiflorum* Italian characters were dominant No genetic linkage between fluorescence and awned glumes
Do -	Jenkin[1]	Welsh Plant Breeding Station Aberystwyth Wales	Various	F_1 fertile provisional conclusion that better results by selecting within either *L perenne* or *L multiflorum* than from the hybrid progeny
L perenne 14 × *L remotum*	do	do	do	F_1 sterile pollen not liberated but in many cases the F_1 plants can be used as female parents for backcrossing, some more readily than others
L perenne 14 × *L rigidum*	Jenkin (14)	do	do	F_1 fertile, but no description of progeny given

[1] Reported in correspondence (Y B Q)

TABLE 3.—*Nature and characteristics of interspecific hybrids previously reported*—Continued

Parents of cross and chromosome numbers (2*n*)	By whom made	Institution	Date of cross	Characteristics of progeny
L perenne 14 × *L temulentum* 14	Jenkin [1]	Welsh Plant Breeding Station Aberystwyth Wales	1922	F_1 sterile pollen not liberated but in many cases the F_1 plants can be used as female parents for backcrossing some more readily than others F_1 of reciprocal cross similar in all essential characters
L temulentum 14 × *L oliaceum* (?)	do	do	1935	Cross reported successful, but characteristics of F_1 unknown
L temulentum 14 × *L remotum* (?)	do	do	1935	Do
Phalaris arundinacea 28 × *P tuberosa* 28	Jenkin (*16*)	do	1930	Chromosome number of F_1, 28, of which 12 are bivalent and 2 univalent The hybrids are very vigorous and easily distinguishable from the parent species
Poa arachnifera ±80 × *P pratensis* 56	E Marion Brown [1]	U S Department of Agriculture and Missouri Agricultural Experiment Station, Columbia Mo	1934 35	About 10 percent of the F_1 hybrids are fertile, progeny of these are productive have more vigorous rhizomes and show greater resistance to heat and drought than *P pratensis*
P pratensis 56 × *P alpina* 32–34	Muntzing [1]	Swedish Seed Association, Svalof Sweden		Cross reported successful, but no description of the progeny given
Sorghum vulgare 20 × *S halepense* 40	Karper and Chisholm (*16*)	Texas Agricultural Experiment Station, College Station, Tex		Chromosome numbers of F_1, 30 an examination of the pollen mother cells of F_1 plant showed univalents bivalents, trivalents, and quadrivalents but none of higher association
S vulgare var *sudanense* 20 × *S halepense* 40	Karper (*2*)		1933	Small percentage of success F_1 partially sterile

[1] Reported in correspondence (Y B Q)

TABLE 4.—*Intergeneric hybrids previously reported*

Parents of cross and somatic chromosome numbers	By whom made	Institution	Date made or reported	Remarks
Aegilops cylindrica 28 × *Agropyron elongatum* 70.	W. J. Sando [1]	U. S. Department of Agriculture, Bureau of Plant Industry, Washington, D. C.	1935	42 flowers pollinated; 3 seeds obtained, all of which produced plants.
Aegilops longissima 14 × *Agropyron elongatum* 70.	do	do	1935	48 flowers pollinated; 18 seeds obtained, none of which grew.
Aegilops speltoides 14 × *Agropyron elongatum* 70.	do	do	1935	106 flowers pollinated; 2 seeds obtained, none of which produced plants.
Aegilops crassa 42 × *Agropyron intermedium* 42.	Verushkin [1]	Central Station of Plant Breeding and Genetics, Saratov, Union of Soviet Socialist Republics.	1935	46 flowers pollinated; 29 seeds obtained, 63 percent pollinations successful.
Aegilops speltoides 14 × *Agropyron intermedium* 42.	do	do	1935	28 flowers pollinated; 8 seeds obtained, 28.5 percent pollinations successful.
Aegilops triaristata 28 or 42 × *Agropyron intermedium* 42.	do	do	1935	6 flowers pollinated; 3 seeds obtained, 50 percent pollinations successful.
Aegilops triuncialis 28 × *Agropyron intermedium* 42.	do	do	1935	12 flowers pollinated; 2 seeds obtained, 16.6 percent pollinations successful.
Aegilops turcomanica 42 × *Agropyron intermedium* 42.	do	do	1936	18 flowers pollinated; 10 seeds obtained, 55.5 percent pollinations successful.
Aegilops variabilis 28 × *Agropyron intermedium* 42.	do	do	1935	22 flowers pollinated; 6 seeds obtained, 27.3 percent pollinations successful.
Festuca arundinacea 42 × *Lolium perenne* 14.	Jenkin (*13*) [1]	Welsh Plant Breeding Station, Aberystwyth, Wales.	1921, 1928–30	429 flowers pollinated; 26.8 percent set seed, but none germinated.
F. pratensis 14 × *L. perenne* 14	do	do	1922, 1928–31	1,513 flowers pollinated; 27 percent set seed; 4.9 percent germinated; 7 plants established F_1 male sterile.
F. rubra 42 or 56 × *L. perenne* 14	do	do	1921, 1922, 1928	181 flowers pollinated; 13 seeds obtained; 7.2 percent set seed, but none germinated.
Lolium perenne 14 × *F. arundinacea* 42	do	do	1921, 1928, 1929, 1931	654 flowers pollinated; 32.9 percent set seeds 39.5 percent germinated; 75 plants established, F_1 sterile.
L. perenne 14 × *F. gigantea* 28	do	do	1921	Successful in obtaining seed, but F_1 sterile.
do	F. Nilsson [1]	Swedish Seed Association, Svalof, Sweden.		Cross reported successful, but no description given.
L. perenne 14 × *F. ovina* 28	Jenkin (*13*) [1]	Welsh Plant Breeding Station, Aberystwyth, Wales.	1930	150 flowers pollinated; 16.7 percent set seed; none of which germinated.
L. perenne 14 × *F. pratensis* 14	do	do	1922, 1928–31	2,046 flowers pollinated; 41.1 percent set seed, germination 0.7 percent; 1 plant established; F_1 sterile.
do	F. Nilsson [1]	Swedish Seed Association, Svalöf, Sweden.		Cross reported successful, but no description given.
L. perenne 14 × *F. rubra* 42	Jenkin (*13*)	Welsh Plant Breeding Station, Aberystwyth, Wales.	1921, 1924, 1928	218 flowers pollinated; 45.4 percent set seed; germination 18.2 percent; 9 plants established; F_1 sterile.

[1] Reported in reply to the Yearbook questionnaire, 1936.

TABLE 4.—*Intergeneric hybrids previously reported*—Continued

Parents of cross and somatic chromosome numbers	By whom made	Institution	Date made or reported	Remarks
L. perenne 14 × *F. rubra* 42	F. Nilsson and G. Nilsson Leissner[1]	Swedish Seed Association, Svalof, Sweden		Cross reported successful but no description given
Triticum dicoccoides 28 × *Agropyron elongatum* 70	W. J. Sando[1]	U. S. Department of Agriculture, Bureau of Plant Industry, Washington, D. C.	1935	96 flowers pollinated, 7 seeds obtained, 4 seeds planted, 2 percent of which produced plants.
T. spelta 42 × *A. elongatum* 70	do	do	1935	54 flowers pollinated, 9 seeds obtained, 7 seeds planted, 6 percent of which produced plants
T. aestivum 42 × *A. elongatum* 70	do	do	1935	2,128 flowers pollinated, 398 seeds obtained, 140 seeds planted, 10.5 percent of which produced plants
T. dicoccum 28 × *A. glaucum* 42	L. E. Kirk and R. McVicar[1]	Central Experimental Farm, Ottawa, Canada	1935	Cross successful. F_1 hybrids male sterile, may be backcrossed on *Triticum* parent
T. durum 28 × *A. glaucum* 42	do	do	1935	Do
T. aestivum 42 × *A. glaucum* 42	do	do	1935	Do
T. dicoccum 28 × *A. elongatum* 70	do	do	1935	Do
T. durum 28 × *A. elongatum* 70	do	do	1935	Do
T. aestivum 42 × *A. elongatum* 70	do	do	1935	Cross successful. F_1 hybrids showed partial fertility
T. durum 28 × *A. elongatum* 70	T. M. Stevenson and W. J. White[1]	Dominion Forage Crops Laboratory, Saskatoon, Saskatchewan, Canada	1935	Cross reported successful but fertility of F_1 not yet determined
T. polonicum 28 × *A. elongatum* 70	do	do	1935	Do
T. aestivum 42 × *A. elongatum* 70	do	do	1935	Do
T. durum 28 × *A. glaucum* 42	do	do	1935	Do
T. polonicum 28 × *A. glaucum* 42	do	do	1935	Do
T. aestivum 42 × *A. glaucum* 42	do	do	1935	Do
T. dicoccum 28 × *A. glaucum* 42	Armstrong (*1*)	Central Experimental Farm, Ottawa, Canada	1935–36	1,196 flowers pollinated, 1,414 seeds obtained, 34.6 percent successful
T. dicoccum 28 × *A. elongatum* no. 820, 70	do	do	1935–36	1,391 flowers pollinated, 538 seeds obtained, 38.7 percent successful
T. dicoccum 28 × *A. elongatum* no. 1083, 70	do	do	1935–36	196 flowers pollinated, 3 seeds obtained, 1.5 percent successful
T. durum 28 × *A. glaucum* 42	do	do	1935–36	1,224 flowers pollinated, 394 seeds obtained, 32.2 percent successful
T. durum 28 × *A. elongatum* no. 820, 70	do	do	1935–36	345 flowers pollinated, 11 seeds obtained, 3.2 percent successful
T. durum 28 × *A. elongatum* no. 1083, 70	do	do	1935–36	164 flowers pollinated, 12 seeds obtained, 7.3 percent successful
T. aestivum 42 × *A. glaucum* 42	do	do	1935–36	1,041 flowers pollinated, 122 seeds obtained, 11.7 percent successful
T. aestivum 42 × *A. elongatum* no. 820, 70	do	do	1935–36	239 flowers pollinated, 25 seeds obtained, 10.5 percent successful
T. aestivum (Kharkov) 42 × *A. elongatum* no. 1083, 70	do	do	1935–36	328 flowers pollinated, 45 seeds obtained, 13.7 percent successful

T durum 28 × *A elongatum* 70	Vakar (34)	Siberian Institute for Scientific Research of Grain Management, Union of Soviet Socialist Republics Omsk		Success with cross, 49 somatic chromosomes in the F_1 hybrid
T aestivum 42 × *A elongatum* 70	do	do		Success with cross, 56 somatic chromosomes in the F_1 hybrid
T aestivum × *A glaucum* 42	do	do		Success with cross 42 somatic chromosomes in the F_1 hybrid
T aestivum 42 × *A intermedium* 42	Verushkin (35)	Central Station of Plant Breeding and Genetics Saratov Union of Soviet Socialist Republics	1935	3 062 flowers pollinated 1 248 seeds obtained, 40 7 percent successful
T sphaerococcum 42 × *A intermedium* 42	do	do	1935	80 flowers pollinated 24 seeds obtained, 30 percent successful
T compactum 42 × *A intermedium* 42	do	do	1935	80 flowers pollinated, 10 seeds obtained 12 5 percent successful
T dicoccoides 28 × *A intermedium* 42	do	do	1935	180 flowers pollinated, 52 seeds obtained 28 8 percent successful
T dicoccum 28 × *A intermedium* 42	do	do	1935	128 flowers pollinated, 39 seeds obtained, 30 5 percent successful
T durum 28 × *A intermedium* 42	do	do	1935	1 207 flowers pollinated 564 seeds obtained, 46 7 percent successful
T polonicum 28 × *A intermedium* 42	do	do	1935	48 flowers pollinated, 21 seeds obtained 43 7 percent successful
T persicum 28 × *A intermedium* 42	do	do	1935	256 flowers pollinated 131 seeds obtained, 51 2 percent successful
T monococcum 14 × *A intermedium* 42	do	do	1935	86 flowers pollinated, 14 seeds obtained, 16 3 percent successful
T aestivum 42 × *A elongatum* 70	do	do	1935	2 136 flowers pollinated 937 seeds obtained, 43 8 percent successful
T sphaerococcum 42 × *A elongatum* 70	do	do	1935	59 flowers pollinated, 31 seeds obtained, 52 5 percent successful
T compactum 42 × *A elongatum* 70	do	do	1935	18 flowers pollinated 3 seeds obtained, 16 6 percent successful
T dicoccoides 28 × *A elongatum* 70	do	do	1935	54 flowers pollinated 22 seeds obtained, 40 7 percent successful
T dicoccum 28 × *A elongatum* 70	do	do	1935	328 flowers pollinated 93 seeds obtained 28 5 percent successful
T durum 28 × *A elongatum* 70	do	do	1935	1 128 flowers pollinated 469 seeds obtained, 41 5 percent successful
T turgidum 28 × *A elongatum* 70	do	do	1935	24 flowers pollinated, 10 seeds obtained, 41 5 percent successful
T persicum 28 × *A elongatum* 70	do	do	1935	70 flowers pollinated 26 seeds obtained, 37 1 percent successful
T monococcum 14 × *A elongatum* 70	do	do	1935	24 flowers pollinated, 0 seeds obtained 0 0 percent successful

[1] Authorities for the botanical names used have been corrected to agree with the International Code and the U. S. Department of Agriculture style. Those names for which no authority was given in the original are indicated by a dagger (†) and the recognized authority for the name has been inserted, but this does not mean that the grasses were correctly identified by the cytologist.

[2] Letters following chromosome numbers denote the number of times this number has been verified by other authors than the one indicated by the reference in the last column. a=1, b=2, c=3, d=4, e=5, f=6, g=7. An asterisk (*) indicates those reported as the "*n*" number, the number here given being double that reported.

[3] Numbers in parentheses refer to References for Chromosome Numbers, p. 1099. Where a number has been verified by several workers, only the first report of that number is cited.

[4] W. N. Myers, personal correspondence.

IMPROVEMENT OF TIMOTHY

MORGAN W. EVANS, Associate Agronomist, Division of Forage Crops and Diseases, Bureau of Plant Industry

TIMOTHY is the common name applied to the species *Phleum pratense* L. About 10 species in the genus *Phleum* are known, timothy being the only one under cultivation. They are all native to northern Europe and Asia with one exception. This one, a native in North America, is *Phleum alpinum* L., alpine timothy—a grass that occurs throughout the mountainous regions in the western United States, and in the East as far south as the White Mountains of New England (*20, p. 122*).[1]

While timothy is of European origin, it was in the United States that it was first brought under cultivation. The early history of the crop in this country is somewhat obscure, but mention of it in colonial days is not uncommon. In New England it was known as herd's grass at least as early as the first part of the eighteenth century—probably earlier. The name "timothy" is said to have been derived from Timothy Hansen, who obtained seed from New England or New York and introduced it into Maryland, and possibly into some of the other southern Colonies, about 1720. Sometime after 1740 an early agriculturalist, Jared Elliott, sent seed from Connecticut, under the name of herd's grass, to Benjamin Franklin. In a letter dated July 16, 1747, Franklin wrote that the grass sent to him "is grown up and proves mere timothy"—indicating that it had become fairly well established as a hay crop in Pennsylvania at that time (*21*). From then on the crop increased in use and importance and has received more attention from agriculturists than any other grass.

In 1909, according to the United States census report, there was a total of 34,228,000 acres of timothy grown alone and in mixture with clover. In 1929 this acreage had decreased to 25,547,000, but it still constituted 37.7 percent of the total acreage used for the production of all kinds of hay in that year. In 1928, the last year in which separate estimates were made by the United States Department of Agriculture of the acreage of timothy alone and in mixture with clover, timothy was grown alone on 8,537,000 acres and with clover on 16,078,000 additional acres.

For feeding horses, of which there are still large numbers, no other hay has been found as generally satisfactory as timothy. The cost of the seed is less than that of most meadow and pasture grasses and it can be sown more readily with the implements used for sowing clover and alfalfa. Although alfalfa produces hay superior to timothy

[1] Italic numbers in parentheses refer to Literature Cited, p. 1116

in yield and in percentage of protein, timothy grows well on many soils on which alfalfa or even clover cannot be produced without a considerable investment for lime or drainage. Timothy is very extensively grown for hay in mixture with clover, and alfalfa can be more readily grown on some soils not naturally suited to it if it is sown in mixture with timothy. As a pasture grass, timothy is more palatable to livestock than many other grasses, including redtop, orchard grass, and Kentucky bluegrass; and the recent increased interest in pastures has created an interest in the possibility of developing varieties of timothy especially adapted for use in pasture mixtures.

HISTORY OF TIMOTHY IMPROVEMENT

Early Efforts to Improve Timothy

According to available information, the first efforts to develop improved strains of timothy were made in the United States. No improved varieties were in existence at the close of the last century, as there were of corn, oats, wheat, and other crops. The appreciation of the wide diversity in timothy plants, which made varietal improvement possible, and the prospect of benefits to the producers of timothy hay, both for market and for use on the farm, if varieties were available that would produce larger yields of better quality than ordinary timothy, created incentives for the breeding programs that were undertaken at this time by several experiment stations and other agricultural organizations.

Figure 1.—Willet M. Hays, the earliest breeder of timothy.

Willet M. Hays, professor of agriculture at the University of Minnesota (fig. 1), made in 1889 a number of selections of timothy plants. He had observed the wide variation in plants of ordinary timothy and thought that by selecting the best from among them it would be possible to develop varieties, suited for growing in mixture with clover, that would prolong the season when timothy could be harvested in condition to make a high grade of hay, and also varieties capable of producing larger yields (*13*). No records have been found of any earlier attempt to improve timothy in this way, although Sinclair recorded the development of varieties of perennial ryegrass, through selection, more than a century ago (*23, pp. 212–213*). Hays discontinued his own work with timothy, but afterward, as the first secretary of the American Breeders' Association and as Assistant

Secretary of the United States Department of Agriculture, he took an active interest in the improvement of this crop.

In 1894, a few years after Hays made his first selections, A. D. Hopkins (fig. 2), then entomologist at the West Virginia Agricultural Experiment Station, selected a number of timothy plants at his farm at Kanawha Station, W. Va. (*14, 15, 16*). He continued this work for several years, making new selections and conducting tests of them, for the purpose of eventually producing varieties with better quality and higher yielding capacity than the single unimproved strain then available. In 1899 he distributed plants of some of his selections to the Department of Agriculture and to a number of State agricultural experiment stations. In 1902 he became forest entomologist and chief of the Division of Forest Insects, Bureau of Entomology, Department of Agriculture, but continued his work with timothy on his farms in West Virginia. About 1907 or 1908 he transferred additional selections he had made to the Division of Forage Crops of the Department.

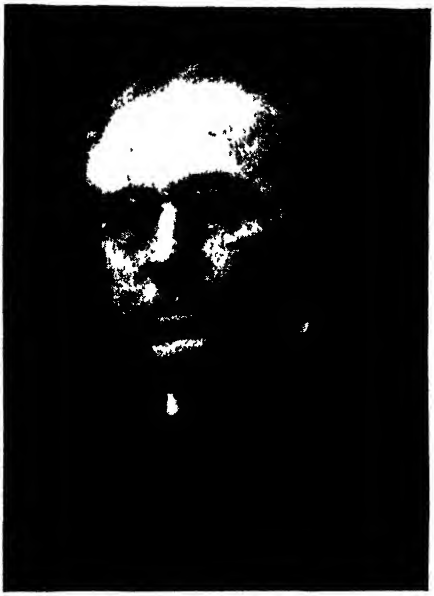

Figure 2.—**A. D. Hopkins, who developed the first varieties of timothy of which plants and seed were distributed.**

Hopkins increased the stock of seed of three of his selections and introduced them as new varieties. Seed was distributed by him and by the Department to a number of farmers and experiment stations. One of these varieties, Hopkins Early, headed and bloomed at somewhat more nearly the same time as medium red clover than ordinary timothy and thus was better for growing in mixture with this clover. Stewart Mammoth, derived from a vigorous, long-stemmed plant, was slightly later and was thought capable of producing somewhat larger yields than ordinary timothy. The third variety, Pasture timothy, did not differ greatly in habit of stem growth from the ordinary strain used for hay, but its leaves tended to remain green late, and, as its name suggests, it was thought well suited for pastures.

Timothy Improvement by State Experiment Stations

One of the cooperators to whom A. D. Hopkins distributed plants or seed was T. F. Hunt, of the Ohio State University. When Hunt went to the College of Agriculture at Cornell University, Ithaca, N. Y., in 1903, he immediately began a timothy-breeding program. His objective was the development of varieties that would give a larger yield of superior-quality hay, and he also wished to study some of the fundamental principles upon which a timothy-breeding program should

be based. Seed was obtained from a large number of sources in the United States and from foreign countries. Plants were grown in row test plots, and from them many variants were obtained as the basis for further selections. When Hunt went from Cornell University to the University of California, the timothy-breeding investigations were continued by H. J. Webber and his associates. At the present time, the timothy-breeding work at Cornell is under the direction of C. H. Myers. A number of technical studies of timothy, the variations occurring in it, and methods of improving it have been described in different published articles. Two varieties have been developed at Cornell, and efforts are now being made to have seed of them introduced commercially. One is somewhat earlier than ordinary timothy; the other is later and produces relatively large yields; both tend to be rust-resistant.

During the period from 1911 to 1924 the Iowa Agricultural Experiment Station tested about 300 timothy selections. Seed of the most outstanding one of these was increased and distributed to Iowa farmers, but the strain was finally lost. In Minnesota the early work started by Hays in 1889 was later discontinued, but in 1916 work was again resumed by others. Early work in timothy improvement was also conducted at the Pennsylvania station, starting in 1908, but was discontinued in 1931. Other stations that have more recently carried on work in timothy improvement are those of Kentucky, New Jersey, and Wisconsin.

Timothy Improvement
by the United States Department of Agriculture

The earliest timothy-breeding work conducted by the United States Department of Agriculture was undertaken in 1899 by F. Lamson-Scribner, Chief, and Thomas A. Williams, Assistant Chief, of the old Division of Agrostology, with tests of some of the selections received from A. D. Hopkins, then at the West Virginia Agricultural Experiment Station. When the Office of Forage Crops—now the Division of Forage Crops and Diseases—of the Bureau of Plant Industry was organized in 1903, C. V. Piper, who was in charge, became interested in timothy improvement. From that time until 1909 a number of new selections of leafy, vigorous timothy plants were made. Tests were conducted at the Arlington Experiment Farm, Arlington, Va., of the new selections in comparison with some of Hopkins' selections, and also in comparison with selections obtained from the New York (Cornell) Experiment Station. The timothy-improvement program, however, did not receive a very great amount of attention until a decade later when the Timothy Breeding Station was established in cooperation with the Ohio Agricultural Experiment Station. This work was conducted first at New London, Ohio. It continued from 1909 to 1915, when the station was reestablished on a larger area of land at North Ridgeville, Ohio. Here the work was conducted until 1935, when it was transferred to the Ohio Agricultural Experiment Station at Wooster. The outstanding varieties developed in this work are Huron and Marietta, described later under the heading Improved Varieties.

Timothy Improvement in Foreign Countries

. Since the breeding of timothy was first undertaken in the United States, similar work has been conducted in Canada and in several countries in Europe.

Some of the earliest European work was done at the Plant Breeding Institute at Svalöf, Sweden. Several varieties have been developed there, some of which are adapted to different regions, as southern Sweden, middle Sweden, and northern Sweden, where winter hardiness is an essential characteristic.

Timothy-breeding investigations were undertaken at the Welsh Plant Breeding Institute at Aberystwyth, Wales, somewhat later than at Svalöf, and have been conducted on an extensive scale. Varieties suitable for hay production in Great Britain have been developed from native timothy plants. Other varieties, characterized by relatively small low-growing plants with procumbent stems that tend to become rooted at the nodes, have been found of value in pastures in Great Britain especially when grown in mixture with white clover. A third type of timothy, midway between the typical hay-producing type and the extreme pasture type, classified as "hay-pasture" timothy, also has been developed. The methods used in timothy breeding at Aberystwyth have been described by Jenkins (*17*).

Timothy-breeding investigations are also being conducted at agricultural experiment stations in Scotland, Belgium, Denmark, Germany, the Union of Soviet Socialist Republics, and possibly elsewhere.

OBJECTIVES IN TIMOTHY BREEDING

It is comparatively easy to develop, within a few generations, a strain of timothy in which some single character, such as earliness or lateness, long stems, freedom from rust, or tendency to produce large yields, is reproduced fairly well in the plants grown from seed. To produce a variety in which all of the desirable characteristics are combined is a much more difficult task. Furthermore, a certain variety of timothy may be adapted only to a more or less restricted area. For instance, in northern Sweden the Bottnia variety is valuable because it is very winter-hardy, but in northern Ohio it apparently has no practical value because it produces smaller yields of hay than other varieties that are sufficiently hardy in this latitude. Some of the late varieties that have produced relatively large yields of high-quality hay in northern Ohio are of no value in Kentucky or farther south. It is therefore necessary to have varieties for certain regions as well as for different uses, and this must be recognized in any well-formulated breeding program.

The most common disease of timothy is rust. Although plants in meadows are not often entirely destroyed by it, yet the growth of those that are badly attacked is checked, and the leaves dry up prematurely. Some plants are more susceptible than others. Selection for rust-resistant strains has been one of the objectives of most breeders of timothy. When plants relatively free from rust have been selected, it has been found that their progeny tend to be rust-resistant. In an investigation conducted at MacDonald College, Quebec, Canada, Bird (*2*) found that, generally speaking, the majority of improved

strains of timothy tested showed marked resistance to rust. Although strains differed greatly in their reaction to the disease, the reaction of individual plants within strains also varied greatly. No strains were found entirely free from the disease. Strains from Scandinavia were generally highly susceptible to rust, yet Gloria and Øtofte, two improved varieties, were outstanding in their resistance.

Some of the earliest public discussions of the possibility of producing improved varieties of timothy, as of other farm crops, took place at the meetings of the Society for the Promotion of Agricultural Science, attended by many of the leading agricultural scientists of the last decade of the past century and of the first decade of the present one. A great deal of interest was aroused by Hopkins' papers on the improvement of timothy. He described many variations, such as early plants in condition to cut for hay about the same time as red clover and late plants producing hay that would retain green leaves and high quality for a longer time than ordinary timothy, and showed the possibilities for developing distinct varieties. Here, it seemed, was a new field of opportunity for service to agriculture. At the meeting at Columbus, Ohio, in 1899, Hopkins said that because of the pressure of official duties he thought he would have to give up his work with timothy. W. J. Beal, of the Michigan Agricultural College, one of the leading American botanists of that time, and also others protested that Hopkins should rather give up his work with insects in order that he might be able to devote all of his time to the improvement of timothy.

Present Search for Leafy Pasture Varieties

The present interest in improved pasture grasses has developed within the last 10 years.

As already noted, pasture varieties of timothy already have been developed and introduced in farm practice by some of the European agricultural experiment stations or plant-breeding institutes. When sown in fields to be used as permanent pastures, these varieties continue to form a better and more persistent turf than ordinary timothy.

At the New York Agricultural Experiment Station (Cornell), excellent results have been obtained with Aberystwyth Pasture timothy S. 50 when grown in association with wild white clover under conditions of close grazing.

In general, these low-growing European types of timothy produce very little seed in the latitude of Ohio; for normal development they require the longer days in spring and summer that occur farther north. If they are used, it may be necessary to have the seed produced relatively far north, either in North America or in Europe, and to import it into localities where it is to be sown in pastures.

Long before any of the special pasture varieties of timothy were introduced, ordinary unimproved American timothy had been used for pasturage. Farmers in the United States very commonly turn their farm stock into meadows during late summer or fall, after the first hay crop has been removed. It is also a common practice to utilize timothy meadows from which hay crops have been harvested as all-season pastures for 1 or more years before plowing for some other crop.

It is not unlikely that some of the improved varieties of timothy, selected primarily for their usefulness in meadows, may also be superior to ordinary timothy for use in pastures.

Variations a Basis for Improvement

Ordinary American timothy plants vary within quite wide limits in season of maturity, length and degree of fineness of stems, breadth of leaves, degree of susceptibility to rust, tendency for the leaves to remain green as the seeds approach maturity, and in other ways. These numerous variations and the different ways in which they are

Figure 3.—A timothy plant of the pasture type grown from seed from northern Europe.

combined in different plants result in a very wide range of variants from which selections may be made.

In Europe, as in the United States, wide variation in timothy plants is common and some of these variants offer special opportunity to the breeder. A form occurs in extreme northern Europe that is entirely distinct from any found in the United States. Plants of this form grown in the latitude of northern Ohio are characterized by short stems, which usually grow more or less procumbent upon the surface of the soil (fig. 3) instead of upright like the stems of ordinary American timothy (fig. 4). Relatively few of the stems have heads, the florets bloom late, and the seed frequently does not form or fails to mature. Some of the more extreme plants of this northern European form produce no heads when they are grown as far south as northern Ohio.

Methods of Developing New Varieties

Timothy is generally cross-pollinated. Experiments have demonstrated, however, that when pollen from the same plant is used to fertilize the florets, usually a small percentage of them produce seed.

Cross-pollination results in the occurrence of many natural hybrids between plants of diverse types. This provides a wealth of forms from which selections may be made, but makes the maintaining of a new variety more difficult.

The method used in the timothy-improvement work conducted by the Department in cooperation with the Ohio Agricultural Experiment Station is as follows:

Seed from single-plant selections is sown in a seedbed or in a small broadcast plot. The growth of the plant of different selections is observed and compared in these plots, and plants are taken from them and transplanted to cultivated row plots where each individual plant has ample space for development. Later, from the row plot of each strain, one or more new selections are made of the plants most outstanding for the desired qualities. When, as a result of repeated observations and tests, a selection of sufficient merit is finally developed, the supply of seed is increased, and it is introduced under an appropriate name as a new variety.

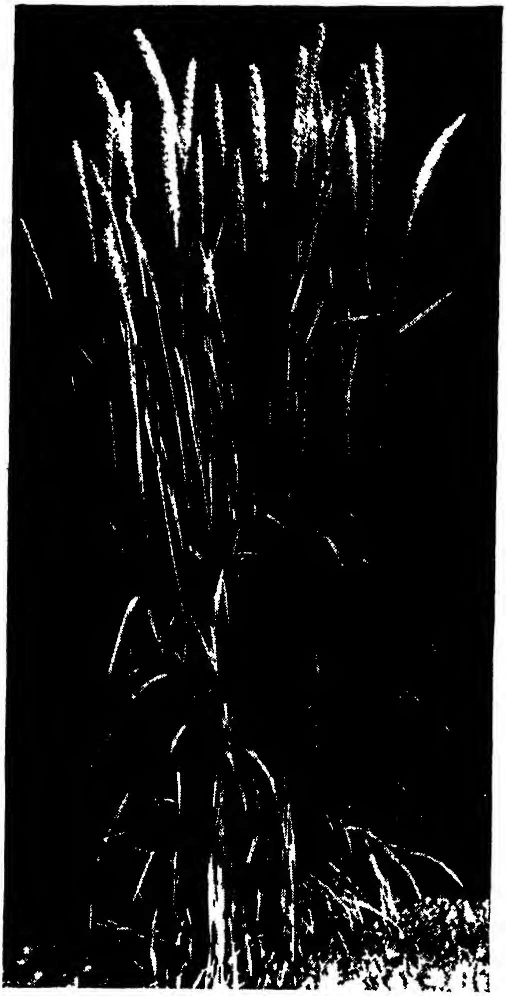

Figure 4.—A timothy plant having the relatively long, upright stems characteristic of the American forms.

Since no provision is made during the early stages of selection to prevent the florets of the plant or plants of one selection from becoming fertilized with the pollen produced by plants of other strains, the method is known as that of selection with open pollination. Experiments conducted over a number of years have shown, however, that when selection for some particular quality or character is continued through several generations plants may be developed that reproduce themselves through seed fairly true for this character (*6*).

At some other experiment stations or plant-breeding institutions the seed of selected plants has been produced from self-fertilized florets, that is, florets fertilized with pollen from the same plant. In this way it is possible to develop selections or varieties in which the plants conform to a certain type more closely than if they grew from seed produced under open pollination. In some strains of timothy

this uniformity is attained only at the cost of much loss in vigor. Our general knowledge of the science of plant breeding indicates that this deterioration may be overcome later by artificially cross-pollinating two established uniform strains and producing a hybrid in which some of the most desirable characteristics of both parents are combined.

At other places where timothy breeding is being conducted both open-pollination and self-pollination are used, one method sometimes alternating with the other from generation to generation.

When a variety of timothy is finally established and its seed is being increased and produced on a larger scale, it is essential that indiscriminate cross-pollination with ordinary timothy or other varieties be avoided, or else the peculiar characteristics by which the variety is distinguished are likely to disappear.

Improved Varieties

Though no improved timothy varieties were available at the close of the past century, at the present time there are a number that are as distinct from one another as varieties of corn, oats, or wheat.

Among those available commercially in the United States are Shelby, Huron, and the recently developed Welsh pasture strain, of which very limited quantities of seed have been imported from Great Britain within the last 2 or 3 years.

In other countries, additional varieties, mentioned in table 1 in the appendix, have been introduced.

The Shelby, an early-maturing variety grown in southern Indiana for many years, apparently is the result of regional selection. William Zoebel, of Shelbyville, Ind., producer of the variety, grew his own timothy seed from about 1855 until the time of his death in 1892, and his two sons continued the practice. Most of the Shelby timothy grown on other farms in the vicinity can be traced to the Zoebel farm. The relative time of maturity of this timothy when William Zoebel began growing it is not known. The information available, however, indicates that the characteristic of earliness developed gradually by natural selection. Zoebel harvested his timothy for hay when the earliest heads were mature. Some of the seeds from the ripe heads shattered in the mow, or where the hay was thrown down to the floor below. The mixed chaff and seed was swept up and the seed was separated with the fanning mill. This process, which was repeated year after year and continued at least up to 1930, supplies an explanation of the origin of the variety that is satisfactory and may be assumed to be correct. Little or none of the seed is shipped away from the vicinity. Many farmers of the district who do not produce their own seed purchase seed of Shelby timothy if it is available. If it is not they get seed of ordinary timothy from somewhere else. Thus the early variety and ordinary timothy have been grown on different farms in the same locality, but Shelby timothy has retained the characteristic of earliness.

The Huron is a late-maturing variety developed in Ohio. Plants grown from the seed of Huron timothy are shown in figure 5 (*5*).

In 1911 the plant from which this variety originated was found growing along a road near Wakeman, in north-central Ohio. It was transplanted to the timothy breeding station at North Ridgeville where it was grown in experimental tests. Seed was later distributed to agricultural experiment stations in other States. In the Pacific Northwest, in nearly all trials, the yields have been larger, the plants have remained in condition to make a good quality of hay later in the

Figure 5.—The six plants at the right, grown from seed produced by the original plant of Huron timothy, are more uniform and are more vigorous and larger than the six plants of ordinary timothy at the left.

season, and they have continued to grow for a longer time in pasture mixtures than ordinary timothy. The Huron is now most extensively grown in northeastern California and western Oregon, though it has been found well-adapted to unirrigated land in northwestern California and western Washington, as well as to the irrigated and moister valleys of eastern Oregon, eastern Washington, and northern Idaho. The use of the variety, especially in pastures in mixture with other grasses and clovers, has been gradually expanding. It was estimated at the Oregon Agricultural Experiment Station early in 1936 that, in addition to its being used on several hundred acres seeded to this variety alone, it has probably been sown in pasture mixtures on at least 8,000 to 10,000 acres.

Another selection developed at the timothy breeding station, North Ridgeville, Ohio, is about to be introduced under the varietal name Marietta. In northern Ohio it is 4 or 5 days earlier and in southern Ohio about a week earlier than ordinary timothy. Tests have demonstrated that it yields more than ordinary timothy, especially in the latitude of southern Ohio. It arrives at a stage of development suitable for cutting for hay at more nearly the same time as medium red clover or alfalfa than does ordinary timothy. The Ohio Seed Improvement Association is planning to assist in the introduction of Marietta timothy into farm practice in those parts of the State to which it is well adapted.

Since the primary objective in most timothy-breeding programs is increased hay production, most of the improved varieties developed

to date are primarily hay varieties. Some of them, like that shown in figure 6, *A*, are earlier than ordinary timothy. One of the characteristics of an early timothy is that it is capable of producing elongated stems with heads, and the florets bloom and seeds form on them under shorter days than are required for late varieties, such as the one in figure 6, *B*. For this reason, early varieties can produce a hay crop in the South, where the days during spring and summer

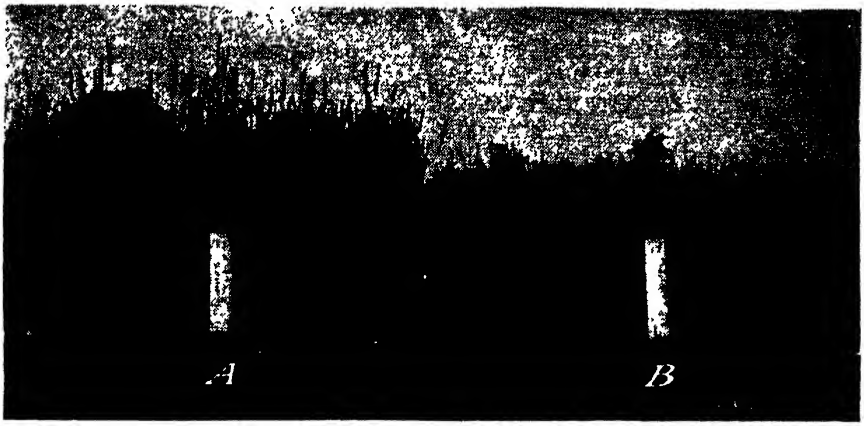

Figure 6.—*A*, A plot of early timothy, full-headed and beginning to bloom; *B*, a plot of late timothy, with stems grown to only a part of their full length. Photographed at North Ridgeville, Ohio, June 20, 1933.

are too short for the proper development of late varieties. Trials in southern Ohio and at the Kentucky Agricultural Experiment Station have demonstrated the correctness of the theory that near the southern border of the timothy-producing area in the United States early varieties produce materially larger yields of hay than late varieties.

Distribution of Improved Varieties

In Sweden certain organizations formed for the purpose of introducing the seed of new and improved varieties of all kinds of farm crops have been instrumental in having some of the new varieties of timothy grown. No organized effort of this kind has yet been made on a large scale in the United States.

At Cornell University and in Ohio seed has been distributed to farmers who expect to harvest a seed crop. The same method is used in Ontario, Canada. In Quebec the seed is sent to the Provincial seed farm and from there to Provincial seed centers. In Great Britain improved strains are now being grown on a commercial scale by seedsmen. In Sweden all seed is sold and distributed by the Svalöf Seed Co., which has a monopoly on all varieties produced by the Swedish Seed Association.

The increased cost of seed must always be taken into consideration in the establishment of new crop varieties. The seed of improved varieties of timothy necessarily sells at a somewhat higher price than that of ordinary unimproved timothy. This is because the seed

grower must use extra care not to have any ordinary timothy plants growing in mixture where seed of the improved variety is being produced. Further, if the seed is certified, the cost of inspecting the meadow must be added. However, the total quantity of timothy seed required for establishing 1 acre of meadow is so small that the slight additional cost for the improved seed should be no objection if the varieties are distinctly superior.

Since relatively long days are required for their development (*7*), it appears probable that the usefulness of late varieties of timothy will be restricted to latitudes no farther south than the northern part of Ohio (*8*). When grown under suitable conditions, it has been found that the better late varieties produce somewhat more hay than ordinary timothy, though usually these increases in yield per acre do not exceed a few hundred pounds. The leaves on the best late selections remain green for a longer time than those of ordinary timothy, and consequently the protein content and quality of the hay remain at a relatively high level for a longer time. On farms in the northern part of the United States, where relatively large acreages of clear timothy hay are harvested and where there is difficulty, because of unfavorable weather conditions or the pressure of other farm work, in harvesting ordinary timothy early enough to produce hay of a high quality, late varieties would have certain advantages.

Timothy is now being grown in mixture with alfalfa in an increasing area each year (*1*). This mixture should be harvested early, before ordinary timothy has begun to bloom. It is apparent, therefore, that an early variety of timothy, that would be in bloom when the crop should be harvested, is most suitable for such a mixture and should be supplied by the timothy breeder.

No varieties of timothy that are primarily pasture types have yet been produced in the United States. The Welsh pasture variety, seed of which is now available to a limited extent, is characterized by its short, low-growing stems, and it would produce much smaller yields of hay than any of the hay types. There has been so little experience in this country with the European pasture varieties, even experimentally, that it is not yet clear just how useful they may be.

As indicated in the preceding paragraphs, the principal objectives in the improvement of timothy are the development of rust-resistant varieties; early varieties suited to the southern part of the timothy-growing area; late varieties for the North, for use where timothy meadows are maintained for 2 or more years; varieties adapted for hay production when grown in mixture with clover or alfalfa, and varieties for use in pastures

TECHNICAL RESEARCH [2]

When T. F. Hunt began the timothy-breeding investigations at Cornell University in 1903, seed was procured not only from many different places in the United States and Europe but also from other countries. The plants grown from these lots of seed revealed the

[2] This section is written primarily for students and others professionally interested in breeding or genetics.

existence of a very wide range of types (*26*). Some of the strains at Cornell were used by Clark (*3*) in a technical study of variation and correlation in timothy. Smith and Myers (*24*) have recently published the results of a biometrical analysis of yield trials.

Investigations at MacDonald College on the rust resistance of improved strains have been previously referred to.

Gregor and Sansome (*10*) found that the low-growing forms of timothy plants with more or less procumbent stems, which occur in Great Britain, have 14 chromosomes ($2n$), whereas the plants with longer, more nearly upright stems have 42 chromosomes ($6n$). Plants of the latter type, which occur both in Europe and in North America, were designated by these authors as the "American" and the low-growing forms as "British Wild" type. Gregor at first found these two types are intersterile (*9*), but according to a recent report (*18*) they later were able to produce artificial F_1 hybrids between them.

Sethi, in a study conducted in India of *Phleum*, *Phalaris*, and *Festuca*, found seven as the basic chromosome number in each genus (*22*). In *Phleum*, while different morphological types interbreed quite readily provided they have the same number of chromosomes, diploid and hexaploid types can be crossed only with great difficulty.

At the Plant Breeding Station at Svalöf, Sweden, Muentzing (*19*) observed and studied spontaneous hybrids between *Phleum pratense* and *P. alpinum* ($4n$). Some of these hybrids were approximately pentaploid.

The extent to which timothy florets produce seeds under conditions of self-pollination has been studied by Witte (*27*), Valle (*25*), and other European investigators. In general, it has been found that when they are self-pollinated the average percentage of florets producing seeds is very much less than under natural conditions that permit cross-pollination.

A series of genetic studies of timothy has been conducted at the Minnesota Agricultural Experiment Station. Hayes and Barker (*11*) found that there is a considerable amount of variation in the extent to which timothy may be self-pollinated. Some plants are highly self-sterile, others are highly self-fertile. Clarke found that although a few of the selfed lines were markedly reduced in vigor the majority compared favorably in yielding ability with the open-pollinated commercial strains (*4*). He observed that when timothy seeds are produced by self-fertilized florets for a few consecutive generations the plants grown from these seeds are more uniform than plants grown from seed from open-pollinated florets.

Hayes and Clarke, in an investigation conducted at the Minnesota Experiment Station (*12*), found that selection in self-fertilized lines is a logical means of freeing the lines of undesirable recessive characters and of obtaining vigorous lines that excel in such important characters as yielding ability and disease resistance. On the other hand, it has also been found elsewhere (*6*) that when selection for any particular type is continued, even under natural conditions favorable for open pollination, the plants of many strains representing several generations of selection show a high degree of uniformity.

ALFALFA IMPROVEMENT

H. M. TYSDAL, Associate Agronomist,
H. L. WESTOVER, Senior Agronomist,
Division of Forage Crops and Diseases,
Bureau of Plant Industry [1]

ALFALFA means "best fodder" in Arabic, the language from which the crop received its name. Botanically it is known as *Medicago sativa* L. In England and most other European countries it is called lucerne, perhaps after Lake Lucerne and Lucerne Canton, in Switzerland, where alfalfa was grown at an early date, though some believe the name was derived from the Spanish or the French.

Alfalfa is a member of that large and important group of plants called the legume or pea family, characterized by ability to provide a home for useful bacteria that take nitrogen from the air and store it in a form available to plants, thereby enriching the soil. The home for nitrifying bacteria is on the roots in what are known as nodules, which look like small detachable lumps or knots. The soil-improving value of legumes, combined with their forage values, makes them one of the great economic plant families.

In 1929 alfalfa hay was produced on approximately 35 million acres throughout the world, according to Klinkowski (*19*).[2] In addition, a proportionately large acreage was devoted to alfalfa-seed production in those regions where climatic and soil conditions are conducive to seed

[1] The authors gratefully acknowledge the assistance of N. I. Petersen, who prepared the key on the common species of *Medicago*.

[2] Italic numbers in parentheses refer to Literature Cited, p. 1147.

THE ***most serious threat to alfalfa growing in the United States is the insidious disease, bacterial wilt, which kills stands of susceptible alfalfa in 2 to 4 years. In the large area where this disease is present—and it is spreading to other areas—it annually destroys hundreds of thousands of acres of alfalfa, with aggregate losses equivalent to those that would be experienced by farmers as a result of flood, drought, or any other major disaster. If varieties or strains could be developed that were sufficiently resistant to maintain stands even 2 years longer, these farmers would be saved many millions of dollars. This is one of the problems on which alfalfa breeders are now working, and promising progress has been made.***

setting and maturity. Argentina reported 14 million acres of alfalfa hay in 1929, the United States nearly 12 million acres (fig. 1), and France 3 million acres. Other countries reported smaller acreages, but the crop was widely distributed. Since 1929 the aggregate acreage of alfalfa is believed to have extended, but there are no available figures to support this belief.

There are many types of alfalfa, and they display wide differences in their adaptation to environmental changes from the Mexican to the

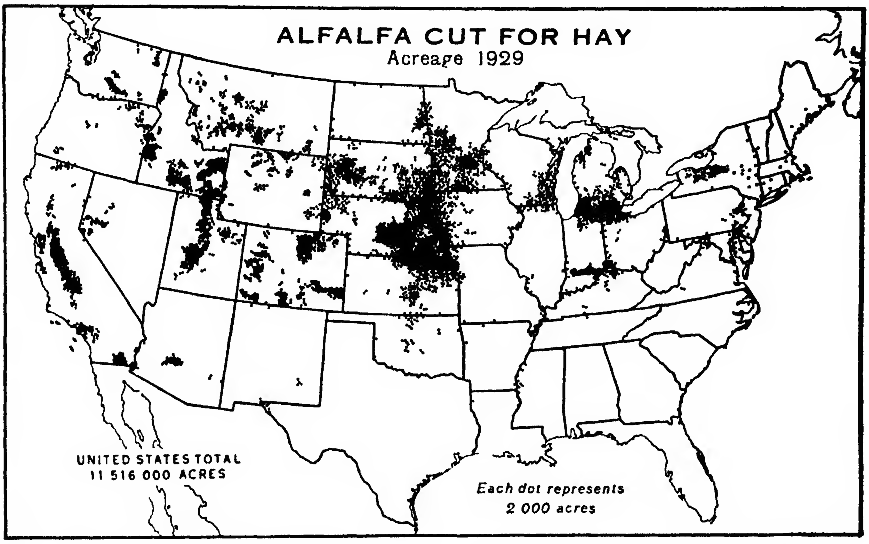

Figure 1.—Distribution of alfalfa production in the United States in 1929. Approximately 11,500,000 acres were cut for hay in that year.

Canadian borders and from the arid West to the humid East. They differ not only with respect to soil and climate, but also with respect to their resistance to disease and insect injury.

These differences, long recognized by alfalfa growers and research workers, are now being utilized by plant breeders as the basis of improvement of the crop, and the results of breeding work to date indicate that superior strains can be developed that will make possible an even greater use of alfalfa on the farms of America.

EARLY HISTORY

The best authorities agree that the original home of alfalfa was in southwestern Asia, from Mesopotamia northward across Persia and Turkistan to Siberia. De Candolle (*4*) states that it has been found wild, with every appearance of being an indigenous plant, in several provinces of Anatolia, to the south of the Caucasus, in several parts of Persia, in Afghanistan, in Baluchistan, and in Kashmir. More recently, Department of Agriculture explorers have found many so-called "wild alfalfas" in the region of Turkistan, so there can be no doubt that alfalfa got its start in this general region.

Alfalfa was probably planted in this region by half-civilized man ages before any history was written. The earliest records indicate that by that time man had discovered the superior feeding value and soil-building properties of alfalfa. One of the earliest Roman agricultural writers, Columella, stated in De Re Rustica, written about 56 A. D., that all emaciated cattle whatsoever grow fat on it and that it fertilizes the land.

Alfalfa was thus developed in dry regions and was usually found in river valleys with soils rich in lime and of alkaline reaction. Wing (*32*) has suggested that the grass eaten by Nebuchadnezzar when he was driven into the fields was none other than alfalfa growing in the fertile valley of the Euphrates River near Babylon. The earliest records alluding to alfalfa were discovered in Babylonian text written in 700 B. C. In this reference alfalfa is listed under its Persian name, aspasti, by the gardener of the Babylonian King, Mardukbalidin, which shows that alfalfa was known in the palace grounds of that day.

From this point on the story of alfalfa becomes history. Pliny and Strabo, both early Roman writers, record that when the Medes and Persians invaded Greece in 490 B. C , they introduced alfalfa into that country for the sustenance of their chariot horses, camels, and domestic animals. The plant was named medic, to denote its Median origin, and it has retained this root in the present botanical name, *Medicago*. This is believed to be the first introduction of alfalfa into Europe. From there it spread to Italy and during the next centuries to other European countries, including Spain. Thus the queen of forage plants, as it has been called, followed the path of historic civilizations and conquering armies from East to West.

Introduction into the Americas

The first introduction of alfalfa into the Americas was through the Spanish explorers. When Cortez and Pizarro had completed their conquest, the natives had alfalfa in lieu of their gold. This was at the beginning of the sixteenth century, and alfalfa soon became distributed over Peru and Chile. It is probable, though not certain, that some of the Catholic missionaries brought alfalfa from Mexico into southern California, New Mexico, and Arizona. Be that as it may, there was no decided spread of alfalfa growing in North America at this time.

The English, French, and Germans introduced alfalfa into the colonies of the Atlantic seaboard under the name of lucerne. There was some success in growing it in Virginia, North Carolina, Pennsylvania, and New York, but there were also some disappointments, due, no doubt, to a general lack of well-drained limestone soils and also to lack of knowledge of the necessity of inoculating for nitrogen-gathering bacteria, which, when present, grow on the roots of legumes. General Washington tried alfalfa at Mount Vernon with enough success to warrant planting a field of it in 1794. Thomas Jefferson, according to Spurrier, took considerable pride in his lucerne field, which was in production prior to 1793.

To trace the further introduction of alfalfa into the United States, it is necessary to return to the west coast, where in the gold rush days of the 1850's many prospectors came via the all-water route around the Horn to California. Some of them stopped at Chilean ports en

route, and, curious as to how this new plant would grow in the new country, took some seed with them. One of the first growers of alfalfa in California, according to the account related by E. J. Wickson to Wing, was W. A. Cameron, of Marysville, in the Sacramento Valley. He produced alfalfa in 1851, and his seed came from Chile.

From the beginning alfalfa produced remarkably good crops in the fertile irrigated valleys of California, and it is not strange that its gradual spread was across the oountry from the West rather than from the East, because, although it had been grown continuously in New York for over a century, it received its main impetus from the success it had attained in the West. From California it was soon taken to Utah, where the Mormons found it extremely satisfactory. It was then introduced into Colorado, Kansas, and Nebraska. According to the 1916 report of the Kansas State Board of Agriculture (*8, p. 11*), one of the first successful growers of alfalfa in Kansas was Charles J. Grosse, of Marion, who received his seed in 1868 from the Trumble Seed House on Sansom Street, San Francisco, Calif. In the 1890's alfalfa had become an important crop in Kansas and spread into Nebraska, where it was also successful. By 1900 it had crossed the Missouri River and become important on the well-drained and alluvial soils of Iowa and Missouri. Then it spread across the Mississippi into Illinois. Wing had previously carried the crop from a ranch in eastern Utah to Champaign County, Ohio, where he established one of the first really successful alfalfa projects in the State.

Considering the historical background of alfalfa production in this country, it is probably safe to assume that the so-called Common alfalfa now being extensively grown originated from the early introductions of Chilean alfalfa. It is also evident that through the years the crop has been remarkably changed by natural regional selection. As indicated by Westover (*30*), strains developed that have the ability to become relatively dormant in the fall and resist cold, as is the case with Northern Common. Other strains, such as the Common alfalfa found in the South, grow rapidly late in the fall; in other words, they do not respond so greatly to the shortening day length. Hybridization no doubt has also been a factor in this adaptation, but segregation by survival has been predominant.

Grimm Alfalfa

At about the time alfalfa was being introduced into California, another circumstance was paving the way for the growing of alfalfa in northern climates. In 1857 Wendelin Grimm brought his family from the Grand Duchy of Baden, Germany, to Carver County, Minn. (figs. 2 and 3). In the spring of 1858 he sowed 15 or 20 pounds of alfalfa seed brought from his native land. This proved to be the origin of what was later called Grimm alfalfa—the first alfalfa grown in this country that had sufficient hardiness to withstand the cold winters of the North. Many attempts had been made to grow the nonhardy alfalfas in Northern States, but this invariably resulted in winter-killing. The advent of Grimm alfalfa greatly increased the acreage importance of the crop.

There can be no doubt that the wide distribution of Grimm today is due to the comparative testing of experiment stations, where its

superiority was proved and given publicity. This alfalfa was grown in practical obscurity for almost 50 years before it came to the attention of experiment station officials, after which it was soon widely known. It would be hard to find a better example of the leadership afforded by experiment stations in agricultural work.

The discovery--and it can well be called a discovery, because very little was known regarding the adaptation of alfalfa in this early period—that certain strains were not adapted to certain regions while others thrived there, was an important one. No longer could a prospective grower just ask for alfalfa seed—he had to be sure of the kind of alfalfa seed he was getting. Some confusion thus arose because it was impossible to tell one variety from another by the seed, but fortunately this difficulty has been overcome by certification and verification services made available by State and Federal institutions.

Figure 2. Mr. and Mrs. Wendelin Grimm, of Chaska, Carver County, Minn. In 1858 Mr. Grimm planted 15 or 20 pounds of alfalfa seed he brought with him from Germany the previous year. This was the beginning of the present widely grown and popular Grimm alfalfa variety. (Courtesy of A. C. Arny, Minnesota Agricultural Experiment Station.)

Early Breeding Work

Without doubt, natural selection in alfalfa, helped here and there by the willing hand of man, has taken place for many generations. This is evident from a comparison of our vigorous-growing, sturdy cultivated alfalfas with the prostrate, slow-growing wild species picked up by plant explorers. But it must also be admitted that no plant of such economic value and antiquity shows so little evidence of deliberate breeding.

Only two examples, both cited by Brand (*2*), 1907, are needed to show what apparently had been accomplished by natural selection, helped along by man. Peruvian alfalfa, which is now grown to a considerable extent in the Southern States, has a very low zero point, that is, ability to grow at a low temperature, but is not at all winter-hardy in northern latitudes. This, Brand suggested, has been due to many centuries of growing in warm climates. On the other hand, it is

rather surprising that the original home of Grimm alfalfa in Germany has minimum temperatures less severe than those observed at Albuquerque, N. Mex. From all available records it is clear that the bulk of the original Grimm seed was not sufficiently winter-hardy for Minnesota conditions. Yet by saving seed from the plants that survived each successive winter, generation after generation, the persistent German immigrant, Wendelin Grimm, showed what could be accomplished in the way of acclimatization or adaptation of alfalfa in Minnesota.

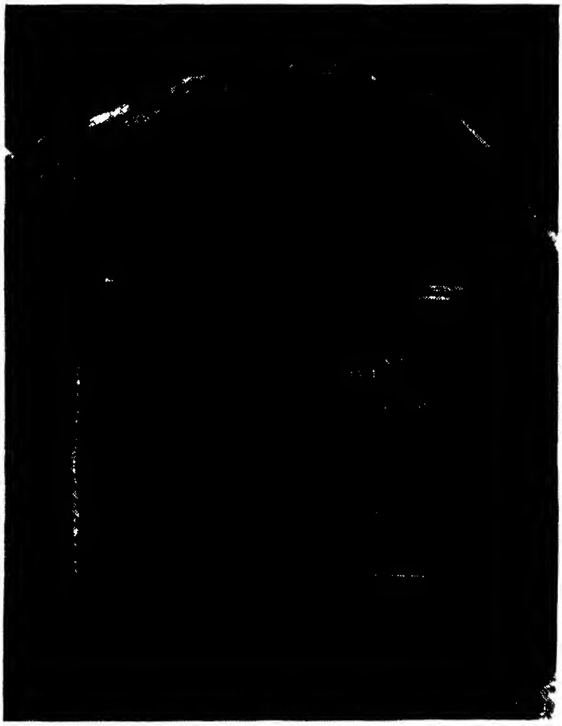

Figure 3.—Monument erected in honor of Wendelin Grimm, who greatly benefited northern agriculture by originating the hardy variety that bears his name. (Courtesy of A. C. Arny, Minnesota Agricultural Experiment Station.)

In a report of the committee for breeding forage crops, made by Piper (*24*) in 1909, a very good picture is given of the alfalfa-breeding program in the entire United States at that time. "It must be borne in mind", the report states, "that alfalfa breeding is a very recent development of plant improvement, apparently no work having been conducted along this line previous to 1903." At the time of the report 11 workers were directly interested in alfalfa improvement: J. M. Westgate, C. J. Brand, G. W. Oliver, and A. C. Dillman, all of the United States Department of Agriculture; G. F. Freeman, of Kansas; W. H. Olin and P. K. Blinn, of Colorado; F. A. Spragg, of Michigan; E. G. Montgomery, of Nebraska; W. A. Wheeler, of New York; and L. R. Waldron, of North Dakota.

Practically all these workers had a well-developed program, chiefly involving mass selection. Only Oliver, Westgate, and Brand report hybridization of varieties or species, but without definite results. Two rather distinct methods of selection were followed. Spragg, Dillman, and others selected mother plants without control of the male parent except cutting back adjacent undesirable material at the time of blooming. Olin, Oliver, Brand, and others self-fertilized the selected plants, using wire cages or bagging. This group thoroughly

understood the possibility of contamination by cross-fertilization, but apparently they did not fully realize that an individual selected plant might not necessarily—probably would not—pass on all its good characteristics to the next generation. Thus too much effort was often spent in picking out the best plant in the entire nursery, only to find when seed was obtained that the daughter plants were not at all like the mother plant. It must be added, however, that even at this early date many breeders knew the value of the progeny test and used it to determine which was the best parental material.

The workers of this period had a considerable number of strains to use for foundation stock. The State experiment stations had access to the collection of the Department of Agriculture, which included introductions from all important alfalfa-growing regions as well as material from more out-of-the-way parts of the world. The major varieties used were Grimm, Common, and Turkistan. There were also introductions of other species, chiefly *Medicago falcata* L., and a few species crosses were made, but apparently nothing came of them.

Among the more important characters selected for at this date were frost resistance, forage productivity, drought resistance, desirable habit of growth, seed productivity, leafiness, and resistance to leaf spot (*Pseudopeziza medicaginis* (Lib.) Sacc.). It is interesting to note, however, that only one worker mentions breeding for disease resistance, and then it is not given much prominence. In reply to the question "What are the most serious difficulties you have found in breeding alfalfa?", made in Piper's survey of 1909, the following answers were received:

(1) Difficulty of keeping strains pure, both during breeding and for increase.
(2) Maintaining a large nursery several seasons to await winter-killing or drought to eliminate undesirable individuals.
(3) Securing seed.
(4) Length of time required to determine the value of any given plant, some suggesting 3 years as the minimum.

Results of Early Improvement Work

The early work can be said to have begun about 1903 and ended about 1915. During this period there was considerable interest in the improvement of alfalfa, one outstanding character sought being winter-hardiness (fig. 4). A group of superior varieties and strains, together with the date they originated, is listed in the appendix, and it may be noted that several of these came into prominence during this early period, notably Grimm, Baltic, Cossack, Ontario Variegated, and Ladak. Figure 5 shows the origin of Ladak and the nursery from which it was selected at the United States Department of Agriculture Experiment Station, Redfield, S. Dak. All of these varieties have superior characteristics, such as cold resistance and adaptation for special conditions. They are all still considered standard varieties. Introduction and selection played a part in their development.

It must be added, however, that many an alfalfa selection was "born to blush unseen" during this period. Some very promising selections made in various nurseries never got any further. Wheeler's Grimm No. 19A was increased to the extent of 100 acres, then turned over to farmers and its identity lost. No doubt the worth-while

characteristics in this strain have through the years gradually made themselves felt in other strains with which it crossed. Thus the work put into such selections has not been entirely lost.

Nevertheless, the early work did not reach full fruition, for several reasons, among them the World War, which focused attention on the food crops to the detriment of the feed crops, and the widespread

Figure 4.—A demonstration of the difference in cold resistance of different alfalfas. Nebraska-grown Common alfalfa at left and Peruvian alfalfa at right, seeded May 16, 1922 Both varieties seemed equally good during 1923 and 1924, but the Peruvian winter-killed almost completely in the winter of 1924–25, while the Nebraska Common was uninjured Photographed May 25, 1925 (Courtesy of T. A. Kiesselbach, Nebraska Agricultural Experiment Station)

introduction of Grimm alfalfa, which largely solved the winter-hardiness problem, wiping out the advantage gained by selection for hardiness in Common alfalfa, and also depriving breeders of a definite goal for selection In other words, for the moment no great catastrophe threatened alfalfa, and most people, including the breeders, were content to let well enough alone

But events were already developing that brought a great revival of interest in the improvement of alfalfa and other forage crops.

New Problems Appear

Crowding into compact communities leads to peculiar problems with plants as with human beings Growers will tell you they can remember when they could plant alfalfa and leave it down almost any number of years without any trouble This cannot be done any longer. The problem of winter hardiness was largely overcome by the general use of Grimm and other cold-resistant varieties, but

another major problem appeared and became increasingly insistent. It manifested itself in the killing out of stands after 2, 3, or 4 years of production. No one knew what was causing the trouble. Finally it became so serious that Department of Agriculture workers undertook to determine the underlying cause.

Finally Jones and McCulloch (*15*) found the disease was produced by a hitherto unknown organism, a bacterium to which was given the

Figure 5.—The original alfalfa nursery at Redfield, S. Dak., from which Ladak was selected. The seed was sent to the United States Department of Agriculture from the Province of Ladakh, in northern India, in 1910 and was planted in 1914. Photographed July 20, 1915. The entire acreage of the Ladak variety now being grown in the United States came originally from the two rows marked by the arrow. The light color of the rows is caused by the profuse bloom, the preponderance of which was yellow in color. (Courtesy of S. Garver.)

name *Aplanobacter insidiosum* McCulloch, the insidious *Aplanobacter*, more recently changed to *Phytomonas insidiosa* (McCulloch) Bergey et al. The disease it caused was called bacterial wilt. Since its discovery in 1925, apparently increasing inroads have been made by the disease until at the present time it is known to occur from the Atlantic to the Pacific and from the Northern States to the southwestern border. It was apparently most severe in the river valleys of Nebraska and Kansas at first, but it is now found in considerable abundance eastward through Iowa, Illinois, Indiana, Michigan, Ohio, Wisconsin, and other States.

Of the approximately 11½ million acres of alfalfa harvested for hay in the United States in 1934, the 1934 census shows that over 7½ million acres were grown in the 14 North Central States bounded on the east by Ohio and on the west by Colorado. At the present time bacterial wilt is prevalent throughout this region, although it is more serious in some localities than in others. In this region, too, alfalfa is usually allowed to remain as long as there is a good stand. When it kills out it must be plowed and another field planted to maintain a hay balance. The available domestic alfalfas such as Grimm, Hardigan, and Common are very susceptible to the bacterial wilt disease

and kill out, where the disease is severe, in from 2 to 4 years. Figure 6 shows the ravages of bacterial wilt in the domestic varieties in field plots at the Kansas Agricultural Experiment Station.

Bacterial wilt annually destroys hundreds of thousands of acres of alfalfa, with aggregate losses equivalent to those that would be experienced by farmers as a result of flood, drought, or any other major disaster. These losses include not only the crop destroyed by the

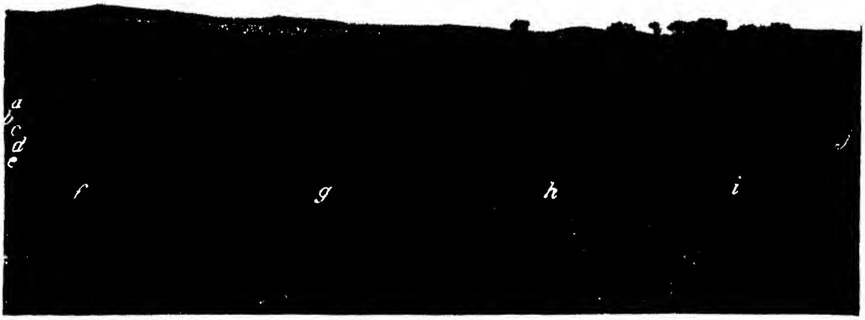

Figure 6.—Experimental plots at the Kansas Agricultural Experiment Station, Manhattan, Kans., demonstrating resistance or lack of resistance of different varieties to bacterial wilt, the plots with a poor stand being covered with weeds. *a*, Kansas Common (poor stand); *b*, Turkistan F. C. 19303 (good stand); *c*, Turkistan F. C. 19304 (good stand); *d*, Grimm (poor stand); *e*, Ukranian F. C. 19315 (poor stand); *f*, Turkistan F. C. 19316 (good stand); *g*, Kansas 308—a resistant selection from Kansas Common (good stand); *h*, Dakota Common F. C. 16081 (poor stand); *i*, Argentine F. C. 15996 (poor stand); *j*, Cossack F. C. 18836 (fair stand). These plots were planted in the fall of 1930: photographed September 1936. The greatest decrease in stand took place during the third and fourth years. (Courtesy of C. O. Grandfield, Kansas Agricultural Experiment Station.)

disease but also the cost of seeding and the loss of production from the land until a new crop is established. If, through the use of resistant strains, growers could maintain stands of alfalfa for even 2 years longer, they would be able to save millions of dollars.

Considerable preliminary work indicated that cultural practices in general would not control the disease. The only avenue of approach that offered possibilities was a breeding program. For a number of years Westover and his coworkers, plant explorers of the Department of Agriculture, have been gathering alfalfas from remote parts of the globe. This collection has progressed until at the present time approximately 1,000 different strains of alfalfa are growing in various nurseries in the United States. Some of these were gathered in areas where the natives had never seen or heard of an automobile. Of the alfalfa strains tested from every continent, and almost every country, practically the only strains having decided resistance to bacterial wilt have been found in the region around Russian Turkistan, northern India, western China, and northeastern Persia. Even some alfalfas

of the wild type and the *Medicago falcata* strains found in this region have shown resistance to bacterial wilt. The objective of the breeding program, then, is to combine the good qualities of commercial alfalfas such as Grimm and Common with the bacterial wilt resistance found in the Turkistan alfalfa.

PRESENT ALFALFA IMPROVEMENT WORK

As already indicated, both new problems and new advances in plant breeding have greatly stimulated alfalfa improvement. At the present time a relatively large number of breeding projects are being started or have recently been started, and there is a great deal of interest on the part of almost all experiment stations, whether or not they are themselves actively engaged in alfalfa-improvement work. In order to make the present status of alfalfa improvement clear, the work that has already been done both in the United States and abroad will be briefly summarized.

Correlation of Characters

When selection is desired for a certain character, it is often desirable to determine, if possible, what other characters of the plant are associated with it. Sometimes certain characters are inherited together. By selecting for one, it may then be possible to secure the other also. This association of characters frequently presents difficulties. In alfalfa, for example, selection for increased forage production usually gives at the same time a more coarse, sparsely leaved plant of poorer quality. In 1914 Freeman (*11*) published a paper of interest from the standpoint of selection of material. He studied correlations between various characters in alfalfa and, among others, found positive correlations indicating that nitrogen content is associated with the percentage of leaves, and green weight with both the average number of stems and the average height. He found negative correlations indicating that greater forage yield is associated with smaller percentage of leaves; smaller percentage of leaves with greater height; smaller number of stems with greater average height. There was no significant correlation between thickness of stand and percentage of leaves.[3] Freeman concludes (*11, p. 367*):

> In economic plant breeding one frequently encounters physiologically negative correlations such as those, in alfalfa, between height and stooling capacity, height and percentage of leaves, and between yield and quality. In seeking improvement, therefore, the breeder must recognize and make use of these facts in the interpretation of results obtained, and also search for races which violate such naturally antagonistic correlations to the greatest possible extent.

Hackbarth and Ufer (*13*) found a relatively high positive correlation between forage yield and height[4] and also a positive correlation between height of stem and length of internode and coarseness of stem.

---

[3]	*r*
Correlation between nitrogen content and percent leaves	0.60±0.06
Correlation between percentage of leaves and thickness of stand	.05± .10
Correlation between percentage of leaves and forage yield	−.39± .09
Correlation between percentage of leaves and height (height 27 to 32 inches)	−.58± .06
Correlation between green weight and average number of stems	.57± .07
Correlation between green weight and average height	.25± .09
Correlation between average height and number of stems	−.25± .09
Correlation between average height and percent leaves	−.40± .09

[4] $r=0.851$.

Thus high-yielding plants were tall and upright but of low quality because they had long internodes, were sparsely leaved, and had thick, woody stems. They suggest, however, that the correlation is not absolute and that with a sufficiently large number of plants to choose from it might be possible to obtain the desired combination of height and quality. Of especial interest is the finding of a positive though slight correlation [5] between forage production and seed production. Since it is considered by many that high forage yield militates against high seed yield, it is noteworthy that they found a number of lines (clones) in which high yield of forage was associated with high seed production. Fleischmann (*10*) has also found strains that combine relatively high forage and seed yield. In this connection Helmbold (*14*) has found some correlation between the following characteristics and high seed production, and selection for these characteristics may help attain the desired end:

(1) A definite (closed) blooming period.
(2) Large flower clusters.
(3) Great individual ability to set seed. (He believes the female parent has a greater bearing on seed productivity than the male)
(4) Many coils per pod with high seed number per pod.
(5) Least possible shattering of seed.

Other workers, including Kiesselbach and Anderson in Nebraska and Willard in Ohio, have also found a very high correlation between nitrogen content and percentage of leaves. Thus it seems evident that for a higher quality crop it is necessary to have a high percentage of leaves and also that the plant retain those leaves until harvest. Thus disease resistance as well as inherent leafiness is involved, because most of the leaf-spot diseases, for example, tend to defoliate the plant.

Hybrid Vigor

The question of how much crossing naturally occurs in alfalfa brings such different answers that there is obviously no exact information on the point. Waldron found 42.7 percent crossing between purple and yellow, the yellow being the female parent, while he found 7.5 percent crossing in the reciprocal, the purple being the female parent. As high as 80 percent crossing has been observed in Nebraska between closely associated plants of the purple-flowered (*Medicago sativa*) and yellow-flowered (*M. falcata*) alfalfa, the female again being yellow. It is more difficult to determine the crossing between purple-flowered strains of similar origin because of the difficulty of determining when a cross is obtained. This difficulty is now being overcome in the production of "testers" by at least three experiment stations. These include a strain produced by the South Dakota station with pure white flowers, the character acting as a simple recessive. Another strain produced at the Wisconsin station has red roots, also simply inherited; and the Nebraska station has a strain producing four or five leaflets instead of the usual three. These strains all have the *M. sativa* type of flower, and by their use reliable information should be obtained on the amount of natural crossing, the distance necessary for isolation, and possibly on the activities of various insects.

[5] $r=0.202$

A considerable body of facts bearing on the question of the influence of self-fertilization on an alfalfa population is gradually being established. The work of Kirk (*17*), Williams (*31*), Torssell (*26*), Dann (*7*), and others suggests, on the whole, decrease in productivity of both forage and seed yield when plants are self-fertilized. The decrease is very marked in most cases; for example, Williams (*31*) reports that 14 parent plants produced an average of 2,433 seed per plant, while the average yield of the first-generation selfed progeny was only 301 seeds. Kirk found that the first generation selfed produced only 62 percent as much as the cross-fertilized parent, and the second selfed generation only 30 percent as much as the original parents.

The German workers, including Dann (*7*), also found a decided decrease in seed production with self-fertilization as compared with cross-fertilization. Helmbold (*14*) found that crossing gave a higher percentage of pods than selfing. By crossing with foreign pollen, 24.86 percent of the flowers formed pods. With close pollination (pollen from the same plant but different flowers) 18.26 percent formed pods, and with strict selfing 17.54 percent formed pods. Crossing also gave the highest number of seeds per pod, an average of 2.34, while inbreeding gave the least, an average of 1.38 seeds per pod. Most workers agree that there is no self-sterility, in the true sense, in *Medicago sativa* or *M. falcata*.

Tysdal and Clark (*27*) found decided decreases of seed production in self-fertilized lines as a general rule, but point out several instances where selection for seed productivity increased production, particularly in Turkistan lines, which as a rule are naturally low in seed yield. These lines were carried into the fourth generation of selfing and represent a decided improvement in the inherent ability to set seed over the original parent. Kirk (*18*) has isolated a strain of alfalfa during the course of his breeding work that he characterizes as "autogamous", that is, it is extremely self-fertile and sets seed readily without manipulation.

The seed production resulting from hybridization compared to that of the original parental stock has not been so carefully worked out. It is evident that open pollination or cross-pollination between selfed lines brings them up nearly to parity with the open-pollinated parents, but there are very few definite examples, if any, of large increases attributable to hybrid vigor. Most of the comparisons have been with the progeny of self-fertilized individuals and not with the original parent, and the relative improvement in the cross is therefore difficult to determine. Carlson (*5*) found decided decrease in seed production upon self-fertilization, and then when open pollination—with no way to determine the amount of crossing—was allowed, seed production increased over that of self-pollination but still did not reach that of the open-pollinated parents. In the work reported up to the present time it has not been possible to recombine desirable inbred strains with the object of producing a superior first-generation hybrid, as is being done with corn, because such inbred strains were not available; but at present there are a number of lines that have superior germ plasm with respect to seed production as well as other desirable characters.

The available data on the influence of self-and cross-fertilization on forage production somewhat parallel those on seed production. Kirk (*16*) found the following percentages of forage yields: Cross-fertilized, 100; first generation selfed, 81; second generation selfed, 72; third generation selfed, 53 (fig. 7); but he also found certain second-and third-generation selfed lines that produced 100 percent or more as

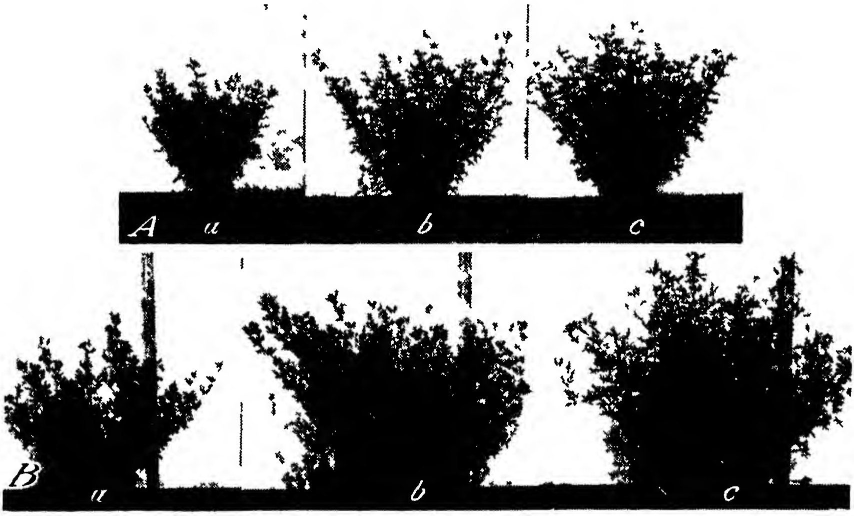

Figure 7—*A*, Representative alfalfa plants from strain no 22, showing reduction in vigor due to self-fertilization *a*, Open-fertilized, *b*, first generation selfed, *c*, second generation selfed *B*, Representative alfalfa plants from strain no 3, showing reduction in vigor due to self-fertilization *a*, Open-fertilized, *b*, first generation selfed; *c*, second generation selfed (Courtesy of L. F Kirk, Dominion Agrostologist, Ottawa, Canada.)

compared with the original parent This coincides in general with results of other workers, there being not such a very great decrease in forage production of some lines, and a tremendous variability with respect to the reaction of different lines—some showing great loss of vigor, while others show very much less. It must be admitted, however, that the chance of obtaining a superior forage-yielding strain of alfalfa by self-fertilization appears rather remote at the present time

As in the case of seed production, most of the comparisons in forage production are between open- and self-pollinated lines. Waldron (*29*), however, as far back as 1920 pointed out hybrid vigor in crosses between two alfalfa species He allowed natural crossing to take place between *Medicago sativa* and *M. falcata* Subsequently he obtained yield data from the first-generation-hybrid individuals compared with other individuals produced by normal pollination within the species He found an increase in forage yield of 51 percent of the *M. sativa* × the *M. falcata* hybrids over the pure *M. sativa,* and 43 percent increase of the *M falcata* × *M sativa* hybrids over the pure *M. falcata.*

This is an interesting observation, particularly in view of the fact that the most widely cultivated alfalfas, in both Europe and North America, are considered to be the result of a natural cross between these two species. Thus without knowing it commercial growers are probably taking advantage of hybrid vigor. In a study of the variegation in flower color of 64 strains and varieties of European alfalfa, Waldron (*28*) found only 5 that did not show any variegation, and 3 of these were Turkistan. Hembold (*14*) states that in his opinion the appearance of any color but pure purple in the flower surely indicates foreign crossing in the *M. sativa* group, and as a rule the introduction of *M. falcata* blood.

The general results of inbreeding and crossing in alfalfa point to the strong possibility of hybrid vigor being obtained for forage yield if the proper combinations of lines are made. The results also point to the possibility of using species crosses to effect improvement. In a later paragraph more information is given on various species that may have possibilities for crossing.

Progress in Selection for Disease and Cold Resistance

In the replies from questionnaires sent to practically all alfalfa workers in the world in connection with this survey, many indicated that they were selecting for cold resistance and others that they were selecting for both cold and disease resistance. In the past Grimm alfalfa was an outstanding example of natural selection for cold resistance. The introduction of various lots of seed and subsequent selection and increase, as in the case of Cossack, Ladak, and other varieties, resulted in the production of additional material of high cold resistance.

In many projects selection is being carried on with the object of purifying strains and making them homozygous for certain characteristics, then recombining the lines to form new varieties. Such work has advanced to the point where some information has been obtained on the breeding behavior of lines, but very little on the behavior of the recombinations.

As a result of a study of the reaction of selfed lines to cold, Kirk (*16, p. 15*) states:

> Inheritance has clearly played an important part and segregation into hardy and non-hardy lines is plainly indicated in the second generation of self-fertilization. Strains IV and VII may be cited as obvious cases in which lack of hardiness has been transmitted in some degree from one generation to another. In one second generation line of strain IV, every plant was winter killed. [The cross-fertilized parental stock of strain IV winter-killed 28 percent.] Lines III and XIII are notable illustrations of segregation in the second generation of selfing for hardy and non-hardy families of plants.
>
> In striking contrast to the strains in which inherent nonhardiness made an appearance are * * * strains * * * in which practically no winter-killing occurred.

Waldron (*28*) found segregation for cold resistance with one generation of selfing, and he also obtained increased cold resistance by selection of mother plants—indicating a great heterozygosity or mixture of inheritance in individuals with respect to this characteristic.

A number of superior lines have been segregated by various workers in the United States. Wisconsin, Kansas, New Jersey, Michigan, and

Nebraska have had rather intensive improvement programs under way, and progress is reported in fixing desirable characters such as cold and bacterial wilt resistance in certain lines. Peltier and Tysdal (*23*) report that selfing alfalfa through the fifth generation has increased the homozygosity for bacterial wilt resistance—that is, a larger and larger percentage of the plants were resistant—provided selection for this character was carried on during the inbreeding process. If no selection for disease resistance was practiced during the inbreeding process, a rather marked decrease in bacterial wilt resistance occurred from generation to generation, although some few lines were consistently high in bacterial wilt resistance. Practically the same results were obtained with cold resistance. Selfing without rigid selection for cold resistance and elimination of the cold-susceptible individuals resulted in a marked decrease in resistance, taking the population as a whole. There was, however, great variation and segregation in different lines, as has been found by other workers. Thus, when the cold-resistant segregations were selected by means of artificially controlled freezing tests, the cold resistance of superior lines was maintained in spite of self-fertilization. It was also found possible to obtain high bacterial wilt and cold resistance either in the same lines or independently, thus indicating independent inheritance. Figure 8 shows two hybrids relatively resistant to bacterial wilt, as compared with the bacterial wilt-susceptible Grimm variety.

Brink, Jones, and Albrecht (*3*) at the Wisconsin station report segregation for bacterial wilt resistance in selfed lines from Hardistan alfalfa, some having a very high degree of bacterial wilt resistance. They state (*3, p. 642*): "Resistance to bacterial wilt in alfalfa behaves in inheritance as an intergrading character and probably rests upon a complex genetic basis. A factorial interpretation is at present impossible."

In certain crosses between resistant and susceptible lines the same workers found varying percentages of resistant offspring. In the case of a Turkistan × Hairy Peruvian cross, 58 percent of the second-generation offspring were resistant, while a Turkistan × Grimm cross gave relatively few resistant segregates.

Thus while complete success has not yet been attained in the fight against winter hazards and disease, it is safe to say that remarkable progress has been made in obtaining lines that are superior in these characters. These lines contain the necessary genetic stability for these characters, and the next step will be to combine them to produce a variety with as much bacterial wilt resistance as is now found in any commercial variety, or even more, together with such desirable characters as high forage and seed yield, freedom from leaf diseases, and other attributes. To say that this is an easy task is to underestimate the difficulty of the problem and the whims and caprices of nature.

In the alfalfa-improvement work, the Department of Agriculture is cooperating with a number of State stations, among which the work in Kansas, Wisconsin, and Nebraska has been longest in progress. At each of these institutions superior strains are now available, some strains having more than twice the bacterial wilt resistance of the best commercial varieties. The Wisconsin station reports that among its

most promising material are lines having very high cold resistance selected out of hardy varieties, and also some bacterial wilt resistance found in occasional plants from well-known and highly susceptible American varieties. The Kansas station has also reported increasing the bacterial resistance by selection in the Kansas Common strain. The Nebraska station has promising lines developed from plant

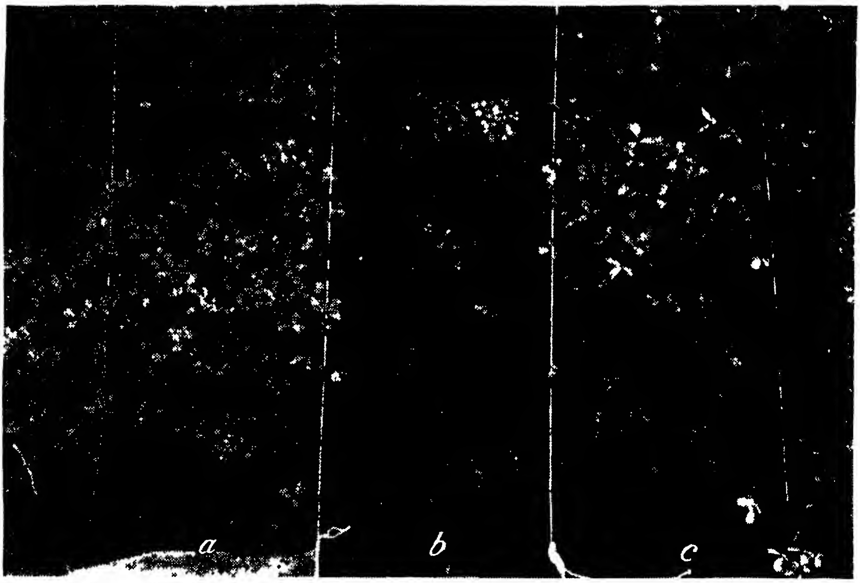

Figure 8.—Looking down on three strains of alfalfa artificially inoculated with the bacteria causing alfalfa bacterial wilt, grown in the Nebraska Agricultural Experiment Station greenhouse: *a*, Cross between a bacterial wilt-resistant Turkistan selection and *Medicago falcata*; *b*, Grimm (originally a natural cross between *M. sativa* and *M. falcata*); *c*, a cross between bacterial wilt-resistant selections from Turkistan and Ladak. All three had an equal number of plants when inoculated, but Grimm has been almost completely killed by the disease, while the two resistant crosses maintain a stand. (Photographed 4 months after inoculation.)

selections from old fields of the State, foreign introductions, and the Ladak and Cossack varieties.

The New Jersey station has had selection and hybridization in progress for some time and reports the possibility of selection for a type of root resistant to heaving, as well as selection for adaptation to particular soil conditions.

Various stations now also have access to strains with rhizomes or underground stems. These are particularly interesting from the standpoint of pasture types and erosion control, as they form a matted growth and bind the soil.

Relation of Insects to Alfalfa Improvement

There is some division of opinion, but in the main considerable agreement, regarding the kinds of insects that assist seed setting in alfalfa. Practically all workers agree that the leaf cutter bees (*Megachile* spp.)

are very effective in causing tripping or forcing of the pistil out of the keel. Piper et al. (*25*) found the bumblebee (*Bombus* spp.) to also be fairly effective for tripping. They found that butterflies caused practically no tripping, and this was true also for moths and other night-flying insects. The ability of the honey bee (*Apis mellifera* L.) to trip alfalfa flowers is not so easily clarified. Piper et al. found that honey bees tripped only from 0.3 to 4.7 percent of the flowers visited and many visits to the flower were required before tripping was effected. Dwyer (*9*), of Australia, has found that honey bees cause a considerable amount of tripping and has suggested the use of honey bees in cages in breeding work. Michigan workers have also found the honey bee to be effective when confined to small areas. Helmbold (*14*) states that honey bees collecting pollen cause tripping and attributes more tripping to them than to bumblebees. He also says that the following bees are effective in tripping alfalfa flowers: *Macropis labiata* F. (female), *Melitta leporina* Panz., and *Anthophora bimaculata* Panz.

There is no doubt from the work of numerous investigators that insect visitation under most conditions will improve seed production, and it is probable that insects can be used to advantage for controlled pollination in certain breeding and improvement work.

There is some evidence that progress can be made in selecting lines resistant to harmful insects. Painter and Grandfield in Kansas have selected individual plants that are much more resistant to aphids (*Illinoia pisi* Kalt.) than the average of the variety. Some workers have also found individual plants that seem to carry resistance to leafhoppers (*Empoasca* spp.). At present these represent only possibilities in superior germ plasm. Insects that harm alfalfa from the standpoint of seed production, upon which little or no selection for resistance has been done, include the clover seed chalcid (*Bruchophagus gibbus* Boh.), certain species of bugs of the genus *Lygus*, and Say's stinkbug (*Chlorochroa sayi* Stål).

The Alfalfa Improvement Conference

In June 1934 a meeting of 27 alfalfa workers from 7 States and the District of Columbia was held at Lincoln, Nebr., and at this meeting attention was given to the formation of an informal association for the benefit of all workers interested in alfalfa improvement. In order to get the reaction of the eastern men it was decided to call another meeting to be held in connection with the American Society of Agronomy meeting at Washington, D. C., in November 1934. Nineteen States, the District of Columbia, and Canada were represented by 54 workers. After a thorough discussion a committee of five was appointed, composed of H. L. Westover, R. A. Brink, T. A. Kiesselbach, D. W. Robertson, and H. B. Sprague, to develop plans and methods for a permanent alfalfa improvement conference. This committee called a meeting of all interested workers to be held in connection with the meeting of the Corn Belt section of the American Society of Agronomy at St. Paul, Minn., June 1935, at which time final organization of the conference took place. At this meeting, representing 15 States and the District of Columbia, with an attendance of 78 workers, the following motion was adopted:

That the guidance of the Alfalfa Improvement Conference be in the hands of an executive committee of five, consisting of H. L. Westover, permanent secretary, and four additional members, one of whom would be chairman, to be elected biennially at the conference to be held in conjunction with the Chicago meeting of the American Society of Agronomy; and that summer conferences be held in alternate years at an experiment station where alfalfa investigations are in progress, the time and place to be determined by the committee.

The following were elected as members of the executive committee to serve until the fall of 1937: R. A. Brink, chairman; T. A. Kiesselbach, H. B. Sprague, and D. W. Robertson. In Mr. Westover's absence on plant exploration trips, H. M. Tysdal has been acting secretary.

Since its inception and organization the Alfalfa Improvement Conference has been active in disseminating information on progress in alfalfa breeding, has taken an active interest in plans for seed increase of desirable improved strains under isolation, has assisted in the exchange of breeding material, and at the biennial summer meeting held at Madison, Wis., in June 1936, laid the foundation of a cooperative program of testing new strains. In this cooperative testing two types of nurseries will be used—(1), an "observation" nursery composed of duplicate rod rows with appropriate standard checks, and (2), an advanced nursery composed of perhaps five or six replications of multiple-row plots. Yields will be taken on the latter nurseries, and also, where possible, on the former.

It is planned to have a considerable number of observation nurseries scattered throughout the country so that experiment station workers will have an opportunity of testing out the available new strains for their own conditions, and this will enable them subsequently to make intelligent varietal recommendations to alfalfa growers of their own States. The advanced nurseries will be located in representative areas to test out any definite regional adaptations that are found in the improved strains. One or more tests are also contemplated in a recognized alfalfa seed producing section to test this character. In addition to these cooperative field tests, attempts will be made to include testing under controlled conditions for such characters as resistance to diseases, to insect pests, and to low temperatures.

The Alfalfa Improvement Conference has already proved itself to be a vital force in coordinating the alfalfa improvement work of the United States. Reports of the conferences already held may be obtained from the Division of Forage Crops and Diseases, Bureau of Plant Industry, United States Department of Agriculture, Washington D. C.

Methods and Objectives of Present-Day Alfalfa Improvement

Even the most optimistic workers fail to see how it would be possible to produce one variety of alfalfa that would be the best for all sections of the country. Some workers, however, recognize a need for the development of strains of alfalfa especially suited to at least four general regions: (1) The northwestern region, north of the southern boundary of Nebraska and west of the eastern boundaries of North Dakota and South Dakota; (2) the northeastern region, which may roughly be designated as the area bounded on the west by the western boundaries of Minnesota and Iowa and on the south

by a line representing approximately the southern boundary of Pennsylvania; (3) in the middle region, including Kansas and Oklahoma and the surrounding territory eastward and westward; (4) the southwestern region, including southwestern Texas, southern New Mexico, Arizona, most of California, and the extreme southern parts of the United States along the Gulf of Mexico.

In regions 1 and 2 it is essential to have an alfalfa of high cold resistance. Bacterial wilt can also be found throughout these regions, but it is severe only in those areas where moisture and other conditions are favorable; it is not serious as yet in the dry-land areas or in the eastern regions where short rotations are the rule. However, it causes severe damage in parts of Ohio, New Jersey, and other Eastern States. The chief difference between the requirements for regions 1 and 2 relate to resistance to various leaf spots, particularly the leaf spot caused by *Pseudopeziza medicaginis* (Lib.) Sacc. and leaf blotch (*Pyrenopeziza medicaginis* Fckl.), and also to dormancy habits and resistance to potato leafhopper yellows. Cold-resistant Turkistan alfalfa has been fairly successful in region 1 but not in region 2, chiefly because of its susceptibility to leaf spots and the fact that in some cases its slow recovery after cutting allows grasses to encroach. At one experiment station in the Union of Soviet Socialist Republics, selections less susceptible to leaf spot have already been made, and it does not appear impossible that eventually a strain can be produced that will combine the qualities necessary for adaptability to both regions, 1 and 2. This would be all the more desirable because seed is often produced in the western area to be used in the eastern area. Also there is some evidence indicating an increase in the severity of bacterial wilt in eastern States, which would make bacterial wilt resistance desirable for this region.

In region 3, cold resistance is a less important factor, but it can by no means be entirely neglected. Bacterial wilt resistance is desirable if not necessary for many areas, and it seems probable that if a strain can be produced combining bacterial wilt resistance and the desirable habit of growth of Kansas Common alfalfa, it will be very well adapted for this region.

In region 4 the climate is so mild that cold resistance need not be considered, although there is apparently considerable difference in ability of the foliage of different strains to resist frost, and it is desirable to select for this character. Since tests have shown that the nonhardy alfalfas grow more rapidly and give better yields of hay in this region, selection work can be confined largely to southern types. Bacterial wilt has not been important in this region, although it has been found. Fortunately certain Persian introductions of the nondormant type have shown some bacterial wilt resistance and these are available for selection and breeding work for the region.

It is apparent from the foregoing that a large amount of selection and recombination of characters must be accomplished before the desirable alfalfas are obtained. Fortunately much of the foundation stock, including lines of high resistance to certain diseases and to cold, is already available. A cooperative arrangement with the various States to give accurate information on the adaptation of all new strains produced is now available under the auspices of the Alfalfa Improvement Conference.

The ultimate objective will be the combination of as many desirable characters in a single individual strain as possible. Most plant breeders constantly bear in mind and guard against the possibility that selection for one character, such as bacterial wilt resistance, may actually lead to the development or retention of characters undesirable in other respects For example, bacterial wilt resistance can readily be ob-

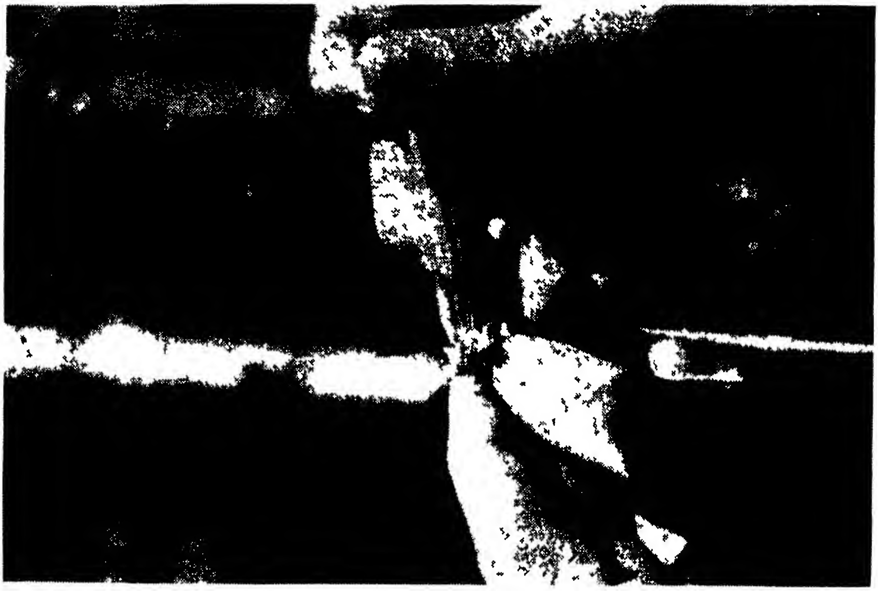

Figure 9—Emasculation of alfalfa flowers by suction. The glass tube is held over the stigma and stamens, and the suction (in this instance supplied by a rubber tube connected to the intake manifold of an automobile) removes the anthers and pollen. If all the pollen is not removed, a jet of water is applied to the stigma and suction finally removes all trace of pollen.

tained in Turkistan lines, but the strain is still undesirable because of other characters, including high susceptibility to leaf diseases.

Naturally present-day alfalfa breeders use a wide variety of methods in attacking the problem of improvement, although the underlying principles are the same. In hybridization work where emasculation is desired most American workers use the suction method or a combination of suction with a jet of water directed on the stigma. The suction method operates on the principle of a vacuum cleaner and is illustrated in figure 9.

It has been found advantageous not to allow the stigma to strike the standard or any other object when it is tripped or forced out of the keel for emasculation. It has also been found that in general it is unnecessary to emasculate the flower at a very early stage; emasculation is usually delayed until full bloom, even though the anthers have become ripe. If the pollen is carefully removed, apparently there is little danger of self-fertilization, and foreign pollen can then be applied immediately.

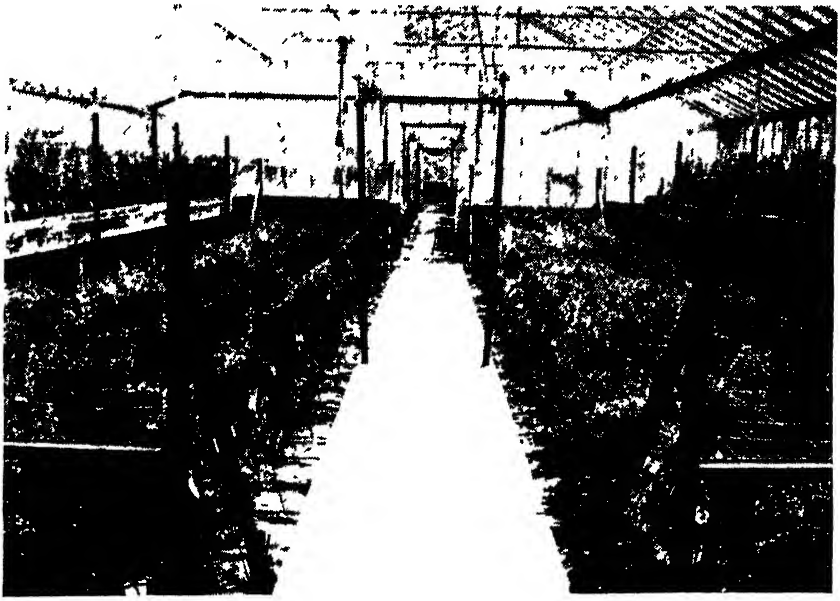

Figure 10.—Increase of seed of selected lines of alfalfa in the greenhouse at the Nebraska Agricultural Experiment Station. The greenhouse is screened against insects, and the flowers are tripped by hand, insuring self-pollination. Good seed setting can usually be obtained in the greenhouse even in unfavorable seasons, although temperatures often reach 120° F. inside.

Figure 11.—Seed increase of a selected alfalfa strain in an isolated block. Such a plot must be separated from any other by at least 20 rods; in this case the separation was about a quarter of a mile. The plants were transplanted to irrigated land in western Nebraska in the spring of 1936 from seedlings started at the United States Yuma Field Station, Bard, Calif., in December 1935. These plants produced a fair amount of seed the first year. The plot is surrounded by corn and sugar beets.

Selfing is accomplished by the use of bags, screen cages, or screened greenhouses, the flowers usually being artificially tripped, although not always. Some strains have been produced that set seed without any manipulation of the flower. Figures 10, 11, and 12 show some of the ways in which the problem of seed increase of selected lines is being met.

Perhaps of greater interest than details of technique are the principles followed in the breeding program itself. Some workers allow open-

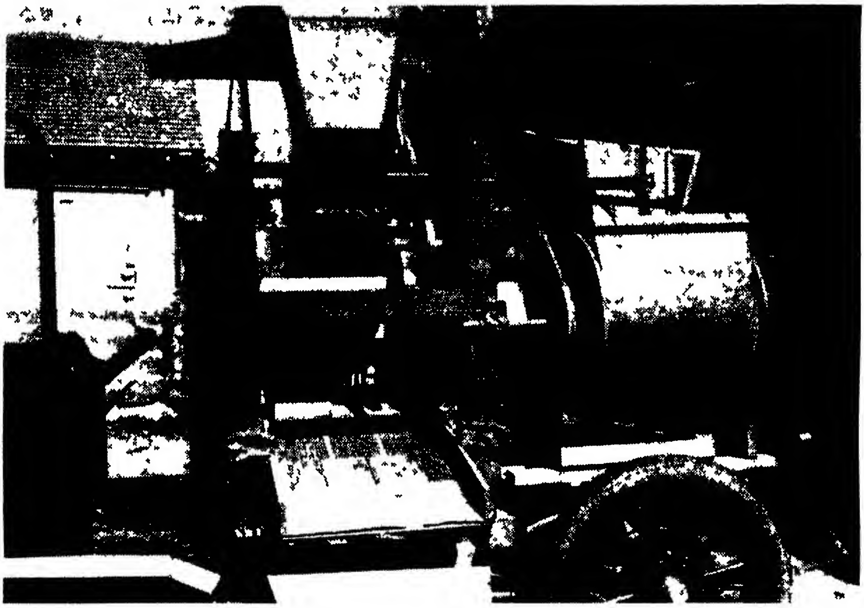

Figure 12.—Small, portable thresher for threshing both single plants and increase blocks of alfalfa. The single-plant material is run only over the rubber drum with apron shown at the right, while larger quantities are put through the cylinder, and pods that are not threshed fall through the screen and are then run over the rubber drum, which rubs all the seed out. The rubber drum is powered through an automobile transmission so the drum can be stopped when not in use, even though the cylinder is going. The whole machine is mounted on the chassis of a car, and the motor of the car used as power. This thresher has proved very satisfactory for relatively small lots.

fertilization in the nursery and select the best individual lines for propagation, while others employ strict inbreeding methods with the object of more rapidly fixing the characters desired and then recombining if necessary. Still others use a combination of these methods. Without doubt many alfalfa breeders are using the same method that has produced such remarkable results in hybrid corn, as described by Merle T. Jenkins in the 1936 Yearbook of Agriculture.

The problem of how to determine which lines when crossed will produce a superior hybrid is of great interest to alfalfa workers. At present the only way to find out is to try the lines in actual crosses, and it is difficult to make as many crosses as are necessary to test all

combinations. Corn workers use the top-cross method rather extensively at the present time for eliminating undesirable strains, and it has been suggested that a modified application of the same principle may be useful in alfalfa.

Evidence seems to indicate that long-continued inbreeding is not necessary to fix desired characters sufficiently for practical breeding purposes. If this is true a great deal of labor and time will be saved and also a larger number of lines can be produced and tested.

The backcross method or its modifications, as, for example, Richey's "convergent improvement" method, is apparently not very much used with alfalfa. Some type of backcross may be useful in such a problem as combining the bacterial wilt resistance of Turkistan selections with the desirable characters of Grimm, Cossack, or Hardigan. The application of the backcross method is not simple when the inheritance of resistance is complex, as is apparently the case with bacterial wilt, but the method should not be overlooked when it is yielding results in various other crops.

To obtain further information on the present status of alfalfa improvement, questionnaires were sent to all experiment stations in the United States and all foreign workers of whom there was a record. Among 40 replies, 23, representing opinions from England, Germany, Australia, and Canada, as well as the United States, indicated that alfalfa breeding or improvement work was in progress. In the replies to the question "What are the objectives in your selection or hybridization work?" the following objectives were mentioned the number of times shown:

Increased seed-setting capacity	10
Higher yield of good quality forage	8
Winter hardiness	8
Disease resistance	8
A type suitable for grazing	5
Adaptation to different soil conditions	4
Resistance to heaving injury	2
Insect resistance	2
Increase resistance to drought	2
Increase in protein content and leaf percentage	2
A type less susceptible to injury from early cutting	1
Larger seed	1

It is interesting to compare these replies with those obtained in 1934, given in the supplement to the Report of the Second Alfalfa Improvement Conference. The most significant change is found in the increased number of workers at present interested in selection for a pasture type of alfalfa for grazing, and also the increased number interested in selection for soil adaptation. This undoubtedly indicates a trend toward the increased use of alfalfa for grazing and a desire to use it on land to which it is at present not well adapted.

In the same questionnaire, in answer to the question "What problems and material need future attention?" the replies indicated further studies would be desirable on—

(1) Technique in methods of hybridization.
(2) The mode of inheritance of various characters.
(3) Hybrid vigor, including interspecies crosses.
(4) Factors affecting seed setting in alfalfa.
(5) Fundamental research on the nature and control of various diseases.

138904°—37——73

(6) The mosaic problem.
(7) Effective means of isolating pure seed for increase.
(8) Interregional testing, including hardiness and disease tests.
(9) Production of improved seed.
(10) The use of the backcross method, or modifications, in alfalfa breeding.

INHERITANCE AND CYTOLOGICAL STUDIES

There is rather a large amount of literature dealing with the general genetic behavior of alfalfa, but very little has been done on the inheritance of any given character. This is to be expected in a crop worked with as little as alfalfa, but nevertheless it is a handicap to the plant breeder in many respects. As self-fertilized strains having a known inheritance are developed, more information of this kind should be forthcoming.

Most of the work so far has involved crosses between the two contrasting species, *Medicago sativa* × *M. falcata*. In such a cross Korohoda (*20*) has reported on the inheritance of flower color, shape of leaves, and structure of the stem. With regard to the inheritance of flower color in the purple × yellow cross, he states that the former supposition that two or three hereditary factors were involved was found to be inadequate. The results of his studies indicated at least four factors, one for each fundamental coloration—cream, blue, and violet—and one or two that intensify these colors.

With respect to the shape of the leaves of the hybrid, the shape typical of *Medicago sativa* was observed in the second generation in 28 plants, that typical of *M. falcata* in 196 plants, and an intermediate in 424 plants. It was not found possible to calculate the relations, assuming the existence of two, three, or four factors.

When examining the structure of the stem in the second generation, stems of the type of *M. falcata* were observed in 565 individuals, and of the type of *M. sativa* in 30 individuals. Since the ratio of these numbers (18:1) is close to 15:1, the workers assumed the existence of two hereditary factors, with the *falcata* type dominant over the *sativa* type.

MacVicar (*22*) reports the results of an investigation to determine the inheritance of black and white seed coat characters in alfalfa and whether or not the former could be utilized in breeding as a marker for identifying improved strains. He says:

> The available evidence indicated that the white seeded parent was homozygous for a recessive factor which results in the absence of yellow pigment, and that the inheritance of this character was comparatively simple. Inheritance of the black seeded character, on the other hand, was fairly complex, requiring the assumption of at least three factor pairs. The original black seeded plant was thought to have arisen as a single gene mutation. This gene, primarily responsible for pigmentation of the seed coat, together with at least two modifying factors was postulated as the most probable genetic factorial basis to account for the breeding behavior of the original black seeded parent.
>
> It was concluded that the character of black-seededness would be valueless from a utility standpoint.

The cytological aspects of alfalfa have also been neglected until recently, when several interesting papers have been published. Among these is a paper by Fryer (*12*), summarizing much of what is known regarding chromosome numbers in *Medicago* species, and another by Cooper (*6*) on embryology, reporting the important fact

that according to his observations the lack of seed production in various plants seems to be due not to lack of pollination or fertilization but to failure of the ovule to develop after it has been fertilized. In plants that fail to set seed after effective pollination takes place, the young embryos abort. Direct evidence regarding the cause of the abortion was not available, but it was believed to be an unbalanced nutritional condition.

APPENDIX

INVESTIGATORS WORKING ON ALFALFA IMPROVEMENT

THE following list includes mainly the breeders and workers employed by institutions that returned questionnaires on superior germ plasm in alfalfa. Nearly all the workers listed as State agricultural experiment station employees devote only a small part of their time to alfalfa-breeding investigations. The remainder

of their time is given to investigations on other crops. This is also true of some of the field staff of the Division of Forage Crops and Diseases, Bureau of Plant Industry, United States Department of Agriculture. Early workers are listed on page 1233. The names of alfalfa breeders listed for foreign countries were all given in the returned questionnaires.

An asterisk (*) denotes United States Department of Agriculture employee.

TABLE 1.—*Historical summary of the development of improved varieties of alfalfa in the United States and Canada*

Variety or strain	Year introduced	Name and location of breeder	Superior characters	Breeding method used	Parent material	Present acreage: In State produced	Present acreage: Elsewhere
Grimm	1905	Wendelin Grimm, Minnesota.	Yield, quality, winter hardiness.	Natural followed by artificial selection.	Seed brought by Grimm from Germany.	700,000	(1)
Cossack	1907	N. E. Hansen, South Dakota.	Winter hardiness, productivity.	Selection from introduced strains.	Seed from Siberia		
Baltic	1908	Wheeler, South Dakota	Cold resistance, productivity	Natural selection	Probably Grimm, although not certain.	(1)	(1)
Grimm 19A	1909	do.	Winter hardiness, productivity.	Line selection	Grimm	100	
Ladak	1910	H. L. Westover, Samuel Garver, U. S. Department of Agriculture.	Yield, cold and drought resistance. More resistant to bacterial wilt than Grimm.	Selection of introduced material at Redfield, S. Dak.	Introduction from northern India as *Medicago falcata*.		
Ontario Variegated	1910	C. A. Zavitz and coworkers, Ontario.	Winter hardiness, productivity.	Inbreeding mass selections and strain building.	Variegated alfalfas from Baden and Alsace-Lorraine and various importations from Europe (Norway) and the original strain of Grimm.	500,000	7
Hardigan	1920	F. A. Spragg, E. E. Down, Michigan.	Yield of hay and seed	Selection	Baltic	400,000	5,000
Meeker Baltic	1920	P. K. Blinn, Colorado	Yield, cold resistance, hay quality.	Natural selection and selection.	do.	20,000	
Grimm 451	1921	J. Bracken, L. E. Kirk, Saskatchewan.	Hardiness, yield	Mass selection	Several Grimm introductions, all tracing back to Minnesota Grimm.	4,000	
Grimm 666	1925	M. Champlin, L. E. Kirk, Saskatchewan.	Seed yield	Single plant line	Selection from Grimm obtained from Lyman of Excelsior, Minn.	1,000	
Hardistan	1930	A. Hecht, T. A. Kiesselbach, A. Anderson, G. L. Peltier, Nebraska.	Bacterial wilt resistance	Selection	Old Nebraska field, probably of Turkistan origin.	375	25
Grimm, M. C.	1931	J. N. Bird, Quebec	Winter hardiness	Recombination selfed lines and strain.	Grimm stock 8, Grimm stock 5, obtained from University of Minnesota in 1911, S. P. I. 29988.	[2] 25	
Kaw	1932	S. C. Salmon, C. O. Grandfield, Kansas.	Resistance to wilt and cold	Natural selection	Provence 34886	(3)	
Kansas 308	1933	C. O. Grandfield, Kansas.	Resistance to wilt and cold, high yield.	do.		15	
S133	1935	R. D. Williams, Wales.	Under test. Increased yields on comparatively poor soils.	Built up from 10 selfed lines.	Mainly Grimm and Canadian Variegated.	(3)	
A number of strains	1920-36	F. A. Spragg, E. E. Down, S. T. Dexter, H. M. Brown, Michigan.	Superior seed production, yield, and cold resistance.	Hybridization selection	Hardigan	(4)	

Approximately 50 strains.	1928–36	H. M. Tysdal, G. L. Peltier, T. A. Kiesselbach, Nebraska.	Wilt and cold resistance, seed production.	Selection in self-fertilized lines, hybridization and selection in F_2.	Plants from old Nebraska fields, introductions from foreign countries, domestic varieties including Cossack, Ladak, *Medicago* sp.	(4)	--------
Unnamed----------- --	(1)	J. R. Fryer, Alberta. --	Accumulation of hereditary factors that contribute to fertility.	Maternal line selection--- --	Grimm, Wiley, Grimm, Disco, Southworth's hybrid, and Ontario Variegated.	(3)	--------
A number of strains---	1930–36	R. A. Brink, F. R. Jones, H. R. Albrecht, Wisconsin.	Wilt and cold resistance, seed production.	Selection in self-fertilized lines, hybridization.	Grimm, Cossack, Ladak, Turkistan, Kansas and Montana Common, introductions.	(4)	--------
Do---------------	1932–36	H. B. Sprague, Glenn Burton, New Jersey.	Adaptation for New Jersey conditions.	Mass selection, hybridization--	Peruvian, *Medicago falcata*, selected lines from other States.	(4)	--------
Do---------------	1930–36	C. O. Grandfield, Kansas	Wilt resistance, Kansas Common type.	Selection in self-fertilized lines, hybridization.	Kansas Common, Kaw, Turkistan, introductions.	(4)	--------
Do---------------	1934–36	G. C. Moe, C. H. Myers, D. B. Johnstone-Wallace, New York.	Pasture types, seed setting -	Hybridization, selection -	Grimm, *Medicago falcata*------	(4)	--------

[1] Unknown.
[2] In Province of Quebec.
[3] Not yet distributed
[4] Not yet released.
[5] Now in process.

Key to Some of the Commoner Species of Medicago

		Chromosome number (2n)
Pods not coiled, straight or curved; flowers yellow.		
Pods not flattened.		
Pods kidney-shaped, one seeded, style as long as ovary at time of blooming	M. LUPULINA	16
Pods straight or curved, several seeded, usually sickle-shaped, style never as long as ovary.	M. FALCATA	[1] 32
Pods flattened, at least twice as broad as in *M. falcata*.		
Pods large, oval, many seeded	M. PLATYCARPA (M. PLATYCARPOS).	16
Pods smaller, with about four seeds	M. RUTHENICA	16
Pods spirally coiled.		
Coil with an open center; plants perennial.		
Shrubby, 4 to 10 feet high; flowers large, yellow.	M. ARBOREA	32
Herbaceous plants; flowers usually not yellow.		
Pods but little coiled, less than a full spiral.	M. HEMICYCLA	32
Pods with one to several windings.		
Flowers uniformly violet or blue	M. SATIVA	32
Flowers variegated, white, yellow, and blue.		
Plants generally without rhizomes.		
Plants glabrous or slightly pubescent.	M. MEDIA	32
Plants glandular pubescent, especially pods and calyx and young shoots.	M. GLUTINOSA	32
Plants with long rhizomes; flowers, seeds, and pods larger than in *M. media*, pod with two and a half to four windings.	M. GAETULA	32
Coil with a closed center; flowers yellow; annuals.		
Pods generally spiny.		
Spines in a double row, those at top of bur turned upward to form a double crown.	M. CORONATA	16
Spines not as above.		
Leaves with a dark blotch in center; seed with a projection by the hilum.	M. ARABICA	16
Leaves without a dark blotch.		
Pods 7 to 10 mm across spines from half to whole width of winding.	M. HISPIDA	14
Pods as above, but spines shorter	M. HISPIDA DENTICULATA	14
Pods without spines.		
Pods small, about size of those of *M. hispida*.	M. HISPIDA CONFINIS	14
Pods much larger.		
Pods flattened; leaflet nearly orbicular	M. ORBICULARIS	16
Pods nearly spherical; leaflets nearly twice as long as wide.	M. SCUTELLATA	32

[1] Also 16

Brief Description of Certain Medicago Species With Particular Reference to Their Economic Desirability

Medicago platycarpa is a low-growing perennial with large broad leaflets, yellow flowers, and large flat pods, found mainly in Siberia. According to Hansen its distribution is mainly along the edges of timberland and in open places in the native

timber, indicating that it might be adapted to sheltered regions such as the timber sections of northern Minnesota and Wisconsin and westward into the Rocky Mountains.

M. ruthenica is a small semierect perennial with small narrow leaflets, yellow flowers, and small pods. Hansen found this species growing wild in a section of the Gobi Desert in nearly pure sand. In general it is found scattered in dry, stony soils. As a fodder plant this species is greatly relished by the cattle, horses, sheep, and camels kept by the Mongolian nomads. Its distribution is farther north than that of Common alfalfa (*M. sativa*).

M. arborea is the largest representative of the *Medicago* genus, attaining a height of upward of 10 feet. It is a native of the Mediterranean region of Europe and does not thrive in cold climates. It is cultivated to a limited extent in various portions of its range, but as it gets woody too quickly and is less productive than *M. sativa*, that species is much more in favor.

M. falcata is an upright to prostrate perennial with small elongated leaflets, yellow flowers, and falcate pods. It is distributed over a wide range in eastern Europe and western Asia. Apparently it combines readily with *M. sativa* to form many of the cultivated varieties such as Grimm and Cossack, which are classified as *M. media* in the foregoing key. Many strains, though not all, are very cold-resistant, and certain types also endure pasturing rather well. It is now being used in breeding programs to a considerable extent.

A point of particular interest has recently been raised by Fryer (*12*), who found different chromosome numbers in *M. falcata*. In two strains he found the number to be $2n = 32$, while in another strain he found it to be $2n = 16$. It is probable these two types would react differently in crosses.

M. gaetula is particularly noted for its rhizomes, by means of which it spreads readily like sod-forming grasses. It is now being used in crosses to produce pasture and soil-binding types.

M. glutinosa is a native of the Caucasus Mountains and Trans-Caucasia generally, especially of Armenia, where it is found up to an elevation of 7,500 feet. It is found growing in a very dry upland region and is more vigorous than most *Medicago* species of Caucasia.

M. hemicycla is found in the Caucasian region and is somewhat similar in morphological type to *M. media*. It is considered to be a natural cross between *M. sativa* and *M. falcata*.

M. coronata is remarkable on account of its very high drought resistance. It is an annual found in all parts of Palestine, but its occurrence on the mountain slopes is particularly interesting, as the soil there is only an inch or two deep over the rocks. The seed setting of this variety is also high.

McKee and Ricker (*21*) state that the nonperennial species of *Medicago* consist principally of bur-clovers, mostly annual plants native to the Mediterranean region. Spotted bur-clover (*M. arabica*), California bur-clover (*M. hispida*), and black medic (*M. lupulina*) are the only species now widely distributed in the United States. The feeding value of bur-clovers, both those with and those without spines, is good. Among the latter the three most promising are *M. confinis*, *M. orbicularis*, and *M. arabica inermis*.

IMPROVEMENT IN SOYBEANS

W. J. MORSE, Senior Agronomist,
J. L. CARTTER, Associate Agronomist, Division of Forage Crops and Diseases, Bureau of Plant Industry[1]

ONE of the most striking agricultural developments of recent times is the rapid rise of the soybean within the last few years from the position of a substitute and emergency crop to a place of considerable economic importance in American agriculture and industry. First introduced into this country in 1804, it was grown for many years only in gardens as a curious plant from the Far East. Its culture has now spread over much of the territory east of the Mississippi River, and it has become well established in the cropping systems of this area as well as in the States bordering the west bank of the Mississippi.

The high nutritive value of the plant and its seeds has made it particularly valuable as a livestock feed. The seed, with its by-products, oil and oil meal, have great commercial possibilities as a food and for industrial purposes. In spite of the extensive investigations that have been conducted, the work of developing this versatile plant to its fullest possibilities is still in its infancy. While much has been done in determining the genetic relations of many seed and plant characters, the plant breeder has many problems of a complex nature ahead in the development of new and better varieties for the various purposes for which the crop is now being used.

HISTORY OF THE SOYBEAN

THE early history of the soybean is lost in obscurity. Ancient Chinese literature, however, reveals that it was extensively cultivated and highly valued as a food centuries before written records were kept. It was one of the grains planted by Hou Tsi, a god of agriculture. The first record of the plant is contained in a materia medica describing the plants of China, written by Emperor Sheng Nung in 2838 B. C. The crop is repeatedly mentioned in later records, and it was considered the most important cultivated legume and one of the five sacred grains essential to the existence of Chinese civilization. Seed of the plant was sown yearly with great ceremony by the Emperors of China, and poets extolled its virtues. The records of methods of culture, varieties for different purposes, and numerous uses indicate that the soybean was perhaps one of the oldest crops grown by man.

Botanically the soybean usually has been referred to in literature as *Glycine hispida* (Moench) Maxim. In an extensive botanical

[1] The authors are greatly indebted to C. M. Woodworth and L. F. Williams, of the Illinois Agricultural Experiment Station, for their cooperation and suggestions in the preparation of this article.

study Piper (fig. 1) came to the conclusion that the soybean must be named *Soja max* (L.) Piper. Other botanists, however, consider *Glycine javanica* L. the type species of *Glycine* and call the soybean *Glycine max* (L.) Merrill.

The cultivated soybean is thought by many investigators to have been derived from *Glycine ussuriensis* Regel and Maack, which grows wild throughout much of eastern Asia. This species is prostrate in habit of growth, has long fine twining stems, small narrow leaves, appressed hairs, purple flowers, small compressed pods, and small oblong seeds of a sooty-black color. Karasawa (*9*)[2], on the basis of genetic data, believes the cultivated soybean might have been derived from this wild species through the qualitative and quantitative changes due to gene mutation, unaccompanied by any change in chromosomes. A plant with characters between the wild and the cultivated species has been described by Skvortzov (*33*) as *G. gracilis* Skvortzov.

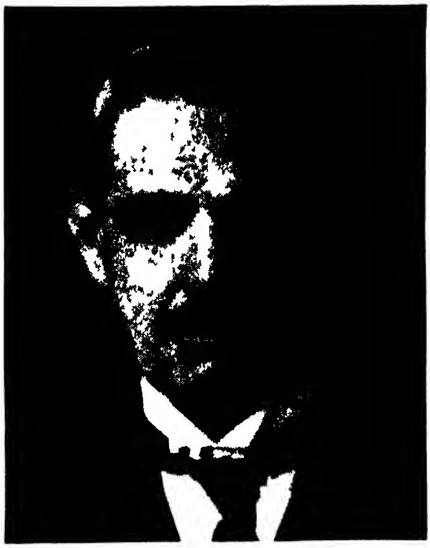

Figure 1.—The late Charles Vancouver Piper, agronomist, United States Department of Agriculture, 1902–26. Pioneer in the introduction and development of soybean varieties for United States conditions.

Europeans knew of soybeans in the seventeenth century, and they were tried in Germany, England, France, and Hungary but did not become commercially established in any part of Europe until in recent years.

The first mention of the soybean in American literature was in 1804, when James Mease wrote: "The soybean is adapted to Pennsylvania and should be cultivated." In 1889 W. P. Brooks, of the Massachusetts Agricultural Experiment Station, brought a number of varieties from Japan, and in 1890 C. C. Georgeson, of the Kansas station, secured three lots from the same country. Undoubtedly other early importations of seed from Asia were obtained through missionaries, but no definite records have been found. Since 1890 most of our agricultural experiment stations have experimented with soybeans and many bulletins have been published dealing wholly or partly with the crop.

In 1898 the Department started to introduce large numbers of soybeans. Previous to this there were not more than eight varieties, with limited adaptation to soil and climate, grown in the United States.[3] Since that time the acreage of soybeans in the United States has in-

[2] Italic numbers in parentheses refer to Selected References on the Genetics of the Soybean, p. 1181.
[3] The eight varieties of soybeans grown in the United States were Ito San, Mammoth Yellow, Butterball, Buckshot, Kingston, Guelph or Medium Green, Eda, and Ogemaw.

creased more than a hundredfold—from less than 50,000 acres in 1907 to nearly 5,500,000 acres in 1935. The increase in acreage and production in this country has been closely correlated with the introduction of varieties from the Orient and their development through selection.

WORLD DISTRIBUTION AND PRODUCTION

The soybean is grown to a greater extent in Manchuria, often called "The Land of Beans", than in any other country in the world (fig. 2). It occupies about 25 percent of the total cultivated area and is the cash crop of the Manchurian farmer (fig. 3). Chosen and Japan are large producers, and south of China the soybean is cultivated more or less in the Philippines, Siam, Cochin China, India, and the East Indies.

In the central part of the Union of Soviet Socialist Republics the districts of the Don and the southwest are said to be especially suited to the culture of this crop. In Czechoslovakia, in 1935, commercial beans were produced on a small scale. Rumania has also succeeded in growing soybeans of high quality, and the production of seed is rapidly increasing. In other parts of the world, particularly Germany, England, South Africa, British East Africa, Algeria, Egypt, New South Wales, and New Zealand, soybeans have been tried or are being grown in a small way.

In the Western Hemisphere the production of soybeans is concentrated chiefly in the Corn Belt region of the United States. In 1920,

---

ONE *of the most striking agricultural developments in the United States in recent times is the rapid rise of the soybean. In 1907 there were 50,000 acres; in 1935, nearly 5,500,000. In 1920, seed production was 3,000,000 bushels; in 1935, about 40,000,000. Remarkable progress has been made in the last few years in developing food and industrial uses. Soybean breeding to meet varied cultural, food, and industrial needs is being conducted by the United States Department of Agriculture and by experiment stations in 32 States, and more than 10,000 introductions have been made for study and experiment. In spite of extensive investigations, the work of developing this versatile plant to its fullest possibilities is still in its infancy. But though the plant breeder has many problems of a complex nature ahead, there appears to be no reason why it should not be possible, by selection and hybridization, to develop varieties that possess all, or nearly all, the important characters desired by oil processors and by manufacturers of food and industrial products.*

14 States produced 3,000,000 bushels of seed, the leading States being North Carolina, Virginia, Alabama, Missouri, and Kentucky—North Carolina producing about 55 percent of the total. By 1931, seed production had increased to nearly 15,500,000 bushels, with Illinois, Indiana, North Carolina, and Missouri leading. In 1935, about 40,000,000 bushels of seed were produced, of which about 37,500,000 bushels (92 percent) were harvested in Illinois, Indiana, Iowa, Missouri, and Ohio, the first three States producing about 87 percent of the total. In Canada, production is confined chiefly to the Province

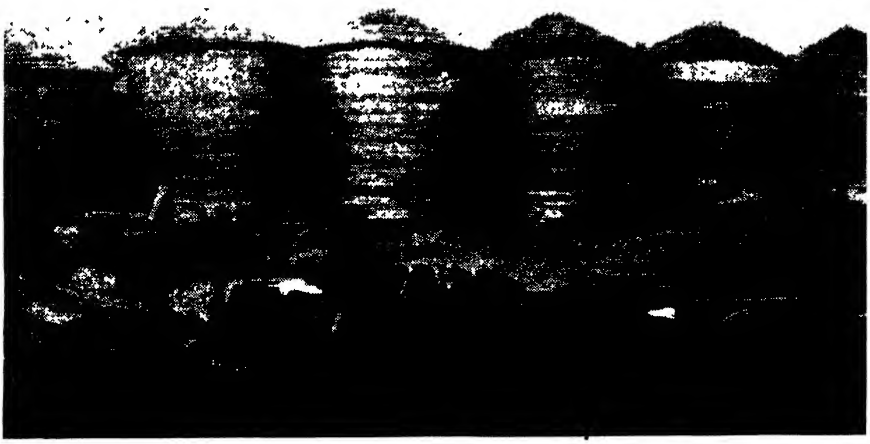

Figure 2.—Storage yard of a Chinese grain merchant near Kungchuling, Manchuria. More than 80 osier bins, each holding four carloads of soybeans, were in this yard.

of Ontario, where about 15,000 acres are planted to this crop. In other parts of the Western Hemisphere the acreage grown in any country is small.

Table 1 shows the increase in production of soybeans over an 11-year period, 1924–25 to 1935–36 inclusive, in the principal producing countries of the world.

TABLE 1.—*Increase in production of soybeans over an 11-year period, 1924–25 to 1935–36, inclusive, in the principal producing countries of the world* [1]

Country	Production in— 1924–25	Production in— 1935–36
	Bushels	*Bushels*
Manchuria	92, 667, 000	140, 444, 000
Chosen	18, 723, 000	[2] 21, 961, 000
Japan	15, 367, 000	[3] 13, 307, 000
United States	5, 190, 000	39, 637, 000
Netherland India	3, 536, 000	[2] 6, 676, 000

[2] 1934–35. [3] 1933–34 (decrease).

Figure 3.—The Manchurian farmer still harvests (*A*), threshes (*B*), and cleans (*C*) soybeans by hand methods inherited from his ancestors, whereas in the United States (*D*) modern machine methods are used.

UTILIZATION OF THE SOYBEAN

In the Orient the soybean is grown principally for the seed, which for centuries has been utilized in the preparation of a great variety of fresh, fermented, and dried food products indispensable in the diet of oriental people. Large quantities of beans are also crushed for oil, which is used for food and numerous industrial purposes; and the resulting cake or meal (fig. 4) is utilized chiefly as a fertilizer and to a small extent as feed for animals. European oil mills have for many years imported considerable quantities of soybeans from Manchuria (fig. 5) for crushing for oil and oil meal.

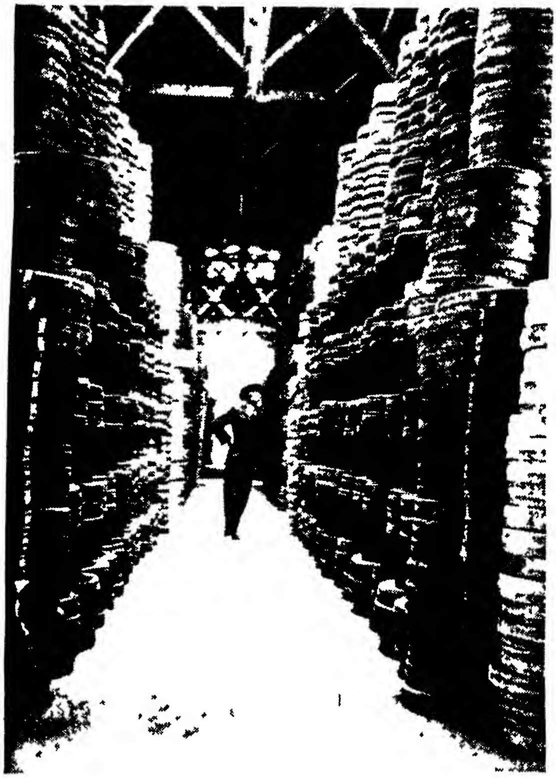

Figure 4.—Millions of soybean oil cakes are stored in warehouses in Manchuria awaiting shipment to Japan, Chosen, China, and the East Indies, where they are used for fertilizing purposes and for cattle feed.

The soybean is used in the United States primarily for forage purposes, being either preserved as hay or silage or cut and fed green as soilage. It is also pastured extensively with hogs and sheep, and is used to some extent as a green manure or cover crop For many years the increasing supply of seed was matched by a steady demand for planting the expanding acreage and for use as a stock feed, but eventually other outlets had to be found. About 1920 the possibilities in home-grown soybeans attracted the attention of oil mills, and by 1929 they began to be a potent factor in the production of the crop for commercial purposes. In 1926 slightly more than 2,500,000 pounds of oil were produced in the United States, while more than 200,000,000 pounds were obtained from the 1935 crop.

Remarkable progress has been made in the last few years in developing food and industrial uses for the soybean, the oil, and meal. At present about 45 oil mills, including a few cottonseed oil mills, are crushing soybeans; more than 40 concerns are manufacturing soybean food products and soybean flour; and more than 75 factories are

turning out various industrial products made from soybeans. Soybean oil has become an important product in many industries. In addition to the use of the meal in livestock feeds, considerable quantities are utilized in the manufacture of foods and industrial products. The high nutritional value of the soybean, known for many centuries in oriental countries, is becoming quite generally recognized in the United States. Many food concerns in various parts of the country are manufacturing numerous products wholly or in part from the soybean.

The following outline shows the diversity of uses to which the different products of the soybean are put:

SOYBEAN UTILIZATION

- Soybean
  - Plant
    - Forage. Green manure. Pasture.
      - Fuel.
      - Furfural.
      - Hay.
      - Silage.
      - Soilage.
  - Bean
    - Meal
      - Celluloid substitutes.
      - Core binder.
      - Feeds
        - Cattle.
        - Dogs
        - Fish.
        - Hogs.
        - Poultry.
        - Rabbits.
        - Sheep.
      - Fertilizer.
      - Glue.
      - Human food
        - Beer brewing.
        - Flour. (See Dried bean.)
        - Seasoning powders.
        - Soy sauce.
        - Vegetable milk.
      - Plastics.
      - Water paints.
    - Oil
      - Candles.
      - Celluloid.
      - Core oil.
      - Disinfectant.
      - Electrical insulation.
      - Enamels.
      - Food products
        - Butter substitutes.
        - Cooking oils.
        - Lard substitutes.
        - Salad oils.

IMPROVEMENT OF SOYBEAN VARIETIES

Soybean breeding is being conducted in the United States, Japan, Manchuria, China, India, Chosen, and the Union of Soviet Socialist Republics, and to some extent in a few European countries. As with other crops, the chief objective has been increased yield under local conditions. Within the last few years, however, with increased utilization of the soybean for industrial and food purposes, attention has also been given by plant breeders to the oil and protein content, the nutritive value, and the quality of beans.

In the United States, more than 50 percent of the acreage devoted to soybeans is used for forage and pasture; breeding work, therefore, has tended largely toward the development of varieties for hay, silage, and pasture. The development of such varieties as Virginia, Laredo, Otootan, Wisconsin Black, Manchu, Wilson-Five, Kingwa, Peking, and Ebony by selection from introductions has been the principal factor in the increased use and acreage.

Beginning with 1929, the use of soybean seed by oil mills has led to a demand for yellow-seeded varieties of high oil content. Agronomists and plant breeders have attempted to meet this demand by making large numbers of selections from foreign introductions and locally grown varieties and by analyzing these for oil content. This has brought about the development of several superior oil varieties and has resulted in a large increase in production of beans for milling purposes. The most popular of these varieties are Illini, Dunfield, Mukden, Mandell, Scioto, Mansoy, Manchu, Mamredo, Delsta, and Mandarin. Results of analyses with more than 1,000 selections and varieties have shown a range of from 12 to 26 percent in oil content. From studies of the oil content of varieties grown in a given locality,

it seems possible, from the breeding standpoint, to produce varieties high or low in oil, at least within the known ranges of variation exhibited by common varieties.[4]

Quality, which may include several characters, the most important of which are the iodine number and the lecithin value, is the chief factor in the use of soybean oil. The drying property of an oil is

Figure 6.—Prize winners. Manchurian farmers are awarded certificates and prizes for producing high-quality soybeans.

measured by the iodine number, that of linseed being about 180. In a large number of tests with varieties and selections of soybeans, the iodine number ranged from 118 to 141. The iodine number of the wild soybean was found to be 155. To give soybean oil a better drying quality for paint purposes, its number must be raised. On the other hand, it is stated that oil with a low iodine number is more suitable for food purposes. Lecithin, a phosphatic compound, of which egg yolk was the chief source of supply, is now being extracted from soybean oil on a commercial scale. It is used extensively in the baking and confectionery trades, and also in textile and leather industries. Varietal studies show a range of 1½ to 3 percent, according to variety. The development of varieties high in lecithin and high and low in iodine number offers a most promising problem to the plant breeder. The best procedure in breeding for quantity and quality

[4] The Agricultural Experiment Station of the South Manchuria Railway at Kungchuling, Manchuria, has conducted experiments for several years toward the selection of varieties for high oil content. One variety, the Kungchuling, with seed uniform in size and shape and an oil content of more than 20 percent, has been widely distributed. To encourage the growing of this variety in regions to which it has been found adapted, the Experiment Station holds an annual soybean fair at which prizes are given to the farmers having the highest quality of seed (fig. 6).

of oil in the soybean is without doubt to analyze adapted varieties and then to isolate the best line from the best variety.

The development of new industrial uses for protein from the soybean and the value of this constituent in foods and feeds has led investigators to give more attention to varietal differences in the amount and quality of protein. Extensive analytical tests show a range of from 28 to 56 percent of protein (moisture-free basis), depending on variety and locality. Investigations of the nutritive value of soybean protein have shown that it contains all the essential amino acids. Studies by the Bureau of Chemistry and Soils of the United States Department of Agriculture with several standard varieties show a wide range in percentage of three amino acids—cystine, tryptophane, and tyrosine—which indicates the possibility of developing varieties of high nutritive value for animal feeds and human foods.

In the Orient, soybean foods to a very considerable extent supply the protein that is furnished largely by meats in the diet of western people. Oriental varieties of soybeans are distinguished not only according to seed and plant characters but also according to use, as for bean curd, bean sprouts, confections, and other food products. Increased recognition of the nutritional value of the soybean in the United States has created a demand for varieties more suitable for this purpose, since the varieties generally grown for commercial uses are not desirable for food. The principal drawbacks to the use of dried beans have been the length of time necessary for cooking and the flavor. Experiments with a large number of selections and varieties used in the Orient showed considerable variation. Some were of excellent flavor and became soft in less than 2 hours of cooking, while others remained hard and had little flavor or a pronounced bean flavor. Several of the most promising have been tested in various sections and the Easycook, Bansei, Rokusun, Jogun, Chusei, and Sousei are now in the hands of growers and seedsmen. Experiments by commercial firms have shown that these varieties are superior to commercial varieties for the manufacture of food products, such as bean flour, roasted beans, bean milk, and bean curd.

In Japan, certain varieties of soybeans were found that were used solely as green shelled beans. Ranging in maturity from 75 to 170 days, many of these introductions, and selections from them, have been found especially promising for various sections in the United States. The vegetable soybean offers an excellent food of high nutritional value, especially in the fall when other green beans are lacking and in sections where the Mexican bean beetle prohibits the growing of garden beans. As a result of selection, cooking tests, and adaptation studies, eight green vegetable varieties—Hahto, Kura, Kanro, Hokkaido, Higan, Chusei, Sousei, and Jogun—have been introduced in various sections of the country.

Although the major objective of soybean breeding has been to increase acreage yields, increasing utilization for food and industrial purposes demands improvement in quality as well as yield. With the vast number of introductions now under test by the Department and State experiment stations, there appears to be no reason why it should not be possible, by selection and hybridization, to develop varieties that possess all, or nearly all, the important characters desired by oil processors and by manufacturers of food and industrial products.

ADAPTATION

The soybean seems to be peculiarly sensitive to changes of soil and climate. Differences in behavior of the same pure-line variety in different localities are often very striking, so much so that it is often difficult to believe the variety is the same. Obviously, this adaptation explains why practically every locality in the soybean regions of the Orient has its own local varieties. Of the many varieties introduced into the United States, the same variety has rarely been secured a second time unless it was obtained from the same locality. In the Orient, limited areas appear to have varieties adapted to their own soil and climatic conditions. For the most part, Japanese varieties are unsuited to Manchuria and Chosen (Korea), and on the other hand, few Manchurian and Korean varieties are suited to Japan. Very few Korean varieties are adapted to the soil and climate of Manchuria. In these countries centuries of experience, aided by natural crossing and natural selection, have brought about the development of varieties adapted to special purposes. In China, Japan, Manchuria, and Chosen varieties are found especially suited for bean curd, bean milk, bean sprouts, green vegetable beans, bean flour, bean confections, oil and oil meal, and fermented products. Different regions in these countries have their own different varieties for these purposes

One of the outstanding results of soybean improvement work in the United States has been the realization of the importance of varietal adaptation. Early investigators noted that introductions from various localities in the Orient differed widely in their adaptation to various regions or localities in this country. This led to the conclusion that by introduction and local selection strains adapted to all localities, conditions, and purposes could be developed. With the increase in the number of introductions and the development of new varieties from these for a greater range of soil and climatic conditions, the acreage in commercial plantings has increased.

In many regions of the United States adaptation experiments comparing standard varieties with newly developed sorts or new introductions indicate that the new types are better adapted than the commonly grown varieties, and it seems likely that varieties for different uses that suit requirements in nearly all our farming regions will be found. At present about 100 named varieties (see appendix, table 4) are generally grown or are being increased for greater distribution in this country. Although it would be highly desirable to limit the number of varieties in the trade, unfortunately each region must have locally adapted varieties suitable for different purposes in order to obtain the best results.

METHODS IN BREEDING

The soybean is normally a self-fertilized plant, the flowers being perfect, producing both pollen grains and ovules. The flowers are completely self-fertile, as shown by experiments carried on by Piper and Morse (*30*) at the Arlington Experiment Farm, Arlington, Va. (near Washington, D. C.), in 1909. Screened or bagged plants set pods and seeds as perfectly as plants in the open. Similar experiments by Woodhouse and Taylor (*54*) in India gave identical results. As

pollination occurs about as soon as the flower opens or a little before, there is little opportunity for cross-pollination to take place. However, natural crossing does occur. Since the plant is self-fertilized, the same general principles of breeding that apply to other self-fertilized crops may be applied to the improvement of the soybean.

Selection within self-fertilized plants is effective in purifying existing strains and makes some improvement possible, but variations are essential for any great improvement within a crop, and the only practical means the plant breeder has of inducing variations is by hybridization. By this method he may combine desirable characters from different varieties in one type and obtain plants that express a character to a greater or lesser extent than it was expressed in either parent. As with other crops, the major problem in the improvement of the soybean is to bring together into one type all the characters that are considered desirable for a certain set of conditions. From this standpoint, hybridization holds much promise for the development of special varieties of soybeans. This involves close study of wild and domestic species, varieties, and strains and their reactions to environment, as well as quantitative and qualitative analysis of oil, protein, and other constituents of the seed.

After varieties are selected or developed the grower faces the problem of maintaining them as pure strains. Commercial varieties of soybeans are in general relatively pure because the plant is self-fertilized. However, in a field of a single variety one often finds more or less offtype plants. Such mixtures may be brought about by careless methods of planting and threshing, by natural crossing, and by mutation. No natural crossing will result if mechanical mixtures are avoided. Mutations rarely occur and therefore are not an important factor. A variety can be kept relatively pure by careful methods of planting and threshing and by roguing out offtype plants.

Natural and Artificial Crossing

Previous to 1907 it was quite generally assumed that natural crossing in the soybean did not occur. In that year oddly colored seeds were noted in the variety rows and plots at the Arlington Experiment Farm, and were selected by Piper and Morse (*30*). The progeny of these seeds in 1908 showed segregation for various seed and plant characters. In that year more than 100 single plants of supposed hybrid origin were selected and most of these broke up in the following year in simple Mendelian proportions, indicating that they were natural hybrids. It is often easy to detect hybrids by the peculiar coloration of the seeds (fig. 7). Among the more striking colors are yellow or green with narrow streaks or bands of black or brown beginning usually at the hilum and extending over half or more of the seed, or mainly centered about the hilum. Hybrid plants are also often distinguished by the unusual form of the pods near the tips of the branches. They are more swollen and the seeds are more crowded than normal; the pods are often thinner walled and much less pubescent, sometimes being nearly smooth.

Natural crossing in soybeans has been studied to some extent by various investigators and it is quite generally agreed that a limited amount does occur, but that it is much less than 1 percent.

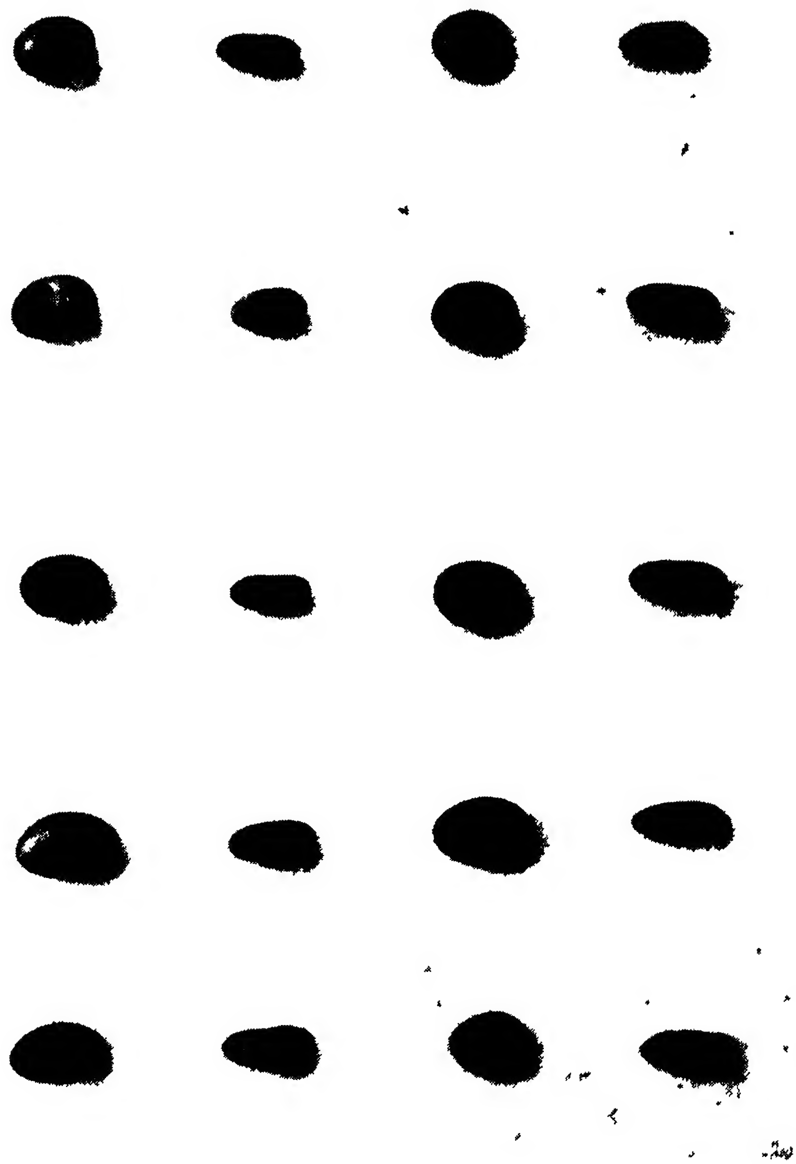

Figure 7.—Seeds of a natural soybean hybrid showing peculiar types of coloration.

Even this small amount of natural crossing undoubtedly is responsible for many of the mixtures now occurring in our standard varieties. The crossing is made possible by the mechanical mixing of seed through careless methods of planting and harvesting. After finishing with one variety, the planters or harvesters are not thoroughly cleaned before starting on another, so that the two varieties are mixed in the same field. An excellent illustration of this is afforded by the Mammoth Yellow variety now produced in eastern North Carolina. For many years this was the only variety grown in that section and it remained pure. As other varieties were introduced, the Mammoth Yellow seed became more or less mixed and it is now difficult to find fields without offtypes.

Natural crossing in soybeans is undoubtedly brought about by small insects. Thrips have been observed to be very common in the soybean flowers at the Arlington Experiment Farm. Bees and other insects have also been observed working on soybean flowers. Studies by many investigators at various places indicate that soybean plants growing in contact with one another are more likely to be crossed than plants separated by a few feet.

Because the flower is very small and easily injured, the work of making artificial crosses with the soybean is a difficult and tedious operation. Under field conditions at the Arlington Experiment Farm, Piper and Morse (*31*) made successful crosses in about 20 percent of the operations. In the greenhouse, where it is difficult to secure normal behavior in the soybean plant in winter, no success has thus far attended efforts to produce hybrids. Under winter conditions, the plants are small and bear few flowers, which do not develop and open normally and which apparently become fertilized in the very early bud stage. Woodworth (*63*), in crossing studies, found that soybean crosses can be made in the greenhouse as well as in the field provided artificial light is used. Light from 500-watt bulbs was used in the early stages of plant growth to induce good vegetative development, and then the light was shut off to induce flowering. The percentage of successful crosses is said to compare favorably with that ordinarily obtained under field conditions.

Crossing the flowers in the afternoon from 3 to 7 o'clock has given the best results, and it also has been found best to emasculate and pollinate a flower the same afternoon. Experience has shown that emasculation is the most difficult part of the operation and must be performed before the soybean flower has fully opened. All of the flower buds should be removed from the raceme except those to be crossed, and in these the purple or white of the corolla must have appeared above the calyx. At this stage, the 10 anthers surrounding the stigma (fig. 8) are immature and may easily be removed without bursting the pollen sacs. After emasculation, pollination is a relatively simple process, the pollen being applied to the stigma at once. In collecting the pollen for crossing, it is advisable to select well-developed flowers just before they open or fresh-looking flowers that have just opened. After the pollen has been applied, the raceme should be enclosed in a small paper or cloth bag, or a leaf may be pinned around it to protect the parts from excessive evaporation.

Mutations

The origin of new varieties of soybeans without hybridization has apparently occurred in several instances that have come under the observation of investigators. Piper and Morse (*30*) cite a case in which a brown-seeded type, the Trenton, arose as a mutation from a yellow-seeded variety, the Mammoth Yellow. Grown side by side at the Arlington Experiment Farm, these varieties were indistinguishable by any character other than the seed color. Woodworth (*63*) explains this by assuming that the gene designated as *ii*, carried by the Mammoth Yellow variety, mutated to the gene designated as *i*, and that this permitted the brown pigment of the Mammoth Yellow hilum to extend over the whole seed coat to produce a brown bean.

A more recent mutation gave rise to the Avoyelles variety. This variety with medium-sized black seed was selected in Louisiana from a field of Otootan, a small black-seeded type, and it gave uniform progeny that in many characters is superior to Otootan. Stewart and Wentz (*36*) discovered a recessive glabrous type which they designated by the symbol p_2 and assumed that it arose as a mutation. Woodworth (*63*) notes the following mutations that have come under his observation: Dark to light pod, normal plant size to dwarf, normal green plant to variegated, and black hilum to brown hilum. In addition to these he has noted a few mutations in vegetative cells that resulted in "chimeras" of various kinds.

Hybrid Vigor

The phenomenon of heterosis, or hybrid vigor, in soybeans was first reported by Wentz and Stewart (*50*), who found in the first-generation hybrid of some crosses considerable increases in height of plant over the average of the parents. Still greater evidences of hybrid vigor were shown by the hybrids in yield of seed, the percentage increases over the parents ranging from 59.58 to 394.37. Studies on hybrid vigor involving a greater number of crosses and more characters were made by Veatch (*46*). In 16 crosses the characters in which the hybrids exceeded, on the average, even the better parents, and therefore the characters in which hybrid vigor was shown, were the following: Number of pods per plant, plant weight, plant height, total stems and branch length, number of nodes, days from planting to flowering, seed weight or yield, and number of seed. Considerable variation, however, was found among the hybrids in the extent of hybrid vigor. Although the average of all the hybrids was higher in all characters studied than the average of all the parents, the average of all the better parents exceeded the average of the hybrids in average seed weight, number of seeds per pod, ratio of straw to grain, and average internode length.

Nagai (*22*) also reports that the individual of the first hybrid progeny is extremely prolific in comparison with its parents. In a cross between the Akazaya (seed yield per plant 34.18 grams) and the Hashikawa Yellow (seed yield per plant 34.18 grams) varieties, the first-generation hybrid yielded 52.97 grams and the first generation of the reciprocal cross 54.84 grams. In two other crosses similar evidences of hybrid vigor were shown in yield of seed over the parents. The problem of utilizing this hybrid vigor for increased production is rather complicated, and in order to make any definite progress more extensive investigations are essential.

INHERITANCE STUDIES AND CYTOLOGY[5]

The many strains differing widely in plant and seed characters and the almost complete self-fertility of the soybean make it an excellent plant for genetic study. The tediousness and difficulty of artificial crossing undoubtedly have been the chief reasons why more extensive genetic analysis of the plant has not been undertaken. Woodworth (*63*) and Nagai (*22*) have perhaps made the most substantial contributions. Considerable information has been collected on the behavior of progeny of natural and artificial hybrids, the most important features of which are presented herein under discussions of various plant and seed characters.

Plant Characters

Flower, stem, pubescence, and foliage

Soybean flowers occur in two colors, purple and white. While variations in intensity and grade of color occur in the purple-flowered varieties, no attempt has been made to differentiate them except by Nagai (*22*) and Takahashi and Fukuyama (*42*). Skvortzov (*33*)

[5] This section is written primarily for students or others professionally interested in breeding or genetics.

mentions a wild species of soybean with yellow flowers in Manchuria. This is perhaps an error, as there has been no hint of yellow flowers in the 10,000 or more introductions of cultivated and wild varieties and strains from all parts of the world, studied by the Department and numerous State experiment stations. In crosses, Woodworth (*58*) found purple (*W*) dominant to white (*w*), with a simple ratio of 3 purple to 1 white in F_2. A dihybrid ratio of 9 purple, 3 purplish red, and 4 white was obtained in an F_2 generation by Takahashi and Fukuyama (*42*). Nagai (*22*) reports purple dominant to white in a simple segregation ratio, or the segregations may be observed in three colors, purple, purplish blue, and white in a 9.3:4 ratio, the purple in the case evidently being determined by two factors. Piper and Morse (*31*), in both artificial and natural hybridization, found flower color to separate in simple Mendelian ratio, the purple flowers being dominant.

The stems of soybean seedlings are either purple or green, the purple color being most abundant just below the cotyledons. Purple-stemmed plants bear purple flowers and green-stemmed plants bear white flowers. In extensive tests at the Arlington Experiment Farm no exception was found to this relationship. Woodworth (*63*) reports similar results and states that the same gene probably is responsible for both characters. Stem color is undoubtedly a reliable indication of the flower color to be shown later by the plant.

According to Nagai (*22*), many Japanese varieties of edible soybeans have a special character known as fasciation (fig. 9). In crosses of such plants with normal plants, Woodworth (*63*), Takagi (*39*), and Nagai (*22*) found fasciation to be recessive, and in F_2 a ratio of 3 normal to 1 fasciated was obtained.

Nearly all varieties of soybeans are pubescent, that is, the stems, leaves, and pods are covered with fine tawny (brown) or gray hairs. In most cases there is no difficulty in distinguishing the two colors, but in some instances in selection from natural hybrids the pubescence color often is intermediate between gray and tawny, and sometimes both colors appear on the same plant. With artificial hybrids, the colors of pubescence have behaved in the same way as with natural hybrids. Tawny pubescence (*T*) is dominant to gray (*t*), and in F_2 a simple ratio of 3:1 is obtained.

Several yellow-seeded Japanese varieties, such as the Hadaka and Mizukuguri, are entirely glabrous, that is, lack pubescence or hairiness. These glabrous varieties of early, medium, and late maturity have been found by Japanese investigators to be highly resistant to attack by the pod borer (*Laspeyresia glycinivorella* Mats.), while pubescent varieties are highly susceptible to injury from this pest. In the United States, Johnson and Hollowell (*8*) found glabrous varieties subject to considerable injury from the leafhopper (*Empoasca fabae* (Harris)), while pubescent varieties were immune. According to Woodworth (*63*), glabrous soybeans fall into two distinct types. When crossed with pubescent varieties, one type behaves as a dominant while the other type behaves as a recessive. In each case the ratio is 3:1, indicating that a single factor pair is involved. Nagai and Saito (*23*) discovered the dominant type and Stewart and Wentz (*36*) the recessive. Glabrous soybean plants are smaller, shorter, and

Figure 9.—A, Stems and pods of fasciated soybean plants, *B*, determinate pod bearing type; *C*, indeterminate pod-bearing type.

yield less than most pubescent plants, according to Nagai and Saito (*23*) and Owen (*25*). Nagai (*22*) had one case in which strictly glabrous plants occurred in the F_3 generation in a cross of pubescent parents. The occurrence of this glabrous progeny was attributed to mutation.

In a study of the differences in amount of pubescence in American and Indian varieties, Woodhouse and Taylor (*54*) noted that the leaves of the Bengal "types I–V" differ from those of the Nepali "type VI" and the American varieties in being covered with soft upright hairs on their upper surfaces, whereas, the upper surfaces of the latter are covered with closely appressed hairs. In a cross between the cultivated and the wild soybean (*Glycine ussuriensis*), Karasawa (*9*) found appressed pubescence in the wild soybean dominant to erect in the cultivated soybean, the segregation occurring in accordance with the monohybrid ratio.

A wide variation occurs in the leaves of soybeans, involving shape, size, color, and degree of persistence. These characters merge by insensible degrees so that they are useful in differentiating varieties only in extreme cases. In shape the leaflets in some cases are ovate-lanceolate or almost linear; in others, nearly orbicular. In color they are usually a pale green but in some varieties dark green. In nearly all varieties the leaves commence to turn yellow as the pods begin to ripen and commonly all have fallen when the pods are mature. A few varieties, however, like the Medium Green, Old Dominion, Kingwa, and Wisconsin Black, retain their leaves until all or nearly all of the pods are mature. It has been quite generally observed that varieties with yellow cotyledons have leaves that turn yellow as they mature whereas some varieties with green cotyledons have leaves that remain green and persist until maturity. It is believed that the retention of green in the leaves is associated or tied up with the green cotyledon color and is separate and distinct from the simple retention of leaves by the plant. Additional leaflets occur not uncommonly in several varieties. This seems to be especially true with the linear-leaved form and with several early green-vegetable varieties from Japan, which frequently have leaves with four or five leaflets.

According to Nagai (*22*) there are two kinds of yellow leaves. One is greenish yellow from the beginning of growth and has little chlorophyll. The other has a normal or nearly normal amount of chlorophyll when young, but the leaves turn yellow as the plant grows. It was found that when either kind is crossed with a green-leaved variety, yellow leaves are recessive to green leaves, segregating in a 3:1 ratio in the former and in a 15:1 ratio in the latter.

Takahashi and Fukuyama (*42*), in studies of hybrids between normal and narrow-leaflet forms, found the F_1 generation to be intermediate, and in the F_2 a ratio of 1:2:1 was obtained. Woodworth (*63*) found essentially similar results in crosses between normal and narrow-leaflet forms, except that the broad shape was partially dominant and the F_2 generation was made up of two main forms, broad and narrow, in a 3:1 ratio. There were a few F_2 plants, however, that seemed to be intermediate in leaflet shape between the two parents.

In a cross made by Takahashi and Fukuyama (*42*) between a variety showing 73 percent of the compound leaves with extra leaflets and a normal variety the hybrid showed 52 percent of the compound leaves with extra leaflets. In the F_2, however, a ratio of 3 plants with extra leaflets to 1 normal plant was obtained.

Woodworth (*63*) found in the F_3 generation of a hybrid a single plant with variegated leaves. As neither parent possessed this character, it was supposed that the variegation arose as a mutation. In crosses with normal and variegated plants, variegation proved to be recessive. While the deviation from the expected 3:1 ratio was rather large, it was believed that variegation (v_1) is a simple recessive to normal in inheritance. Takagi (*39*) has reported a type with greenish-yellow leaves that appeared in one-sixteenth of the F_2 progeny of a cross between two normal, green-leaved plants.

Height of Plant and Maturity

Two cases of inheritance of size in the soybean plant have been reported in which definite segregation in plant height was observed. Woodworth (*58*) describes a natural hybrid that segregated in the ratio of 3 tall-growing plants to 1 short, stocky, early-maturing plant. Stewart (*34*) reports a dwarf form that behaved in inheritance as a simple recessive to the normal.

In soybeans there is a complete series of varieties ranging from very early (about 75 days) to very late (200 days or more). With very few exceptions earliness is correlated with size, the tallest varieties being latest. The maturity character usually has a complicated mode of inheritance because it is determined by numerous genes. Woodworth (*58*), however, describes a progeny of plants that segregated for two plant sizes, tall and short, in a 3:1 ratio. Coupled with plant size was a difference in maturity. The tall variety matured usually about 2 weeks later than the short variety. In this case, late maturity was dominant. Studies by Veatch (*46*) tended to confirm this, but Owen (*25*) found the F_1 of crosses between early and late varieties to resemble the early in time of maturity more than the late, and in F_2 the range in maturity due to segregation covered the entire parental range.

Pod-Bearing Habit and Pod Characters

In a classification of soybean varieties Etheridge, Helm, and King (*5*) placed 100 or more varieties into classes with respect to pod-bearing habit as determinate and indeterminate (fig. 9). The determinate class has a dense array of pods on the central stem, terminating in a blunt apex, with a thin dispersal on the lateral branches. The indeterminate class has a sparse and comparatively even distribution of pods over all branches and stems, a diminishing frequency toward the top of the central stem being notable. Woodworth (*63*) obtained a segregation for pod-bearing habit of 69 indeterminate plants to 19 determinate plants, a single-factor difference appearing to be involved.

The pods of the soybean exhibit a wide variation in color, ranging from very light straw yellow through numerous shades of gray and brown to black. As yet very little work has been done in classifying varieties as to pod color or in studying pod-color inheritance; however, pods usually have been divided into two groups—dark pods, which are

mostly black or nearly so, and light pods, ranging from a very light tan to light brown. In inheritance studies, Woodworth (*58*) and Piper and Morse (*31*) found dark pods dominant to light and in the F_2 obtained a ratio of 3 dark to 1 light.

While the pods in most varieties of soybeans are distinctly compressed, some are cylindric, and all possible intermediate forms exist. Nagai (*22*) places pods into two general classes, flat and bulky. In crosses he found the segregation of these two characters quite distinct, the flat (compressed) being dominant to the bulky (cylindric).

Soybean pods in most varieties contain two to three seeds, rarely one or four. The linear-leaf soybeans from Manchuria possess a large percentage of four-seeded pods, although a few five-seeded pods have been found. Without doubt, seed number per pod is a hereditary character, although in some instances it is quite unstable, depending upon method of culture, season, and fertility of the soil. Nagai (*22*), in a cross between two-seeded and three-seeded varieties, found that about 70 percent of the pods that segregated in the F_2 generation were two-seeded.

Under changeable weather conditions most soybean varieties tend to shatter their seeds readily. Some varieties, however, such as the Biloxi and Manchu, have been noted that hold their seeds better than others. The wild soybean shatters very easily and the Medium Green begins to shatter with the first mature pods. Piper and Morse (*31*), in a cross between the Medium Green and a glabrous nonshattering variety (F. P. I. No. 22876) from Japan, found the nonshattering character to be dominant to the shattering character of the Medium Green. Nagai (*22*) found in hybrid progeny of cultivated and wild soybeans that the shattering character was dominant to nonshattering, the segregation ratio in the F_2 being 3 shattering to 1 nonshattering.

Sterility, Growth Habit

As early as 1908, Piper and Morse (*31*) found small dwarflike plants, bearing few or no pods, in the different hybrid selections at the Arlington Experiment Farm. These plants were sterile or nearly so. Owen (*28*) describes a sterile strain in which both ovules and pollen grains were nonfunctional. This strain was found in a progeny of Manchu soybeans that segregated into 3 normal to 1 sterile, apparently a single-gene mutation being responsible.

All soybeans are strictly determinate as to growth, that is, the plants reach a definite size according to environment and then mature and die. The great majority of varieties are erect and branching with a well-defined main stem. The branches may be all short, or the lower ones elongated, either spreading or ascending. In other varieties the stems and branches, especially the elongated terminals, are more or less twining and usually weak, so that the plants are only suberect or even procumbent. The latter kind is represented by varieties from India and certain Siberian varieties of *Glycine gracilis*. The stem of the wild soybean (*G. ussuriensis*) is long and twining with a procumbent habit. Karasawa (*9*) in crossing experiments with the wild and cultivated soybeans found the F_1 hybrid of a twining nature. All of the plants of the F_2 and F_3 generations were more or less twining.

SEED CHARACTERS

Color of Seed Coat, Hilum, and Cotyledon

Most varieties of soybeans have unicolored seeds of straw yellow, olive yellow (greenish yellow), green, brown, or black. In some varieties straw-yellow seeds are very pale, especially when old, and they are sometimes erroneously called white, but no truly white seeds are known in soybeans. In straw-yellow varieties, the seeds have a greenish tinge if harvested before they are fully mature, which sometimes makes it difficult to distinguish them from varieties whose fully mature seeds are greenish yellow. Bicolored seed occurs in several varieties such as Black Eyebrow, Meyer, Taha, and Kura. The most common of the bicolored patterns is green or yellow with a saddle of black or brown, the latter not being sharply delineated. Some varieties have their seeds brindled brown and black, the two colors somewhat concentrically arranged. One variety has black seeds faintly marked with minute brown specks. On heterozygous plants the seeds are often irregularly bicolored and in some cases tricolored. Several black and a few brown varieties, with the outer layer of the testa broken by numerous cracks so as to expose the inner white layer, have been introduced from Chosen. In the case of the black-seeded and one or two brown-seeded introductions, this splitting has a net-like appearance that gives the beans a black-and-white or brown-and-white color.

Individual selections of natural hybrids by Piper and Morse (*31*) at the Arlington Experiment Farm gave some rather interesting results in the breaking up of the various seed colors. The selections with a single seed color, as straw yellow, black, or brown, broke up in simple Mendelian proportions, while those with more than one color presented a different ratio in the progeny.

Nagai (*20*) makes the following classification of soybeans according to color of seed coat:

(1) Beans producing no anthocyanin pigment in the seed coat.
(2) Beans producing anthocyanin pigment in the seed coat.

Owen (*27*) found the following classification of seed-coat color in soybeans most useful for the purpose of interpreting Mendelian characters:

(1) Self-color type.
(2) Bicolor type.
(3) Eyebrow pattern with green or yellow background.
(4) Green or yellow seed coat with dark hilum.
(5) Green or yellow seed coat with light hilum.

The genetic relationships of seed-coat colors and the effect of other genes on the colors have been studied extensively by Woodworth (*55*), Nagai (*22*), Owen (*27*), Terao (*43*), and Stewart (*35*). The inheritance of seed-coat color in soybeans differs somewhat from that of other members of the legume family. In soybeans, those seed-coat colors producing no plastid pigments as a rule mask those producing plastid pigment. The black pigment, according to Owen (*29*), is a very intense purple belonging to the general class of anthocyanins. The brown pigment is closely related to quercetin, and the green and yellow are plastid pigments.

According to Woodworth (*55*), the black and brown pigments are genetically independent of green and yellow in inheritance. Black is dominant to brown, and in F_2 a ratio of 3 black to 1 brown is obtained. Green is dominant over yellow, and in F_2 a ratio of 3 green to 1 yellow is obtained. When black or brown is crossed with green or yellow, the results are influenced by genes for inhibition of black and brown pigments over the seed coat. Owen (*27*) cites a case of incomplete dominance over brown. A natural hybrid was accidentally found that segregated according to a ratio of 3 black to 1 brown in the progeny that was grown, but all heterozygous plants bore seed slightly speckled with brown. It is believed that this brown speckling or flecking on the black seed coat is different from that symbolized by Woodworth (see table 2, symbol *Fl.*).

Varieties of soybeans exhibit a wide range of color types in the hilum, ranging from a pale-yellow or colorless hilum through various shades of brown to black. Two complementary genes for black pigment formation in the seed coat and hilum have been affirmed by Nagai (*22*), Woodworth (*55*), and Owen (*27*). The symbols for these genes were designated *C* and *L* by Nagai, *B* and *H* by Woodworth, and *R* and R_2 by Owen, the symbolism given by Owen appearing to be preferable according to Woodworth (*63*). In some early experiments which led to the suggestion of complementary factors for black hilum, Woodworth (*55*) obtained, in a cross between a strain with a black hilum and a strain with colorless hilum, black- and brown-hilum plants in the ratio of 9:7 He pointed out, however, that the ratio probably was 9 black: 6 brown: 1 colorless, because, on account of mottling of the seed coat, the plants having seed with brown hilums could not be easily distinguished from plants having seed with colorless hilums, and consequently they were classed together. Nagai (*22*) found in a cross between a plant having seed with a light-brown hilum and a plant having seed with a dark-brown hilum that the F_1 plants have slightly brownish seed and the F_2 may be dark brown, brown, and light brown in a 1:2:1 ratio. Woodworth (*63*), in crosses with parents of dark-brown hilum and light-brown hilum, found that the difference in the intensity of hilum color is due to the genes *T*, *t*, for tawny *v.* gray pubescence. Plants with *T* have dark-brown hilums, and plants with *t* have light-brown hilums. The genes for purple and white flowers (W_1w_1) have also been found to influence black and brown seed coat or hilum colors.

The cotyledons in the soybean are of two colors, yellow and green. When young the cotyledons are green, but in most varieties they turn to yellow toward maturity, while some varieties retain the original green. The behavior of the green and yellow cotyledons in natural and artificial hybrids has given some very interesting results. In 1909 Piper and Morse (*31*) noted in hybrid selection work that, with many plants having straw-colored to greenish-yellow seeds, seeds with green cotyledons and seeds with yellow cotyledons occurred on the same plant and sometimes in the same pod. These plants produced three kinds of progeny— those bearing only yellow-cotyledon seeds, those bearing only green-cotyledon seeds, and those bearing both kinds. The ratio was approximately 1:1:2, respectively, indicating that yellow was a simple Mendelian dominant to green. This

segregation in cotyledon color has been confirmed by Woodworth (*55*), who found evidence for two (duplicate) genes for yellow cotyledon. Terao (*43*) found in crosses that the cotyledon color of the hybrid progeny was the same as that of the female parent in every case and that there was no evidence of segregation in succeeding generations, indicating that cotyledon color in soybeans is maternal in inheritance. Maternal inheritance of cotyledon color in the soybean has been substantiated by Piper and Morse (*31*) and by Owen (*24*).

At least two kinds of transmission of the colors of the cotyledon are known. One is transmission through the maternal plant—that is, if the female parent is yellow the cotyledon of F_1 becomes yellow, and if it is green F_1 shows green cotyledons. Terao (*43*) suggests that there are two factors, *G* and *Y*, representing chlorophyll in two cotyledon colors. *G* is the one that always remains green and *Y* is the one that changes to yellow. In the other case of the inheritance of the cotyledon color, a simple Mendelian ratio has been obtained in F_2 in which yellow- and green-cotyledon seeds occur in a 3:1 or 15:1 ratio according as the parents differ by one or more genes.

Other Seed Characters

Defective or cracked seed coats have been observed by several investigators in black-, brown-, and yellow-seeded varieties and rarely in those having green seed. In some yellow and green seeds mottled with brown, the defects, or cracking, are found to occur mostly in brown areas. The character is undesirable, for in the defective or cracked areas the very thin inner coat cannot furnish the protection against unfavorable weather and disease organisms that is afforded normal soybeans in which the seed coat completely covers the seed. Stewart and Wentz (*37*), in a cross between the Wisconsin Black and Mandarin varieties, obtained in the F_2 51 normal to 5 defective or cracked, suggesting a 15:1 ratio. Nagai (*22*), in a cross between plants with normal and defective seed coats, found the defective or cracking character to be partially dominant. In F_2 a large number of individuals were produced showing different degrees of cracking, a rough estimate giving a ratio of 9 defective or cracked to 7 normal.

Nearly all varieties of soybeans have a comparatively smooth seed coat but differ more or less in the degree of smoothness. In some varieties the seed coat is rather dull in appearance, while in others it is bright and glossy. In the variety Sooty, some black and brown Siberian varieties of *Glycine gracilis*, and the wild soybean there is a distinct bloom covering the entire seed coat. The bloom can easily be scraped off, exposing the comparatively smooth seed coat underneath. In a cross between the Sooty and Manchu varieties, Woodworth (*63*) obtained a 3:1 ratio in the F_2 generation, while in another cross a 27:37 ratio was found in the F_2. In interpreting these ratios, he assumes that three genes, B_1, B_2, and B_3, are involved and that all three must be present together to manifest the bloom. If any one of these genes is not present, the character does not develop.

The range in size of soybean seed varies according to the variety, each variety having its own typical seed size. Varieties and introductions tested at the Arlington Experiment Farm ranged in average weight of 100 seeds from about 4 grams for the smallest to about

40 grams for the largest. Although seed size is mentioned in numerous published descriptions of soybean varieties, Nagai (*22*) and Takagi (*39*) are apparently the only investigators who have made studies of the inheritance of this character, the same results being obtained by both. In a cross of small seed (100 seeds=10.2 grams)×large seed (100 seeds=25.5 grams) Nagai obtained from the F_1 generation seed intermediate in size (100 seeds=14.2 grams). The segregation in the F_2 plants gave a wide range of variation between the seed sizes of the parent. Nagai states that it is very difficult to find plants bearing seeds of the same size as those of the larger plant and believes that many factors are involved in the inheritance of size of seed.

A considerable mottling of the seed of many yellow- and green-seeded varieties occupied the attention of plant breeders more than a decade ago. This mottling consisted of patches, blotches, or bands of black or brown pigment, irregular in outline and extent, superimposed on a ground color of yellow or green. Seeds with black hilums were mottled with black, and seeds with brown or colorless hilums were mottled with brown. In 1924 Woodworth and Cole (*66*) described the character and believed the cause to be physiological rather than genetical. After further studies, Woodworth states that the problem of mottling has some genetic aspects and also that a strain may be developed by selection that lacks the objectionable feature of mottling exhibited by the original variety. This is substantiated by selection of nonmottling plants from the Dixie variety, resulting in a pure yellow-seeded strain. Owen (*26*) concluded after an extensive investigation of this subject that mottling is due both to hereditary and environmental factors. In artificial hybrids the pubescence color was found in one instance to influence the extent of mottling, tawny pubescence increasing it, gray pubescence decreasing it. Owen, however, could not designate any particular factor as being the most important in causing mottling. The problem had certain genetic aspects, but the environmental effects were also quite evident. In recent years, mottling has not appeared to any great extent and it has been suggested that perhaps the wider use of varieties not subject to mottling has been an important factor.

Yield of Seed

In considering the most desirable character in varieties of soybeans, the most valuable single desideratum, as with other crops, is high yield of seed. Other characters of course are important, such as habit of growth, seed quality, color of seed, ease of shattering, etc., but extensive tests are being conducted at experiment stations in States where soybeans are an important crop to determine the best yielding varieties.

From the standpoint of inheritance, seed yield is a very complex character. The amount of seed produced is determined by heredity and environment (soil fertility, soil type, method of culture, and seasonal conditions). Woodworth (*63*), in studies of the yield character, has analyzed yield of seed into its component parts—number of nodes, number of pods per node, number of seeds per pod, percentage of abortive seed, and size of seed—and attempted to evaluate each variety studied with respect to these components. The general

situation was that any particular variety was found to rank well in one or more components and low or medium in others. No variety was found to rank highest in all. The conclusion reached was that the method of cross-breeding that has for its object the production of types with all yield components expressed to a higher degree than in the parents appears to be a promising method of breeding for increased seed yield in the soybean.

Disease Resistance

Although the soybean is attacked by a number of bacterial and fungus diseases, none of which reach serious proportions in oriental countries, no one disease as yet has caused serious injury to the crop in the United States. As cultivation continues, however, diseases undoubtedly will increase and assume more serious proportions. Breeding for disease resistance, therefore, may become an important factor in the improvement of the soybean. Studies of the various diseases of the soybean already found in this country indicate that varieties differ markedly in relative resistance to certain bacterial and fungus diseases.

Woodworth and Brown (*65*), in studies on varietal resistance and susceptibility to bacterial blight (*Bacterium glycineum* Coerper), found that field experiments indicated that soybean varieties vary greatly in their relative susceptibility to the bacterial blight. Of 48 varieties studied, about half were completely resistant, and the other half ranged from complete susceptibility to partial resistance.

A bacterial blight (*Bacterium sojae* Wolf) of soybeans was found on a number of varieties in North Carolina by Wolf (*52*). Studies failed to disclose any evidence of varietal resistance or susceptibility in any of the varieties.

Lehman and Woodside (*16*) made a very extensive study on resistance and susceptibility of soybean varieties to the bacterial pustule disease (*Bacterium phaseoli sojense* Hedges). After field observations and inoculations in greenhouse plantings, they were able to classify 56 varieties with respect to their resistance and susceptibility to the disease.

Extensive studies and experiments have been made on the mosaic disease of soybeans by Kendrick and Gardner (*13*). Results indicated quite clearly that varieties differ greatly in relative resistance and susceptibility.

"Brown spot" (*Septoria glycines* Hemmi), a fungus disease attacking the foliage of the soybean, has been studied by Wolf and Lehman (*53*), who noted differences among soybean varieties in relative resistance and susceptibility.

Another fungus disease, fusarium blight (*Fusarium bulbigenum* Cke. and Mass. var. *tracheiphilum* (E. F. Sm.) Wr.), was observed in North Carolina by Cromwell (*3*). In extensive variety tests, all varieties were found susceptible with the exception of the Black Eyebrow, which in two tests showed considerable resistance.

Lehman (*15*), in a study of another disease, frogeye leaf spot (*Cercospora daizu* Miura), attacking the foliage of the soybean, found that the early-maturing varieties in a certain group escaped serious injury while the late-maturing sorts suffered most.

Identification of Genes and Chromosomes

Several synonymic difficulties were encountered in establishing the identity of genes that different investigators have studied and designated differently. In cooperation with Woodworth and Williams, of the Illinois Agricultural Experiment Station, literature on the genetics of the soybean was reviewed thoroughly as to the genes of the soybean, and symbols were designated for each by the various geneticists. Liberty was taken in some cases to assign symbols to genes that have been studied but not named and certain symbols have been changed

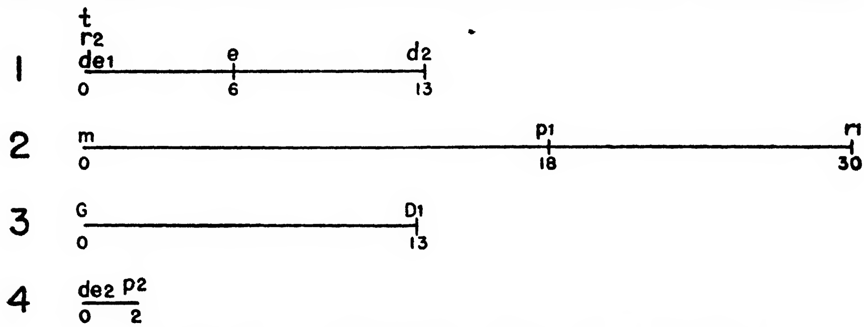

Figure 10.—Chromosome chart showing four groups of linked genes in soybeans. (Courtesy of C. M. Woodworth and L. F. Williams, Illinois Agricultural Experiment Station.)

(Woodworth, *63*) in order to bring them into line with current usage. Every effort has been made to make the list given in table 2 of the appendix as complete as possible, and it is hoped that the list given here will help to establish greater conformity in the designation of soybean genes in the future.

According to counts made by Karpetschenko, Kawami, Fukuda (Karasawa, *9*), and Veatch (*48*), the chromosome number in soybeans is given as 20 for the haploid and 40 for the diploid condition. The same number has also been counted in the wild soybean by Tschechow and Kartaschowa (*45*), as well as Fukuda (*6*). In F_1 hybrids between the wild and cultivated species of soybeans, Karasawa (*9*) found the same somatic chromosome number as in the parents. No abnormalities were found in the pollen mother cell in the course of sporogenesis, and the pollen therefrom was normal. Moreover, the fertility of the F_1 and its progeny was quite normal, indicating that the two species contain on the whole the same kind of genom.

Linkage studies in the soybean have not been very extensive, due largely, perhaps, to the difficulty of making artificial crosses. Woodworth, Nagai and Saito, Owen, and Stewart and Wentz have been the chief contributors to our meager knowledge of the association of genes in inheritance in the soybean. In table 3 of the appendix are shown the linkage groups reported up to the present time.

A provisional chromosome map of soybeans showing linkage relations of a few factors is given in figure 10. In chromosome 1, the gene order may not be as represented, since E and D_2 have not been studied together. In chromosomes 3 and 4, the order may be as represented or reversed.

TABLE 2.—*List of genes in soybeans*

Symbol	Dominant-recessive characters	Authority	Date published, observed, or reported
A	Appressed pubescence; a, erect pubescence	Karasawa	1936
B_1, B_2, B_3	Complementary genes for bloom on seed coat	Woodworth	1932
C_1, C_2	Complementary genes for cracking on seed-coat surface	Nagai	1926
D_1, D_2	Duplicate genes for yellow cotyledons; d_1d_2, green cotyledons.	Woodworth	1921
De_1	Normal seed coat; de_1, defective seed coat	Stewart and Wentz	1930
De_2	Normal seed coat; de_2, defective seed coat	Williams	1935
Df	Normal type; df, dwarf type	Stewart	1927
Dt	Indeterminate growth; dt, determinate growth	Woodworth	1923
E	Early maturity; e, late maturity	Owen	1927
F	Normal stem development; f, fasciated or flattened stem	Takagi, F	1929
Fl	Black seed coat flecked or speckled with brown; fl, self or solid black.	Woodworth	1930
G	Green seed coat; g, yellow seed coat	Nagai	1931
I, i^i, i^k, i	Multiple allelomorphic series responsible for inhibition of black or brown pigment in seed coat: I, Total inhibition; seeds show no black or brown pigment even in hilum. i^i, Partial inhibition; permits pigment only in hilum. i^k, Partial inhibition; responsible for Black Eyebrow pattern. i, No inhibition; seeds entirely black or brown.	Owen	1928

TABLE 2.—*List of genes in soybeans*—Continued

Symbol	Dominant-recessive characters	Authority	Date published, observed, or reported
L	Dark-colored or black pods; l, light-colored pods	Woodworth	1923
M	Responsible for black mottling on a self-brown seed coat; *m*, no mottling.	Nagai and Saito	1923
N	Normal hilum such as is found in most soybean varieties; *n*, abnormal hilum such as is found in Soysota variety.	Owen	1928
Na	Broad leaflet of most varieties; *na*, narrow leaflet	Takahashi and Fukuyama.	1919
P_1	Inhibition of pubescence, causing glabrousness; p_1, no inhibition.	Nagai and Saito	1923
P_2	Pubescence; p_2, no pubescence	Stewart and Wentz.	1926
R_1, r_1, r_1^o	Multiple allelomorphic series for seed-coat color *R*, complementary with R_2 for black seed coat or hilum. r_1, Complementary with R_2 for brown seed coat or hilum; recessive to R_1. r_1^o, reddish-brown seed coat; recessive to R_1 and *r*.	Nagai	1921
R_2	Complementary with R_1 for black seed coat or hilum; r_2, complementary with R_1 and w_1 for buff coat or hilum; r_2, R_1, and W_1, imperfect black.	Owen	1927
S	Tall, late-maturing type; *s*, stocky, early-maturing type	Woodworth	1923
Sh	Nonshattering of F. P. I. 22876, dominant to shattering of Medium Green; *sh*, shattering of Medium Green.	Piper and Morse	1911
Sh_2	Shattering of wild soybean, dominant to nonshattering of Kuradaizu; sh_2, nonshattering of Kuradaizu.	Nagai	1926
Sp	Spreading or fan-shape habit of growth; *sp*, erect compact habit of growth.	do	1926
St	Normal production of seed; *s*, sterility	Owen	1928
T	Tawny or brown pubescence color; *t*, gray pubescence color.	Piper and Morse	1910
V_1	Normal chlorophyll development; v_1, variegation	Woodworth	1932
W_1	Colored flowers; w_1, white flowers	Piper and Morse	1910
W_2	Complementary with W_1 for purple flower color; w_2 with W_1 gives purplish-blue flowers; w_1 with W_2 or w_2, white flowers.	Takahashi and Fukuyama.	1919
X	Extra leaflets in compound leaf; x, normal number, three	Nagai	1926
Y_1	Normal green plant; y_1, greenish-yellow leaves; weak plant.	do	1926
Y_2, Y_3	Complementary for green plant; $y_2\ y_3$, leaves turn yellow as plant grows; vigor fair.	do	1926
Y_4	Normal green plant; y_4, yellowish leaves; mutant found in Wilson-V.	Woodworth	1931
Y_5	Normal green plant; y_5, yellow-green leaves; mutant found in F. P. I. 65388; plant low in vigor.	do	1932
Y_6	Normal green plant; y_6, pale-green leaves; mutant found in Rokusun variety.	Williams	1936
Y_7	Normal green plant; y_7, leaves, stem, and pods become yellow as plant develops. Mutant found in Fuji	do	1936
Y_8	Normal green plant; y_8, yellow-green leaves in young plant, becoming green as plant develops.	Woodworth	1935

Table 3.—*Linkage of soybean characters*

Characters associated	Symbols	Percentage crossing over	Authority	Date published, observed, or reported
Green seed coat and green cotyledons	*G*, d_1	13	Woodworth Owen	1921 1927
Tawny pubescence and black seed coat or hilum color.	*T*, R_2	0	Woodworth	1932
Early maturity and tawny pubescence	*E*, *T*	6	Owen	1927
Defective seed coat and gray pubescence	de_1, *t*	0	Stewart and Wentz.	1930
Inhibition of pubescence and brown seed coat or hilum.	P_1, r_1	12	Owen	1927
Inhibition of pubescence and black mottling on a self-brown seed coat.	P_1, *M*	18	Nagai and Saito	1923
Pubescence color and cotyledon color	*T*, d_2	13	Williams	1935
Defective seed coat and pubescence	de_2, p_2	2	do	1935

CLOVER IMPROVEMENT

A. J. PIETERS, Principal Agronomist, E. A. HOLLOWELL, Senior Agronomist, Division of Forage Crops and Diseases, Bureau of Plant Industry

THROUGHOUT the world clover has been repeatedly referred to as the keystone of a permanent agriculture. Its introduction into agricultural use in the sixteenth century profoundly affected the entire system on which the old agriculture was based. As early as 1663, Yarranton wrote, in The Great Improvement of Lands by Clover, "for I perceive the land doth receive wonderful advantage by these leaves and branches; and as the leaves and branches, so the root doth very much contribute towards the enriching of the land." The improvement noted by Yarranton has been observed in every generation since that time, and to this has been added an increasing appreciation of clover as forage. Red clover, especially, is today the most widely adapted dual-purpose crop available to the farmer of the humid parts of the United States. Even older is the belief in clover as a lucky plant. Systematic attempts at improvement, however, are of recent origin.

Many plants have been called clovers, probably because of a similarity in usefulness and appearance to the true clover; but the true clovers and the sweetclovers only will be considered herein.

The true clovers belong to the genus *Trifolium*, of which there are some 250 described species of annual, biennial, and perennial forms that are widely distributed. In nearly every continent there are found indigenous species that occur only in that continent. In general they inhabit cool, moist regions or their growth is confined to the season of the year when cool climatic conditions prevail. Only four species—red (*Trifolium pratense* L.), alsike (*T. hybridum* L.), white (*T. repens* L.), and crimson (*T. incarnatum* L.)—are of primary importance and widely used, although several others are minor agricultural plants, in some cases of great importance locally.

Though recently considered a weed, sweetclover has had a phenomenal rise to the position of a forage crop of major importance in the United States. As an immigrant, it established itself along roadsides and railroad beds before its value was recognized. Sweetclover is now widely distributed over the world, but its native habitat appears to be in Asia Minor. Twenty species of sweetclover are recognized by Engler and Prantl. Three species—*Melilotus alba* Desr., *M.* [illegible]*lis* Lam., and *M. indica* All.—are of importance in agriculture.

RED CLOVER

OF THE true clovers, red clover (*Trifolium pratense*) is by far the most important. In the wild state it ranges over most of Europe and far into Siberia. The plant was known to be generally cultivated in the

Netherlands 370 years ago, and it is possible that there may have been a much older clover culture among the ancient Letts.

Natural Development

In the wild, red clover is an extremely variable plant. There are known to be early, late, smooth, hairy, prostrate, erect, and semierect forms. These forms can be found today, and it seems probable that one of them was the ancestor of the clover first used in agriculture, which was substantially like the double-cut clover of Europe today. The many varieties that have developed since the introduction of red clover into England in 1645 have resulted from the action of local conditions rather than conscious selection by man. Many such more or less local forms still exist, but they differ physiologically rather than morphologically; that is, they differ in resistance to cold and disease or in yielding ability rather than in characters that can readily be distinguished by the eye. In the Netherlands, however, a variety occurs, known as Maas, that is characterized by the almost total absence of the crescent-shaped white spot on the leaflets; and the character of rough hairiness readily distinguishes the American clover from its European progenitor.

Nothing is definitely known regarding the origin of red clover now common in North America. It is known that red clover was grown in Rhode Island in 1663 and that in later years there was a constant importation of seed from England. The American red clover is therefore certainly descended from the cultivated red clover of England, which in turn was introduced from Flanders. Just how the American form developed its characteristic hairiness is not known, but it has been surmised that it may have been because of the continued attacks

IN 1928 *the United States Department of Agriculture, through the cooperation of the State agricultural experiment stations, began a thorough search for red-clover stocks that had been grown continuously on the same farms or in the same communities for periods of 10 years or more without the introduction of seed from outside sources. These were planted in small observation plots and used as a basis for determining regional needs in red-clover-breeding programs for the humid Eastern States. It turned out that in the southern region red clover must be especially resistant to anthracnose; in the central region it must be both winter-hardy and disease-resistant; in the northern region it must be able to withstand a long period of winter dormancy; and in all regions resistance to powdery mildew is of varying importance. Breeding work based on these needs is now in progress, and some superior strains have already been introduced or are well advanced.*

of leafhoppers, which are common on clover and which prevent seed production in the smooth more than in the hairy plants. The English clover contains a certain percentage of hairy plants that, on this theory, would persist and hence gradually develop a hairy form (fig. 1).

Figure 1.—Stems of Italian red clover (*A*), American (*B*), and English broad red (*C*), showing the hairiness of American, believed to have been derived from the English by natural selection.

Classes of Cultivated Red Clover

In both Europe and North America the cultivated red clovers fall into two classes—(1) early, or double-cut, these giving two hay crops in a season; and (2) late, or single-cut, these giving but one hay crop in a season; and in most cases two or more forms are known in each class. Such forms are more numerous in the double-cuts than in the single-cuts and with a few exceptions are local or regional, rather than true varieties. Thus, in England, among double-cut clovers are the English Broad Red, Dorsett Marl, and Vale of Clwyd Early; among the single-cut clovers, Montgomery, Cornish Marl, English Late, and Vale of Clwyd Late. In the countries of continental Europe also, several regional varieties occur, distinguished by the name of the country or local area where the seed is produced, as Silesian, Hungarian, French, Italian, Swedish. Claims of superiority are made for all of these regional strains, and the evidence of comparative trials shows that in most cases each such regional variety is superior to others in the environment where it was developed. Some varieties,

as the Mattenklee of Switzerland, are reported by investigators to be especially distinguished by persistence.

These strains have not arisen as a result of conscious efforts toward improvement of clover, but are rather the products of different environments acting on a highly variable plant. It seems probable also that in some cases, as in England, natural crossing with the native wild red clover may have affected the progeny of the cultivated form first introduced from the low countries.

In North America regional strains are present as they are in Europe and differ in productivity, winter hardiness, and disease resistance. In the main, again, such characteristics have developed as a result of the action of local environments. In many States these strains have been grown continuously for 15 to 40 years without being mixed with other seed and have in many cases proved themselves decidedly superior. It must not be thought, however, that just because seed was grown in a certain State it has taken on a special character. A given lot of seed may represent one generation or many, and the trade names "Ohio", "Michigan", etc., have little significance.

Improvement Work in the United States

Definite attempts at the improvement of clovers are of relatively recent origin. In the United States studies looking toward the selection of a superior red clover have, at one time or another, been started at several State agricultural experiment stations, but, with the exception of the Tennessee anthracnose-resistant strain, such work has never been brought to fruition. The Kentucky station has found a superior strain that is called Kentucky 101, but it did not result from conscious selection but rather is an old stock grown for many years under the same environmental conditions. Similar valuable stocks exist in other States and can doubtless be made the basis for future breeding work.

In 1906 the Tennessee Agricultural Experiment Station selected a red clover resistant to the attacks of the fungus *Colletotrichum trifolii* S. M. Bain (fig. 2). Here again the form arose through the elimination of susceptible plants—man aided by seizing the opportunity to preserve a character brought out by the environment. The same process of selection, with perhaps less conscious human aid, has probably taken place elsewhere, since lines of long standing, highly resistant to this disease, are found in Kentucky and Virginia.

In 1928 the United States Department of Agriculture, through the cooperation of the State agricultural experiment stations, began a thorough search for red clover stocks that had been grown continuously on the same farms or in the same communities for periods of 10 years or more without the introduction of seed from outside sources. Approximately 75 strains or lots were secured, many of which had been grown for a continuous period of 40 years. These were planted in small observation plots, in cooperation with the Kentucky, Ohio, and Iowa Agricultural Experiment Stations. As a result of these studies and previous observations on the adaptation of foreign and regional strains of red clover, three regions of adaptation have been recognized in the humid eastern part of the United States, namely, the southern, central, and northern.

138904°—37——76

The chief limiting factor to which the plants must become adapted in the southern region is disease, such as that caused by southern anthracnose (*Colletotrichum trifolii*). In addition the plants must be able to survive frequent great changes of temperature during the winter months, and high summer temperatures. This southern region is composed of the States of Tennessee, Kentucky, and Mary-

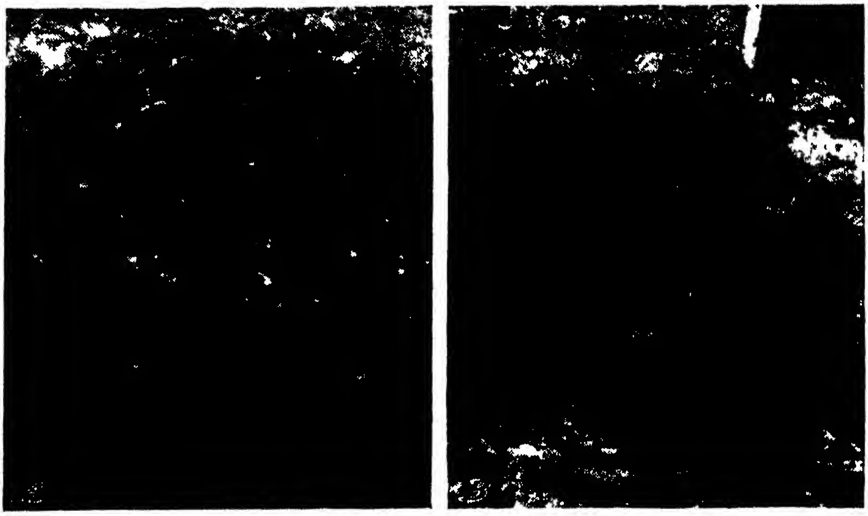

Figure 2.—Strains of red clover resistant and susceptible to southern anthracnose, caused by *Colletotrichum trifolii*: *A*, Tennessee anthracnose-resistant strain; *B*, Italian red clover. Arlington Experiment Farm, Arlington, Va.

land; the piedmont area of North Carolina and Virginia; parts of New Jersey; the southern parts of Ohio, Indiana, and Illinois; and a section of Missouri.

The central region includes the territory north of the southern region to approximately the latitude of the Illinois-Wisconsin boundary. Red clover adapted to this region must be disease-resistant and winter-hardy, since low temperatures with little snow protection are often met.

The northern region extends from the Wisconsin-Illinois line to the Canadian border. In this region no serious diseases are encountered, but the plants must be capable of tolerating a long period of dormancy, which at times may be accompanied by very low temperatures.

Throughout the three regions attacks of the powdery mildew fungus (*Erysiphe polygoni* DC.) and the potato leafhopper (*Empoasca fabae* Harr.) occur regularly with fluctuating intensity. In general the injury produced by the clover root borer (*Hylastinus obscurus* Marsham) is one of the principal causes of red clover killing-out during the second winter. In each of these regions the severity of the adverse factors varies from season to season and according to location.

After several years of study of the old strains in the central region of the red clover belt, superior strains were selected as a basis for

breeding studies. Several hundred plants of each of 10 strains were studied, and it is of interest that the percentage of superior plants in these strains ranged from 22 to 58, indicating the need of improvement.

In cooperation with the Kentucky station, seed of Tennessee anthracnose-resistant and Kentucky 101, two superior strains, was planted under controlled conditions, and the plants were artificially

Figure 3.—Resistance of red clover to the powdery mildew disease, caused by *Erysiphe polygoni: a*, Seedling plants from commercial seed, covered with mildew; *b*, seedling plants from mildew-resistant lines. University of Wisconsin, Madison, Wis., 1935.

inoculated with spores of southern anthracnose (*Colletotrichum trifolii*). In these tests the percentage of resistant plants of Kentucky 101 and of Tennessee anthracnose-resistant were, in 1925, 57 and 41, respectively, while only 10 percent of the plants of an old strain from Wisconsin remained alive.

In cooperation with the Wisconsin station, studies are in progress to develop lines resistant to powdery mildew (*Erysiphe polygoni*). Several lines have been developed that are resistant to two physiologic forms of the fungus (fig. 3). Both self-fertile and self-sterile mildew-resistant lines have been developed, but all of these are lacking in vigor and require further selection and hybridization.

Investigations on the improvement of red clover are in progress at the Minnesota, Pennsylvania, Tennessee, Indiana, New Jersey, and Idaho stations, and at the Kentucky, Wisconsin, and Illinois stations in cooperation with the United States Department of Agriculture.

Improvement Work Outside the United States

Attempts to develop improved clovers are being made in nearly every country in Europe and also in Australia and New Zealand.

In Canada two double-cut forms and two single-cuts are the result of deliberate selection. The Ottawa selection, the result of a mass selection process begun by the late M. O. Malte and carried forward for many years by the late R. I. Hamilton, is claimed to be of superior winter hardiness and is now coming into general use in Ottawa. An early or double-cut strain, called the Dollard, of superior winter hardiness, has been produced by J. N. Bird at MacDonald College, Quebec.

The Altaswede red clover, selected by G. H. Cutler from a Swedish strain, is said to be widely used in Alberta, but being a smooth clover it is not satisfactory for use in the eastern United States. The Manhardy, another smooth strain of single-cut, was selected at the Manitoba Agricultural College by W. Southworth out of various escaped and cultivated lines and is believed by Canadian authorities to be the hardiest strain of red clover in Canada.

In England the firm of Sutton & Sons selected a clover the seed of which was pure yellow instead of purple or yellow and purple. The stock came from yellow seed picked out of Chilean red clover. The effort to place the variety on the market was abandoned, however, since it was found impossible to prevent crossing in the field, and the purple color again appeared in the seed.

The firm of Gartons, Ltd., in England, began development work as early as 1890, but nothing of value has resulted from these efforts nor from the efforts of other private workers. Since the establishment of the Welsh Plant Breeding Station, systematic work has been undertaken on the study of red clover. Breeding of red clover under the direction of R. D. Williams has been important. So far one improved variety, S–123, has been offered to the public. This was released in 1936 and is believed to be useful for 2- and 3-year meadows. The following strains, built up through crossing various lines, are being tested but have not been released: S–87, S–106, S–110, and S–141.

Work of a similar kind has been undertaken in the Irish Free State, but results are not yet available. In New South Wales, Australia, an effort is being made to select a more persistent type out of a local strain known as Santhia. In New Zealand a strain known as Runciman's red clover is said to be truly perennial and of great value in pastures.

Martinet, and later Lindhard, tried to produce a variety with a short tube or corolla. Lindhard (1921) claimed that honeybees visited this variety freely and that it produced seed abundantly.

In Denmark various selected strains have been introduced as being more valuable than the local parent stocks. These are Øtofte early, semilate, and late. The Øtofte late was selected from a local strain of red clover. The strain called Øtofte semilate was bred from

Hersnap, another improved late clover used in Denmark. There is also Tystofte 40, a late form, and others.

In Germany various attempts have been made at improvement, notably at Bonn-Poppelsdorf, but no record has been found regarding results. Among private breeders was A. Dreger, who commenced his work in 1908 and produced violet-seeded and yellow-seeded varieties. According to Nessler (1931) the only bred clover in use in Germany is Original Lembke's red clover. This is an early red clover developed by Lembke in Wismar.

In Sweden such local strains as Norrum, for dry conditions; Karaby, produced by L. Karaby; and Mardal, said to be resistant to *Sclerotinia*, have become locally established. The experiment stations have also introduced Svalöf Purebred red clover, produced by H. Witte, and Mercur red clover, produced by N. Sylven, both of these strains being valued for yield and resistance to *Sclerotinia* and *Tylenchus*. Mercur was developed by mass selection from a local strain called Spannard. Weibwell's Smaragd, out of a Finnish local strain, and Göta Red, out of middle Swedish strains, are also in use. The improvement work in Sweden has been carried on by mass selection following intercrossing of various Swedish strains, or by mass selection out of a single strain.

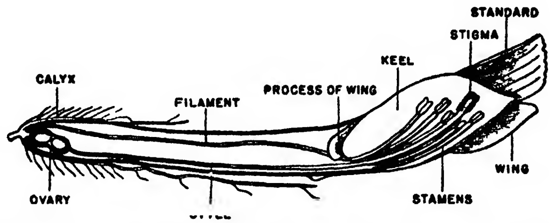

Figure 4.—Longitudinal section of a red clover flower, showing how anthers and style lie in the keel. (From Stebler and Schröter, The Best Forage Plants, pl. 24, fig. 2.)

F. Chmelar, of Brno, in correspondence, advises that original Dregers, out of Bohemian stock, and Mattenklee Rekord, selected by K. Holy out of Swiss Mattenklee, are bred varieties grown in Czechoslovakia.

In the Union of Soviet Socialist Republics special attention has been paid to native strains of wild red clover. These wild strains are said to vary in earliness, winter hardiness, production of aftermath, leafiness, and resistance to disease. The opinion is held by Lissitzyn and certain other Russian workers that these wild red clover strains rather than selections from existing cultivated forms should be made the basis of improvement.

Fertility and Pollination Relationships

Red clover heads are composed of from 50 to 150 florets, which in themselves are complete units of reproduction. The florets develop and open in an ascending order from the base to the top of the head. The pistil is usually curved, the stigma extending beyond the anthers, though florets have been found in which the style was greatly shortened, thus placing the stigma deep in the corolla tube (fig. 4). The ovary of red clover has two ovules, one normally developing upon fertilization and the other aborting. Plants have been found with a high percentage of pods having two seeds.

The anthers shed their pollen in the bud stage shortly before the floret or individual flower of the head opens. At this stage the pollen does not scatter freely. After the floret is open the stamens and pistil remain in the keel, and the pistil becomes exposed only after the floret is tripped. When the pressure causing the tripping is released, the stamens and pistil return to the keel unless the floret is ruptured. Fertilization occurs from 18 to 50 hours after pollination, the time depending on the temperature. When the atmospheric temperature is high, fertilization occurs much earlier than when it is cool. The degree of success of pollination can be approximately determined 2 to 3 days after fertilization.

Figure 5.—**R. D. Williams, Welsh Plant Breeding Station, Aberystwyth, Wales, who has devoted much attention to the subject of fertility and sterility of red clover.**

Self-sterility in red clover has generally been recognized since Darwin caged plants to exclude bees. The more recent studies of Fergus of Kentucky, Kirk in Minnesota, and Williams in Wales have clearly established the fact that nearly all the plants are self-sterile. However, lines have been established that are homozygous or pure for self-fertility, and Johnson in Minnesota has inbred one line for nine generations without materially decreasing the self-fertility. One of Fergus' self-fertile lines maintained its self-fertility for six generations, after which the line was lost.

Self-sterility in red clover is due to the slow growth of the pollen tube in the style, the ovules disintegrating before the generative nucleus reaches the egg. Recent investigations by Williams (fig. 5) in Wales indicate that this phenomenon is controlled by a series of many sterility alternative genes or allelomorphs. Whenever the same sterility factor is present in the pollen and in the female plant, growth of the pollen tube is inhibited. He has also shown that in self-fertile lines of red clover the presence of a noninhibitory self-fertility factor or gene permits the pollen tube to grow at the same rate as it does in the case of pollen from an unrelated plant.

Self Fertility

It is true that upon self-fertilization many red clover plants do produce a few seeds, but there is a distinct incompatibility in the succeeding progeny and the line cannot be maintained beyond the second or third generation. This phenomenon may be called pseudo-self-fertility as distinguished from true self-fertility.

Self-fertilization in red clover is accompanied by a decided decrease in vigor of the plants. This decrease is most pronounced in the first

and second generation and differs in different lines. Apparently Johnson's inbred line in Minnesota has maintained more vegetative and reproductive vigor that any other.

The number of true self-fertile plants in red clover is relatively small. Out of many hundred self-pollinations only a few self-fertile lines have been secured, though a large number of pseudo-self-fertile lines have been found. In connection with red clover breeding studies in the Department of Agriculture, from a spaced population of approximately 4,000 plants, 500 superior open-pollinated plants were selected; each of these 500 plants was self-pollinated, but not a single true self-fertile progeny was obtained.

Pollination

The structure of the red clover floret prevents cross-pollination by wind, since the anthers and pistil remain enclosed in the keel unless artificially tripped (fig. 4). Under natural conditions pollination is done by insects, nearly all of which are bees (order Hymenoptera). The bumblebees (*Bombus*) and the honeybees (*Apis*) are the principal pollinators, although at certain times and places bees of other genera, such as the ground bees (*Tetralonia* and *Melissodes*) and the leaf-cutter bees (*Megachile*), contribute to cross-pollination.

Bees visit the red clover floret for nectar and pollen or both, tripping the florets and transferring pollen from plant to plant, thus constantly maintaining the condition of mixed inheritance in the species. Other insects, such as moths, are constantly seen on red clover heads, but they do not come in contact with the pollen and therefore do not effect cross-pollination.

There has been considerable controversy as to the extent to which pollination can be accomplished by honeybees. Discussion has centered upon the fact that the tongue of the honeybee is not long enough to reach the nectar. The literature on this subject is voluminous and cannot be reviewed here. More recent investigations clearly indicate that honeybees visit red clover principally for pollen and seldom obtain nectar, but regardless of what is obtained, pollen is transferred and cross-pollination is effected.

Breeding Methods

In the breeding of red clover inherent difficulties exist that have greatly retarded advancement in the improvement of this crop. These factors are chiefly the small size of the red clover floret and the fact that the plants are self-sterile. In general the method followed in the past in breeding for an improved variety of red clover has been to start with a valuable local stock and attempt to secure a better strain by mass selection of the most desirable types. Because of the necessity for cross-pollination, red clover is in a hybrid condition and the progeny of selected plants will continue to produce a certain percentage of undesirables. These may be eliminated in some cases by continued selection and in others by unfavorable factors in the environment. The latter is the case with the anthracnose-resistant strains produced in the southern region of the red clover belt and the winter-hardy strains of the northern region, since they are naturally subjected to disease or to severe winter conditions. All varieties successfully

established in the United States and Canada to date have been developed by the aid of this natural selection.

Special inoculation beds with favorable conditions for development of the disease organisms have proved to be advantageous in studies on disease resistance. Experience has shown that field inoculations are not always successful, and there is always the possibility that surviving plants may have escaped inoculation rather than that they are resistant. The worker must also consider the susceptibility of the host as related to age and environment.

In details, the method of making crosses varies with the individual investigator. Toothpicks, camel's-hair brushes, cards, and crooked needles have all been successfully used for the transfer of pollen. Since most of the red clover plants are self-sterile, reciprocal crosses can readily be made without the emasculation or removal of anthers necessary with many plants.

Bumblebees from which pollen has been washed have been successfully used by Williams for cross-pollination, and this method offers the distinct advantage of securing large numbers of seeds in any specific cross. Lindhard caught queen bumblebees in the spring and developed the broods in special boxes that could be moved to cages in which the plants were enclosed. Natural nests have been transferred to artificial domiciles and moved about at will in studies by the Bureau of Plant Industry. Honeybees have been successfully used when many plants were to be cross-pollinated.

Williams (*17*),[1] of the Welsh Plant Breeding Station, follows three methods: (1) Strain building—selecting superior plants of old stocks and combining them by controlled crossing; (2) brother-and-sister matings—combining desirable sibs of the same families for several generations, eliminating plants with undesirable recessive characters after each crossing, and later outcrossing to unrelated families that have been sib-crossed; (3) dialed crossing—intercrossing several lines with one another to determine the combinations producing the best progenies, followed by intercrossing among such progenies to form a new strain.

The development of mildew-resistant lines in Wisconsin has resulted from selections made from artificially inoculated beds. The progeny of these selections were sib-crossed and selfed to secure lines homozygous or pure for mildew resistance. The crossing of unrelated lines resistant to mildew is in progress to restore vigor.

The results of studies by Williams and by the Bureau of Plant Industry clearly show the effects of sib-crossing. Loss of vigor with succeeding sib crosses for several generations is usually evident. Whether full vigor can be restored and maintained by combining a limited number of unrelated lines remains to be proved. Experience has shown that the growing of large populations of spaced plants is essential if progress is to be made. While controlled crossing may be accomplished in the field, a greenhouse is a valuable asset. The necessary manipulation can be more easily performed and a higher percentage of seed may be expected in the greenhouse than in the field.

The isolation and use of self-fertile lines in the breeding of red clover, while discredited by some investigators as offering little promise,

[1] Italic numbers in parentheses refer to Selected References, p. 1211.

has the distinct advantage of developing plants that are pure (homozygous). The loss of vigor by making sib crosses for several generations is practically as great as that resulting from selfing, and self-fertile lines are more readily maintained. The selfing of one head per plant is sufficient to determine whether it is self-fertile.

Isolation of Breeding Material

In Europe the problem of isolation of stocks in the early stages of development has been met by planting in an isolated field among other plants. Lang planted his red clover in the midst of a field of other plants blooming at the same time so that the bees might work on these plants first and thus have any foreign red clover pollen cleaned off before they arrived at the red clover plants. Dreger isolated his breeding stock in a field of *Vicia villosa*. By this means he claims to have produced a strain of red clover with uniformly violet seed.

Williams and Evans found that contamination by extraneous pollen depended on two factors—(1) the distance separating the bred strain from other red clover plants and (2) the profusion with which the strain flowers. In their experiments it was found that when there was little bloom on the pure strain the percentage of contamination was great, no matter how well isolated the plot. On the other hand, with abundant bloom relatively little contamination occurred even when the plot was not well isolated.

WHITE CLOVER

White clover, a common inhabitant of lawns, pastures, and roadsides, is widely distributed in every continent of the world, with a natural distribution probably as great as that of any other plant of the legume family. Moist and cool situations are its most favorable habitat and under such conditions growth is continuous. Though it is believed not to be indigenous to North America, it was brought over very early and the year of its introduction is not known.

The white clovers of agricultural value have been grouped as wild, cultivated or Dutch, and Giant or Ladino. Five other varieties are mentioned but are only of botanical interest.

In form these groups differ chiefly in plant size, the English wild white clover being smaller in all vegetative parts than the Dutch, and this again smaller than the Ladino. In England the wild white clover differs also in being more persistent than the Dutch white clover, which is often short-lived. As a group, the native or wild white clover is distinguished from the Dutch white clover and the Ladino white clover by the presence of a cyanophoric glucoside. This is an organic substance present in many herbage plants and which in the course of digestion forms hydrocyanic acid. The quantity present in white clover is small and harmless. The more persistent plants have a high glucoside content, while the short-lived Dutch and the Ladino have but little or none.

Origin of Varieties and Forms

The development of varieties and strains of white clover has resulted from the action of environment on this variable species. Thus in the United States it is possible to distinguish the strain produced from

Louisiana seed from that produced from Wisconsin seed, the Louisiana strain being more persistent under summer conditions but slightly less winter-hardy than the Wisconsin strain.

White clover was introduced into New Zealand from England, but the best white clover produced as wild white in New Zealand today differs from the wild white of England in its larger growth.

In New Zealand, where intensive work has been done with white clover, Bruce Levy has distinguished four strains of New Zealand white clover, differing in productivity and persistence, the best strain being like English wild white clover and the least satisfactory form like Dutch white clover. In Denmark two distinct varieties of white clover are grown, Morsø and Strynø. Of these the Morsø appears to be the more permanent and the better seed producer, but the Strynø is the better yielder of herbage. In Sweden a very persistent strain called Svea has been produced at Svalöf and is now on the market. In Finland the Tammisto strain, which has proved hardy and a good yielder, has been developed from native Finnish stocks.

Though no critical studies have yet been made, observations indicate that the white clover growing in old pastures in the northeastern United States has the same growth habit and persistency as the English wild white clover. A common descent may be presumed, since white clover was brought to this country by the early settlers.

Ladino white clover was first discovered in northern Italy, but its exact origin is unknown. It does well under irrigation but has not been successfully established in the eastern United States.

Breeding Investigations

The difficulties experienced in the breeding of white clover are similar to those in the breeding of red clover, and the same procedure is applicable. White clover, like red clover, is extremely variable in leaf size, color, and markings; flower and seed color; size of runners; and persistence. Combinations of one or more characters in individual plants have been observed from time to time. In many cases these have been perpetuated by vegetative propagation, and in a few cases strains have been developed that are homozygous for certain characters. All the strains to which reference has been made are the result of natural selection with only incidental help from man.

At present special breeding work is being conducted at the Weraroa station in New Zealand, where the Weraroa strain was isolated as no. B–95. It is said to be truly perennial and a good yielder. At the Welsh Plant Breeding Station a variety, S–100, was released in 1936 and is described as being more productive than commercial white clover and as lasting longer. It was produced from Dutch, New Zealand, and wild white clover and is intended for use in 1- to 3- year meadows. Another variety, S–99, has not yet been released. Breeding work is also being carried on at various stations in Germany, Denmark, Czechoslovakia, and Sweden.

Experiments by Williams (*17*), Erith (*3*), and others have clearly shown that self-sterility in white clover is not so marked as in red clover but is the result of a similar phenomenon. The possibility of developing self-fertile lines is, therefore, slightly greater. A pro-

nounced reduction in vigor results from inbreeding, with the appearance of dwarf and chlorophyll-deficient seedlings and other recessive characters.

OTHER TRUE CLOVERS

Crimson Clover

Crimson clover—the most important winter annual of the true clovers—was first introduced in the United States in the early part of the nineteenth century, and the Patent Office made a distribution of the seed in 1855. This species is self-fertile and is less variable than the clovers previously discussed. The florets are not self-tripping and for maximum seed crops require insect visitation.

Several varieties of crimson clover are recognized, differing in date of bloom and in color of the flowers. Vilmorin-Andrieux & Cie., of Paris, refer to Extra Early Crimson, Early Crimson, Late Crimson, Very Late White Flowering, and Extra Late Crimson Flowering. A difference of 4 to 5 days in time of maturity is shown between each of these varieties in the order named. An early white variety is also said to exist.

In the United States a local strain, developed in northern Georgia and known locally as Pitt's clover, is said to have given better results in Georgia than commercial seed.

Alsike Clover

The first recorded introduction of alsike clover into the United States occurred about 1839, when the Genesee Farmer, an agricultural journal, made a small distribution. No recognized varieties exist, but regional strains give varying results. In Sweden the native strain yielded more than that from Silesia or that from North America. In preliminary studies in the United States, differences of this sort have been noted. The plants are generally self-sterile, though Wilson in Minnesota has shown that self-fertility exists; loss of vigor follows inbreeding.

Subterranean, Berseem, and Persian Clovers

The clovers known as subterranean, berseem, and Persian are all annuals, the first two distinctly winter annuals, and are used for hay or grazing. Subterranean clover is little used in the United States. In Australia several strains of subterranean (*Trifolium subterraneum* L.) differing chiefly in date of maturity, are known, and in Egypt and elsewhere three or four distinct strains of berseem (*T. alexandrinum* L.) are recognized. Strains of Persian clover (*T. resupinatum* L.), differing in maturity, have been selected by workers in Turkistan. In none of the other true clovers are strains recognized, and no special improvement work, so far as known, is being carried on with these.

SWEETCLOVER

Although a relatively new crop, sweetclover offers one of the most promising possibilities for forage improvement. The different species appear on the whole to be self-fertile, although some are not self-pollinating. Large numbers of honeybees visit the florets, effecting a certain amount of cross-pollination and thus increasing variation among the plants.

In general, the sections where sweetclover is principally grown are the north-central region and the Great Plains States. This territory may be divided into two areas of adaptation—(1) the area east of the Nebraska-Iowa boundary and (2) the Great Plains States. In the eastern region resistance to a disease complex is of first importance in connection with the development of more palatable late-maturing strains for pasture. In the Great Plains States diseases as yet are of minor importance, but drought-resistant palatable strains for hay and pasture are needed. A coumarin-free strain would be desirable everywhere, since the presence of coumarin affects the palatibility of the herbage and, as shown later, is probably related to the development of a toxic substance in spoiled hay.

The sweetclovers grown in the United States belong to the genus *Melilotus*. They include white sweetclover (*M. alba*), yellow sweetclover (*M. officinalis*), and sourclover (*M. indica*). Redfield yellow, an early introduction of the United States Department of Agriculture, appears to be *M. suaveolens* Ledeb., though in many respects it resembles *M. officinalis*. The first species mentioned includes both biennial and annual forms, while *M. indica* is an annual, and of *M. suaveolens* and *M. officinalis* the biennial form only is known.

Varieties

Of the white sweetclover group, the Grundy County, Hubam, Arctic, Alpha, Iowa Late White, Ohio Evergreen, and Madrid White varieties have characteristic qualities and are in use to a greater or less extent. Grundy County White was first noted in Grundy County, Ill., in 1917, but is of unknown origin. It is early, of erect habit, with slender stems, and it is not so tall as the common biennial white sweetclover. Arctic was named by J. Bracken at the University of Saskatchewan, Saskatoon, Canada, and was derived from a Siberian importation brought in by N. E. Hansen. It is especially noted for winter hardiness and behaves as a dwarf variety in the central part of the United States, although making a much greater growth in Canada.

Madrid White, introduced by the United States Department of Agriculture through seed received from the Botanic Garden in Madrid, Spain, is a large-growing variety characterized by early seedling vigor and tolerance of the first year's growth to frost. Hubam is an annual mutation from *Melilotus alba* and was first brought to general attention by H. D. Hughes, of Iowa, in 1917. This variety resembles common biennial white sweetclover, except that it blooms and seeds freely the season of planting and does not survive a second year.

Alpha sweetclover is a variety developed by L. E. Kirk at the University of Saskatchewan. The first plants were found in a field of Arctic sweetclover in 1924, and Kirk developed the variety by a process of inbreeding and selection. The plants of the Alpha variety branch profusely at the crown, the slender stems being leafy and resembling alfalfa. It is a dwarf variety in the central part of the United States and is not adapted to that region.

Iowa Late White is a large-growing, late-maturing selection made by the late F. S. Wilkins, in 1935, at the Iowa Agricultural Experiment

Station, from a lot of seed secured from an Illinois farmer. Ohio Evergreen is similar in growth habits and maturity to the Iowa Late White. Selections of this variety were made by J. B. Park, of the Ohio Agricultural Experiment Station, as a result of several years of mass selection of desirable types secured from roadside plants. A selection made by the Illinois Agricultural Experiment Station and called Illinois No. 8 is another late-maturing uniform strain selected from wild plants. Selections made by Brink at the University of Wisconsin were developed in the effort to improve disease resistance. Hayes, Johnson, and Doxtater, of the Minnesota station, have made selections from Alpha and commercial white, resulting in a strain called Minnesota No. 1 and a strain of Alpha that is more disease-resistant than Alpha from Canada. In the Pacific Northwest the growing of sweetclover west of the Cascade Mountains was unsuccessful until the development of a strain resistant to what is believed to be stem rot. This variety was developed by H. A. Schoth, at Oregon Agricultural Experiment Station, over a period of years, by growing successive generations in the same soil, allowing the disease organism to eliminate the susceptible plants.

Figure 6.—L. E. Kirk, Dominion agrostologist, Dominion of Canada Experimental Farm, Ottawa, Canada, who has pioneered in the genetics of sweetclover.

Less attention has been given to the selection of varieties from yellow sweetclover (*Melilotus officinalis*) than from white sweetclover. In general, the varieties of yellow sweetclover are less productive and mature earlier than those of white sweetclover. Many varieties, such as Albotrea, Madison County or Switzer, and St. Louis Valley, are very much like the commercial yellow. Zouave, developed at the University of Saskatchewan, is more erect the first year than the commercial yellow and has seed that is densely mottled with purple. Daghestan Yellow, introduced from the Province of Daghestan, Transcaucasia, and having large and rounded leaflets, appears to be a form of *M. suaveolens*.

Redfield Yellow, a variety received by the Department of Agriculture from Manchuria in 1915 as *Melilotus alba*, but which later proved to be a yellow form, was developed and named at the Department's forage-crop field station at Redfield, S. Dak. The fact that Redfield Yellow crosses readily with *M. alba* while *M. officinalis* does not cross with *alba* and the further fact that Redfield Yellow does not cross with known varieties of *M. officinalis* appear to confirm the classification as *M. suaveolens*. Madrid Yellow, introduced by the Department from seed received from the Madrid Botanical Garden,

has vegetative characteristics similar to those of Madrid White, previously described. The character of early seedling vigor makes both the Madrid Yellow and the Madrid White superior for Great Plains conditions, where early establishment is of the utmost importance. In addition to the above-mentioned varieties of both white and yellow sweetclover, other local strains

Figure 7.—Segregating sweetclover line, showing branched dwarf character in center, compared to normal growth on each side. Arlington Experiment Farm, Arlington, Va., 1936.

are in existence, developed largely by the continued growing of strains over a period of years.

Breeding Work in North America

Definite breeding work has progressed more in Canada under the direction of L. E. Kirk than elsewhere (fig. 6). Kirk has made extensive studies on pollination, selfing, and crossing. Improvement work in Canada has been directed toward "the production of winter-hardy, fine stemmed, leafy, disease resistant and more palatable sorts." Three methods are used—(1) isolation of desirable plants or of plant groups so as to provide for immediate increase of a superior form; (2) isolation of desirable forms through selection within inbred lines; and (3) hybridization, to combine the desirable features of the best inbred lines (fig. 7). Studies of variations in coumarin content of individual plants have given promising results. Lines have been selected that

appear to be approaching homozygosity for low and for high coumarin content.

The Wisconsin station, in cooperation with the Department of Agriculture, has been studying the relationship between coumarin and palatability and toxic properties of spoiled sweetclover hay. Results indicate that coumarin is intimately connected with the toxic principle and is one of the important factors in the palatability of sweetclover for pasturage. Hybridization experiments are in progress within and between lines of *Melilotus alba*, *M. suaveolens*, *M. officinalis*, *M. dentata* Pers., and other species.

At the Minnesota station various lines have been inbred for 4 years. In agreement with the work in Canada, selfing has not resulted in any material reduction in vigor in either common biennial white clover or Alpha. The development of a variety of low coumarin content and high yield is the objective of this work.

In Kansas, Washington, and Texas, and at Guelph, Canada, selection of desirable sweetclover lines is in progress. The Nebraska and Illinois stations, in cooperation with the Department, have established nurseries for selection and breeding looking toward the development of varieties having superior value. In West Virginia various selfed lines are being grown with a view to securing one that will thrive at a higher acidity level than that at which sweetclover now does well. The Idaho station reports the development of a sweetclover having purple seeds, a crown similar to alfalfa, and nonshattering pods. A report for 1934 stated that none of the purple-seeded types proved homozygous for this character and that the plants were segregating for numerous other characteristics.

Breeding Work Abroad

The Russians have been interested in the breeding of sweetclover, especially at the Institute of Plant Breeding, at the Black Soil Regional Plant Breeding Center, at the Maikop and the Detsko-Selo stations in the north Caucasus, and at Saratov. Both commercial varieties and native wild strains are said to be used, various forms having been isolated to serve as breeding stock. Attention is being paid to variations in coumarin content.

At the Kaiser Wilhelm Institut für Züchtingsforschung, Müncheberg, Germany, under the direction of M. Ufer, many thousands of plants from different sources have been grown and studied for relative freedom from coumarin. Of these, 51 individuals were selected. Among the species studied were *Melilotus alba*, *M. officinalis*, *M. wolgica* Poir., *M. dentata*, and *M. indica*. This work was reported in 1934, but no later information is available.

Pollination and Fertility

Pollination of sweetclover under natural conditions is effected principally by honeybees, except insofar as the species, varieties, or individuals are spontaneously self-fertilized. Various workers have studied this problem, but only a brief summary of the information as given by Kirk and by Kirk and Stevenson can be given here. While *Melilotus alba* is generally highly self-fertile, three groups have been recognized: (1) Plants in which nearly all florets produce seed without

manipulation—spontaneously self-pollinated and self-fertile; (2) plants that do not produce seed without manipulation—self-fertile but not self-pollinating; and (3) self-sterile plants. The varieties of *M. officinalis* are not spontaneously self-pollinated, but are not completely self-sterile as is commonly thought. When the stigmatic surfaces are scratched in selfing, some seed is formed, though the proportion is not so great as when the florets are open-pollinated. The Redfield Yellow variety is spontaneously self-pollinated and self-fertile, and this is also the case with many lines of *M. dentata*.

GENETIC STUDIES IN CLOVER [2]

With the advent of more extensive genetic studies of plants, an occasional investigator became interested in the inheritance of particular characters of red clover. For the most part, however, the inherent difficulties occasioned by the self-sterility of the species and the manipulation of the florets in making crosses discouraged the initial efforts. Until recent years the published reports of such investigations were principally confined to general statements of what appeared to be evident.

Red Clover

Flower and seed-coat color of red clover were the basis of most of the early observations. De Vries (*14*) described the selection of a line that in the fifth generation had a large proportion of leaves composed of seven leaflets. He also reported that white flower color was recessive to red, being inherited in a simple ratio.

In 1903 Fisher likewise developed lines in which 85 to 100 percent of the progeny had yellow seed coats and another line in which 86 to 99 percent had dark-violet seed coats. In 1912 Kajanus (*6*) studied a blue-flowered red clover plant and reported that blue was recessive, being inherited in approximately a 15:1 ratio. He also stated that red flower color was dominant over white. In 1921 Witte (*20*) reported finding a white seeded red clover in which the white seed was associated with white flower. When this plant was crossed with those having yellow seed, the F_2 generation segregated in a 3:1 ratio.

In any large population of red clover plants, many have a crescent-shaped leaf marking while in others no markings are evident. Gmelin's (*5*) studies in 1916 showed that the presence of leaf markings was dominant. His work also confirmed the report of Kajanus (*6*) that white flower color was recessive to red. Fruwirth also studied flower color, counting the number of plants producing white and red flowers. The more recent work of Wexelsen (*16*) on the presence and size of leaf spot, leaf color, anthocyan pigment and its presence in stems and stipules, flower color, and resistance to mildew indicates an increasing interest in the inheritance of characters of red clover. Nijdam (*11*) also investigated incompatibility, seed-coat color, flower color, chlorophyll difference, sterile stamens, and dwarfs. These studies include the occurrence, variation, and segregations of crosses. Segregation ratios were reported.

With the establishment of the Welsh Plant Breeding Station an orderly investigation of red clover breeding began. Experimental

[2] This section is written primarily for students and others professionally interested in breeding or genetics.

proof by Williams and Silow (*19*) of sterility and fertility relationships of red clover, mentioned in a preceding section, affords a basis on which genetic studies may proceed soundly. The comprehensive studies of Williams (*18*) on flower color clearly show the presence of additional epistatic recessive factors with linkage relationships to the sterility genes, a condition not unexpected when the characters of large populations are critically examined. Besides the characters mentioned above, many investigators have observed the occurrence of dwarf forms, chlorophyll-deficient seedlings, abnormal flower-head development, and other variations.

Cytology of Red Clover and Other Trifolium Species

With the increased interest in cytological study as related to genetics, and its apparent usefulness in interspecific hybridization, studies on chromosome number and morphology have been undertaken by a few investigators, notably Bleier (*1*) Karpechenko (Karpetschenko) (*7*), and Wexelsen (*15*). In the majority of cases these investigators agree on the number of chromosomes, particularly in the most important species. Differences of opinion exist, however, on some points, and additional studies, with improved methods, are needed for a clearer understanding. The basic numbers of chromosomes are seven and eight, with multiples thereof, but species belonging to a given subsection of the genus *Trifolium* do not always have the same number of chromosomes. Ascherson and Graebner record various alleged hybrids as having been found in Europe, but experimental interspecific crossing has invariably been unsuccessful. A table of chromosome numbers of all species of *Trifolium* for which data are available is presented in the appendix.

White Clover

Genetic studies on the inheritance of different characters of white clover are in the developmental stage. In a preliminary report on a few crosses made between several varieties, Erith (*3*) states that leaf color and flower color are inherited as a single-factor difference. Normal green leaves are dominant to purple, and pink flower color is dominant to white. Cytological studies by Wexelsen (*15*) on two varieties—English wild and Ladino—show no difference in the chromosome numbers. Those of Ladino are, however, much larger, though considerable variation in this regard exists between plants of the English wild white clover. In crosses between varieties, the chromosome size of the F_1 generation was found to be intermediate between those of the parents.

Sweetclover

As indicated in the preceding section, improvement of sweetclover has been principally concerned with the introduction and trial of various sweetclovers from the Old World. The occurrence of natural hybrids and mutations has stimulated interest in characters and their inheritance.

In breeding sweetclover, emasculation is necessary unless the female parents carry a recessive character that may readily be determined in the F_1 generation. Kirk's water-suction method for greenhouse studies

and Savage's automobile vacuum method for field emasculation, as described in the article on Alfalfa Improvement in this Yearbook, are ingenious devices that have been successfully used. In view of the numerous hazards in breeding work, the need of greenhouse facilities cannot be overemphasized. A plant generation can be grown in the greenhouse in the winter either by placing the young seedlings under continuous light or by freezing seedlings a few weeks old and then placing them under a long-day exposure. These methods have been successfully used by Kirk in Canada and by Johnson in Minnesota.

Cytological studies are necessary for intelligent plant breeding, particularly when interspecific hybridization is to be undertaken. The studies of Castetter, Elders, Clarke, Smith, Fryer (*4*), Chekov (Tschechow), and Cooper all show that the diploid number of chromosomes of the species studied is 16. The morphology of the chromosomes of all the species investigated appears to be similar, although those of the species of the subsection *Campylorytis* are smaller than those of other species.

The appearance of Hubam and of the Alpha form undoubtedly stimulated inheritance studies. Smith concluded from his studies that the annual character was dominant and counts of segregating progeny indicated a close agreement of a 3: 1 ratio. Elders, Kirk (*9*), and Clarke (*2*) have shown that the Alpha type is recessive to normal and is inherited in a ratio of 3 : 1. Clarke also reports the presence of a recessive spreading dwarf character and of two factors for pale-green seedling. Linkage between pale green and spreading dwarf is evident.

Using the F_2 and F_3 lines developed from a natural hybrid between *Melilotus alba* and *M. suaveolens* (Redfield Yellow), Kirk (*8*) reports that the inheritance of flower color is in close agreement with a three-factor hypothesis, two factors for cream, varying in intensity, together giving yellow, and a third factor that inhibits the action of factors for cream and yellow giving white. Segregations in several of the above lines, however, indicate a deficiency of yellow plants. Reference to seed-coat color has been the basis of determining whether seed is from *M. alba* or *M. officinalis*. Various workers have considered the clear seed coats of *M. alba* as a distinguishing characteristic differing from those of *M. officinalis* in which a varying percentage of seeds are flecked with purple. Kirk and Stevenson have reported the finding of speckled seed coats in a line of Alpha (*M. alba*). Previous crosses indicated that color markings are dominant over clear seed-coat color. Kirk and Armstrong (*10*) also describe a mutation characterized by a reduction of the size of leaf with a pattern dissimilar to normal. This abnormality is also expressed in size and pattern of corolla. The plants are dwarfed, self-sterile, and cross-sterile to pollen from normal types.

The characters in sweetclover are as diverse as in other plants; purple seed coats, green cotyledons, dwarfs, and chlorophyll-deficient seedlings, germinable seed not needing scarification, and floret abnormalities have already been observed.

Interspecific Hybridization

The fact that all species of *Melilotus* have the same basic number of chromosomes, supported by the occurrence of natural and artificial

hybrids between species, has encouraged the belief that interspecific hybridization may be successful. The reports of early botanists on the occurrence of natural hybrids have been summarized by Schulz (*12*) and later by Ascherson and Graebner in their systematic treatise on the genus *Melilotus*. These authors mention hybrids between *M. alba* and *M. altissima* Thuill, *M. alba* and *M. officinalis*, *M. altissima* and *M. officinalis*, and *M. officinalis* and *M. wolgica*. The authors describe these alleged hybrids as having characters of both supposed parents, but genetic data on the supposed hybrids are wanting. Kirk and Stevenson failed to obtain a single hybrid between crosses of *M. alba* and *M. officinalis*. In an experiment designed to favor natural crossing between a line of *M. alba* and its varieties and species of yellow-flowered sweetclovers, Kirk secured one hybrid with cream-colored flowers. This is similar to hybrids secured later from artificial crosses between *M. alba* and Redfield Yellow. Furthermore, reciprocal crosses between Redfield Yellow and Albotrea and between Zouave and Redfield Yellow failed to produce a single hybrid. Natural hybrids of the same nature, involving crosses between Redfield Yellow and *M. alba*, have been selected by Garver at Redfield, S. Dak., and at Arlington Experiment Farm, Arlington, Va. Sylven, in Sweden, reports a natural hybrid between *M. alba* and *M. officinalis*, selected from seed secured from Canada. It is possible that this hybrid may have arisen from the cross between *M. alba* and Redfield Yellow or the reciprocal. More recent work of Stevenson and Kirk (*13*) shows that hybrids can readily be secured by artificial cross-pollination between *M. alba* (Alpha) and *M. suaveolens* (Redfield Yellow). The evidence tends to the conclusion that, while *M. alba* and *M. officinalis* and *M. officinalis* and *M. suaveolens* are reciprocally sterile, *M. alba* and *M. suaveolens* are reciprocally fertile. Compatibility varies, however, between individuals, depending upon which species is used as the male or female parent. In several cases crosses between *M. alba* and *M. officinalis* and between *M. alba* and *M. dentata* have resulted in the development of pods and shrunken nongerminating seed. Efforts to dissect out hybrid embryos at an early stage of development and grow these to maturity in nutrient cultures have failed. Further attempts at interspecific hybridization are in progress at several places.

Intergeneric crosses between *Melilotus*, *Medicago*, and *Trigonella* have been attempted by Fryer (*4*) and by Stevenson and Kirk (*13*), but without success.

VARIETAL IMPROVEMENT IN HOPS

D. C. SMITH, Formerly Agent, Division of Drug and Related Plants, Bureau of Plant Industry [1]

LUPULIN, a substance consisting of resins and essential oil, imparts to beer, ale, and other malt beverages their characteristic bitter flavor. The scales or bracts of the hop—which resembles a fir cone in its general makeup—possess small, yellow, granular bodies or lupulin grains, easily visible to the eye (fig. 1). These contain the resins and oil. The oil, contributing also to the aroma, is usually driven off in the boiling process but may be replaced later. Materials known as tannins occurring in the scales and stem of the cone aid in the clarification of the brew after boiling.

Each 31-gallon barrel of beer brewed in the United States requires only a half to four-fifths of a pound of hops, though abroad the figure sometimes reaches 1¼ pounds. Thus in spite of the extent of the brewing industry, the acreage of hops required is of minor importance agriculturally when compared with many crops. Hops are all-important to the brewers, however, since beer is made principally of malted barley, hops, and water. There are rather exacting requirements in quality of hops, and both yield and quality are determined by many influences. Breeding of better hops, therefore, becomes an undertaking of vital concern both to brewers and to growers.

In other countries attention has been given to hop breeding as a means of improvement for many years. Such work with hops in the United States is at its beginning, though much progress has been made in recent years in breeding other crop plants. Some of the back-ground of hop culture will help the reader to better understand the breeder's work.

USE OF HOPS ANCIENT IN ORIGIN

JUST when hopped beer was first made is not known. The Egyptians had a sweet-sour alcoholic beverage made like beer but without hops. Hops were apparently used by the Greeks only as a salad plant; even today young hop shoots are eaten like asparagus by some people. In early times hops were supposed to free the blood of "all impurities, tumors, and flatulence", cure the itch and other skin diseases, and "relieve the liver and spleen." Taken as a fresh vegetable, they may well have had some beneficial effect in the diet. Today individuals may be found who believe that sleeping on a pillow stuffed with dried hops somehow contributes to health.

[1] Previously in charge of hop-breeding investigations. The author is indebted to G. R. Hoerner, agent, Division of Drug and Related Plants, for collaborating on some parts of this paper dealing with pathology, and to Frank Rabak, associate biochemist in the same Division, for making the chemical and physical examinations and furnishing the data in tables 1 and 6

But the overwhelming utilization of hops has been in brewing, this use being first developed either in Russia or in Germany. German records go back to 768 A. D., in the time of Charlemagne, when King Pepin le Bref donated hop gardens to the monastery of St. Denis. Subsequently many monasteries became famous for their brews. By 1320–30 A. D., hopped beer was in general favor in Germany. Hop culture spread to the Netherlands, and John the Bold, Duke of Burgundy, founded a Knightly Order of the Hop. Late in the fifteenth century the plant was introduced into England, but Henry VII and Henry VIII liked beer without hops and prohibited their use. Swedish tastes were the opposite; an ordinance of 1440 required every farmer to grow 40 poles of hops. In Bohemia the Emperor Charles IV personally selected the spots most suitable for hop growing. Today leading producing countries abroad are England and Wales, Germany, Czechoslovakia, France, and Belgium.

Figure 1.—Branch of hop vine with mature, well-developed cone below and blighted, withered cones due to downy mildew above and to the side.

In North America, hop growing began in New Netherlands as early as 1629 and in Virginia in 1648, though it did not become important until about 1800. In 1808 the first hop yard was established in New York. In 1849 the New England States and New York produced nearly 1,500,000 pounds, of which New York grew 70 percent. After the Civil War the industry developed in Wisconsin, reaching a maximum of 25,000 bales[2] in 1869. In 1865, Oneida County, N. Y., produced 1,265,000 pounds, and in 1879 the State reached an all-time maximum of 21,629,000 pounds.[3]

The growing of hops on the Pacific coast was started between 1859 and 1869. Though New York was still the leading State in 1899, the production in Oregon and that in California each exceeded that of New York by 1909. In recent years hop cultivation in this country, except in Washington, Oregon, and California, has been negligible.

[2] Present commercial bales weigh approximately 200 pounds.
[3] Attention of the reader is called to the appendix at the end of this article, listing sources of information available.

In 1935 these three States harvested 47,746,000 pounds of hops on 38,900 acres. Slightly over half of the tonnage was grown in Oregon.

During the twenties hop growing in New York was practically wiped out by powdery mildew, but there is a revival of interest in that State, as indicated by the work recently begun by the New York (State) Agricultural Experiment Station at Geneva looking toward the improvement of hop varieties.

The growing of hops is somewhat similar to that of pole beans. The vines are trained on poles or pole-and-wire trellises, ordinarily 10 to 20 feet in height. Plants are spaced from 4 to 8 feet apart, the latter distance being most general on the Pacific coast. At harvest the vines are let down and the cones are picked by hand. The green hops are then hauled to drying houses, piled in bulk, and slowly dried with artificial heat for about 20 hours. Later they are compressed into bales of about 200 pounds each, sewn over with burlap, and the grower's part is completed.

Hops are long-lived perennial plants propagated by root cuttings and having a strong climbing habit. Curiously enough, the vines always wind in the same direction. New shoots are produced each year, and after harvest old growth is removed as in the case of cane fruits. Plants may be grown from seed, but they then exhibit great diversity in characters, many being strikingly inferior. Few growers have noticed hop seeds germinate. Hop plants possess remarkable vigor, young vines having been observed, under favorable conditions, to elongate 12 inches in 24 hours.

Hops are closely allied only to elm, mulberry, hemp, and nettles among the commonly known plants and are known to botanists as *Humulus lupulus* L. A native American type has been segregated as *H. americanus* Nutt. An annual ornamental variety called the Japanese hop (*H. japonicus* Sieb. and Zucc.) is a cousin, as is *H. neomexicanus* (A. Nels. and Cockerell) Rydb., a native sort found in

---

BEER, *ale, and other malt beverages depend principally on hops for their characteristic flavors, and no satisfactory substitute has ever been found. Improvement of hops by breeding is, therefore, of vital concern to both brewers and growers. The attainment of a choice product is very difficult, since the hop plant is extremely sensitive to sun, wind, heat, rain, insects, and diseases, and the quality of the cone depends on type, color, soundness, aroma, and content of resins and essential oils. Breeding may play an important part in improving most of these characteristics. The varietal improvement program is new in the United States and though the hop plant is not easy to deal with, the progress made in developing superior varieties in Europe suggests what may be accomplished with sustained and active investigations.*

Colorado and vicinity. The first two species mentioned include all commercial hop varieties.

PECULIARITIES AND PROBLEMS IN HOP BREEDING

THE HOP is one of the few cultivated plant species in which male and female flowers are borne on different individuals. Since commercial hops are the dried and pressed cones from the female plants and these develop without fertilization, the males are not indispensable in commercial culture. The latter do serve to stimulate production of larger, heavier, and earlier maturing cones by the female plants (*20*).[4] Such hops contain seeds, which contribute to the weight but which have no value in brewing, and in parts of continental Europe the presence of male plants in yards is forbidden by law. In the United States and England about 1 male to 100 female plants may be grown.

To the breeder, seed production is necessary, since it is in seedling progenies that opportunity for selection of improved varieties is most promising. The breeding problem is closely analogous to that in dairy-cattle improvement. There is no method of determining the value of a sire in providing desirable heredity to obtain high-producing cows except by progeny tests, since milk production, like hop development, is a purely female character. Nevertheless, from a hereditary viewpoint, the male contributes markedly in each case.

BREWING REQUIREMENTS, YIELD, AND MATURITY

The characteristics of choice hops, from the brewmasters' viewpoint, are relatively few. They should possess a high soft-resin content, delicate aroma, and a clean, bright appearance, and contain few or no seeds, leaves, and stems. Because of the slow, gradual development and fragile nature of the cone, coupled with the extreme sensitivity of the plant to sun, wind, heat, rain, insects, and diseases, the attainment of a choice product is exceedingly difficult. Harvesting operations also play no small part in determining the quality of hops received by the brewery. Though much investigational work has been done in attempts to find suitable substitutes for hops, the use of this crop continues to be the only means in use of giving the desired qualities to beer.

In the culture of hops, the grower has many serious troubles. Most important among these are maintenance of yields, control of diseases and insects, standardization of high quality, and many minor difficulties arising from these. The first task of the breeder is to recognize and understand these factors.

The world over, yields of dry hops per acre may range from 300 to 4,000 pounds. While much depends on the country and locality, the variety used is of chief interest in this respect. The principal varieties of the Pacific coast are Late Clusters, comprising about 75 percent[5] of the acreage; Fuggles, about 15 percent; and Early Clusters, 10 percent. In good years, Late Clusters produce an average of about 1,500 pounds, Early Clusters 1,300 pounds, and Fuggles 1,100 pounds of dry hops per acre. Incidentally, yields in continental Europe are

---

[4] Italic number in parentheses refer to Literature Cited, p 1239.
[5] Includes some Canadian Red vines.

usually from 600 to 1,100 pounds per acre while those of England and Wales approximate those of the United States.

Fuggles is the earliest maturing variety, usually being ready for harvest about August 20, with Early Clusters closely following. Ripening of Late Clusters, which is the main crop, begins in Oregon in early September. Maturity of hops is generally earlier in California and to some extent in the Yakima Valley of Washington. Harvesting of Late Clusters may extend into early October. Many growers have acreages of two or more varieties, which allows a longer harvesting season. Increased yields are always a breeder's objective and the period of maturity is of importance in most sections.

Downy Mildew, Scourge of the Hop Plant

Like other plants, hops are attacked by various diseases, the most serious of which, at the present time, is downy mildew. Other important troubles in the United States are blue mold or powdery mildew, sooty mold, which accompanies infestations of plant lice, and crown gall. Blue mold, a serious disease in England and to some extent responsible for the decline of hop production in New York, has not been reported on the Pacific coast. Sooty mold may be serious in any year when plant lice are prevalent. These diseases may attack hop cones, leaves, roots, or stems causing lowered quality or complete destruction. The effects of downy mildew on cone development are shown in figure 1. In addition to those mentioned, other minor diseases of various types have often been present in Europe and the United States.

In recent years hop growers throughout the principal hop-growing countries have been greatly concerned with downy mildew. Its ravages have resembled in many respects those of the late blight disease of the potato, which caused the Irish famine in 1845 and 1846, or of the frequent stem rust epidemics of cereals in the Middle West.

Downy mildew was first described in Japan in 1905. In 1909 it was observed in the United States, being found in Wisconsin. In 1920 minor attacks of the disease were seen at Wye, in Kent, England, but in 1921 it was not observed there. During 1922 and 1923 it increased in prevalence at Wye, and in 1923 it was reported in Germany and Czechoslovakia. Belgium and France reported it in 1924 and the Union of Soviet Socialist Republics in 1925. In 1926 it appeared in Italy. Beginning in 1927 serious losses were caused, England suffering damage estimated at nearly one-third of the crop and Bavaria also experiencing heavy losses. Some Bavarian growers sprayed 10 times during the season to control the spread of the trouble. Since 1927 the disease has appeared irregularly in Europe, but in individual localities losses may involve the entire crop. Weather conditions are important influences in the development of the disease.

Though found in Wisconsin in 1915, downy mildew did not cause economic losses in North America until 1928, when it appeared in New York, Manitoba, and British Columbia. In 1929 it developed extensively in western Washington and in 1930 was severe in western Oregon. The disease did not appear in coastal California until 1934 and in the Sacramento Valley until 1935. During 1936 it was prevalent in all areas where it had been found previously and caused

a marked reduction in the yield and quality of the crop. To date it has not been officially recorded as existing in the Yakima Valley of Washington, though experienced growers have reported traces of it.

While downy mildew appears irregularly, it has been estimated that 20 to 25 percent of the crop is annually lost through the depredations of this disease in the Pacific Coast States. The source of the organism causing downy mildew (*Pseudoperonospora humuli* (Miyabe and Tak.) Wilson) is problematical, but it is thought to be native on wild hops in the United States. The control of this devastating disease is perhaps the most important concern of hop producers both in the United States and in Europe and is a major objective of the breeder.

Quality and Other Considerations

Particularly in recent years, but more or less persistently over a long period, growers have been concerned with problems affecting quality. Considered from the variety-improvement viewpoint, items of importance are soft-resin content, aroma, and the existence of seeds. Commercially, hops are bought on the basis of general variety or type, color, aroma, lupulin content, and soundness. These might be termed "sight", "smell", and "touch" characters, and experienced growers and dealers rely greatly on these three senses. Recently resin content as determined by chemical analysis has become a greater influence in the hop trade.

Proper attention to the various steps in harvesting and curing favors quality to a large extent, but aside from this, variety and locality are also extremely significant factors. With respect to soft-resin content, American-grown hops are equal or superior to the best European lots. The latter are reputed to be preferable in aroma. Continental hops are also noteworthy for their freedom from seeds as compared with the English and American products. German and Bohemian hops continue to sell at a high premium over domestic lots in the New York markets. Though sufficient domestic production of hops for supplying the American trade usually exists, the use of a certain percentage of foreign hops for brewing is a general practice in this country. To improve the quality of domestic hops is thus another primary object of breeding efforts.

Insects affecting hops most frequently are plant lice or aphids and the red spider. These pests exist in both European and Pacific coast hop sections. Root borers, cutworms, flea beetles, and other insects occasionally do considerable damage. Aphids have been generally present and, where they are numerous, the secretion of honeydew, a sticky sweet substance, reduces quality and serves as a substratum for molds to develop. Red spiders affect the foliage mainly and are usually prevalent under conditions of slow growth and dry, warm weather.

In picking, hops that separate readily from the vines are harvested with the least crumbling and breaking. Types that tend to remain without disintegration in the complete processes of ripening, harvesting, and drying result in the best dried samples. Plants must be long-lived to keep down yard maintenance costs and maintain high yields.

EARLY DEVELOPMENT OF VARIETIES

The natural variability of the hop plant and the futility of attempting to propagate commercially by means of seed was recognized at an early date (*13*). In 1669, different types were distinguished, and by 1726 the existence of male and female plants was noted by European growers. Many varieties were known by 1799. The desirability of growing uniform sorts was also acknowledged though in England during the nineteenth century there was a great confusion of varieties.

During the development of the industry in the United States, as in Europe, many named varieties have been grown that, with the exception of the four now grown on the Pacific coast, have disappeared from commercial fields. Introductions of foreign types made from time to time by producers of extensive acreages have also vanished for the most part.

In the important years of production in New York several varieties grown included English Cluster, Grape, Canada Red, Palmer Seedling, and Humphrey Seedling. The latter types were also cultivated in California and in addition the so-called "American hop" was grown. The Fuggles variety did not prove popular in California.

The earliest recognition by the Department of Agriculture of the need of improved varieties of hops in the United States was in 1900, when David Fairchild imported roots of the best European varieties. After thorough tests it was found that these did not yield well enough to make their production under American conditions profitable. In 1904 he started breeding work and crossed European varieties with American male plants. Prior to this American hop growers had from time to time sought to accomplish the same purpose in the same way with similar results.

In 1908 Stockberger (*17*) outlined a program he had undertaken in the Department of Agriculture. He referred to the failure of the earlier attempts to adapt European varieties and suggested a different procedure based on a recognition of the fact that the hop plant is greatly influenced by soil and climatic conditions, so that improvement by selection of the best varieties already being grown in this country would be simpler and give quicker results. He proposed a careful study of the domestic varieties, the selection of promising individual seedlings, and thereafter the development of desirable types by hybridization. Although the chief objectives he sought related to productiveness and quality, he stated that individual hop plants had shown a marked resistance to disease and that these were being propagated to determine not only whether that character is transmittable but to note their general qualities from other standpoints.

Progress on this project was reported in brief statements in the Yearbooks of the Department of Agriculture for 1911 and 1912 in which the selection of several promising hybrid seedlings and the continued introduction of foreign sorts is referred to. By 1916 several thousand seedlings were under cultivation. About this time a number of circumstances forced the abandonment of the project. A reduction in funds made a continuation of the field work impossible. The European war interfered with further importations of foreign varieties, and a few years thereafter the advent of prohibition greatly reduced the commercial importance of hops.

The investigations of State experiment stations have not until recently been directed toward problems concerning hop varietal improvement, and early Federal experiments have not been continuous.

Principally because of the inroads of downy mildew, experimental work with hops was initiated in 1930 by the Division of Drug and Related Plants of the Bureau of Plant Industry, United States Department of Agriculture, in cooperation with the Oregon Agricultural Experiment Station. The principal purpose of the program was to investigate disease control through field practices and to work toward the development of improved, disease-resistant varieties. Experiments have been in progress since that time. More recently varietal improvement of hops has been started by the New York (State) Agricultural Experiment Station at Geneva, as previously mentioned.

In Europe there seems to have been from early times a careful selection of stocks, varieties appearing and disappearing frequently. Though the origins of many strains are obscure, numerous ones are known to have resulted from selection of chance seedlings and others by propagation from desirable plants. The Late Clusters variety is thought to have arisen from a chance seedling of the wild hop. The origin of Fuggles is typical of the development of many strains. Concerning it Percival (*6, p. 87*) wrote:

> The original plant was a casual seedling which appeared in the flower-garden of Mr. George Stace, of Horsmonden, Kent. The seed from which the plant arose was shaken out along with crumbs from the hop-picking dinner basket used by Mrs. Stace, the seedling being noticed about the year 1861. The sets were afterwards introduced to the public by Mr. Richard Fuggle of Brenchley, about the year 1875.

Another old English variety, Colgate, was started from a likely looking plant found growing in a hedge. Bates Brewer was developed from root cuttings obtained from an outstanding plant that was paid for in whisky (*6*). Many of the continental varieties undoubtedly began with similar plant selections. The varietal history of hops closely resembles that of potatoes. Selections of seedlings by growers, followed by vegetative propagation, have frequently originated new types in both plants.

Fruwirth (*4, pp. 77–88*) assigned the origin of several early varieties, including Golding, Early Brambling, and Semsch, to bud variations, the variants then being propagated independently by cuttings. This is comparable to the bud or graft propagation of new apple types appearing on trees of old varieties.

Individual workers, not growers primarily, undertook independent investigations late in the last century. Fruwirth began selection of promising individuals in 1888. Other workers mentioned by Fruwirth were Stambach, who first planted seedlings in 1894, and Remy, who in 1898 was making studies of the resins and tannins of seedlings. Early work also included that of Beckenhaupt at Weissenburg and Wagner at Weihstephan, Germany, who grew local and introduced varieties in comparative trials.

Organized efforts for hop improvement began fairly late in the last century. A testing garden was established near Saaz, Bohemia, in 1897, and many varieties were grown. Breeding by seedling selection had begun in Belgium by 1903. About 1898 the Agricultural College

of Wales began investigations on hop improvement, and breeding was undertaken in 1907. One of the oldest and most active investigational projects has been in progress in England since about 1904. In 1913 visitors to the college hop nursery at Wye, Kent, selected promising seedlings for trial and subsequently 2,830 cuttings from 23 varieties were supplied to growers. A testing station especially for determining brewing value was established at East Malling in 1917 and has made important contributions to the English work. By 1911 Denmark had begun variety investigations. Additional stimulation was given to hop breeding in Europe generally by the severe losses due to downy mildew in 1926 and 1927. In 1926 a society for hop research was founded in the Hallertau district of Bavaria. In 1932 a large German hop company placed its acreage at the disposal of the government for testing purposes. The work of hop selection in the Union of Soviet Socialist Republics, undertaken by the Agricultural Academy of Moscow, began in 1926. In addition to those mentioned, other state, governmental, and private agencies in Europe are concerned with varietal improvement of hops. In the appendix are listed some of the workers and the countries in which experimental work is in progress.

RECENT BREEDING WORK

The improvement of hop varieties concerns the cone-bearing female individuals particularly. When seeded hops are grown, male plants that produce abundant pollen at the time of the flowering of the female plants are needed. Thus selection of desirable male plants may be necessary.

Considering grower and trade demands, an ideal variety would embody resistance to downy mildew, high yield, suitable resin content, and good aroma. It would be medium leafy, easily picked, resistant to insects, and capable of remaining on the vines a reasonable time after maturity without deterioration. Excessive fragility and large stems would be undesirable. This indicates the varied character of the hop-breeding problem. Meanwhile, new diseases or other troubles may appear to provide additional complications. Considering all these points, no varieties commonly grown at present quite "fill the bill."

Recent work has developed along several important lines. In 1930 and 1931 an extensive survey was made of the plant material being grown in commercial yards of Oregon, to determine the possibility of selection of superior types in old hop yards. In 1935 a similar, though less comprehensive, inventory was made in coastal California. Superficial examinations have also been made of a few Yakima Valley yards in Washington. The general result of these surveys has been failure to find occasional plants, which might be propagated as improved types, strikingly superior to the general lots of the four important varieties. There has frequently, however, been a varying percentage of inferior sorts, the elimination of which would allow a sizeable increase in production. Such types have been chiefly hermaphrodites[6] and sterile plants producing no flowers, often called bastard hops by

[6] Hermaphrodites, as in animals, are individual plants developing both male and female sexual characters. In hops such plants produce pollen and also cones.

growers. In many yards male plants are unnecessarily numerous for pollination purposes. Additional work is being done on vegetative selection among commercial varieties and the breeder is constantly watching for superior individuals.

In all plant improvement one of the most promising methods of obtaining better types is the introduction of varieties from foreign

Figure 2.—Vines of the Late Clusters variety of hops, with side branches covered with glassine bags to control pollination. Bags are held in place by paper clips, and operations are recorded on small marking tags attached to the stems.

countries having growing conditions comparable to those in our own hop areas. Experience has not been promising as to the value of this practice in hop improvement, but it is hoped that useful breeding material will be acquired by this means. Beginning in 1931, attempts have been made to obtain propagation stock of superior English and continental varieties to grow in the experimental nursery at Corvallis, Oreg., in comparison with domestic sorts. Though some European countries have prohibitions against the exportation of cuttings, in all about 35 foreign strains have been obtained by the Division of Plant Exploration and Introduction and are now being grown. Cuttings for propagation improperly packed are perishable and in some instances difficulty has been experienced in obtaining living roots shipped long distances. Plants from imported cuttings do not usually bear hops until the second year.

The third method of attack that may be used for variety improvement is the selection of superior plants from those grown from seed. This plan appears to offer most promise. Since it is difficult to designate male individuals according to variety, all seeds produced may be considered of hybrid nature. Thus seed may be collected from any good female in the hope that some of the progeny will excel the

mother plant in various characters. The nature of the male parent in such a case is unknown. It is also possible to obtain seeds from plants that have been pollinated artificially. In these cases the nature of the male is known, and vigorous, desirable types may be used. When controlled pollination is practiced, the female flowers are covered with

Figure 3.—View of experimental yard showing plant variation among hop seedlings. Those in the foreground are superior types.

small bags and pollen of the male plant is shaken over the blossoms. A plant undergoing artificial pollination is illustrated in figure 2.

Hop Yards for Experimental Testing

The experimental field at Corvallis, Oreg , consists of an area trellised and spaced like a commercial yard and another smaller section for growing seedlings for the first year's observations. The larger area, pictured in figure 3, is capable of accommodating about 3,500 plants spaced 8 feet apart. Included in this section are plantings of all domestic and available foreign varieties, together with seedling plants that appear worthy of growing beyond the first year. The smaller area, known as the seedling yard, is designed for growing first-year seedling plants for preliminary observation. Seedlings are planted 15 to 18 inches apart in the row and trained on strings attached to a wire approximately 6 feet from the ground level. About 3,000 plants may be grown under these conditions (fig. 4). Seedlings that appear to be of the types sought are then transplanted to the standard yard for further tests. Hop seeds may be sown in greenhouses or in coldframes in the field in early winter or early spring. In the growing season the

138904°—37——78

Figure 4.—First-year hop seedlings in nursery yard. Note closeness of planting and variable growth.

Figure 5.—Seedling hops in greenhouse beds. The dome lamps may be used to supplement daylight during fall and winter months. Strong seedlings are thus developed for field planting in the early spring.

plants obtained are moved into the seedling yard or into field rows to be later included in the nursery. Seedlings growing in greenhouse beds are shown in figure 5.

Though, in general, growing conditions are kept favorable for plant growth in the experimental areas by following common commercial methods, the nature of the information sought requires certain widely divergent practices. One of these is the actual fostering of the development of the downy mildew disease by cultural practices favorable to its spread so that it will "run wild" among both the older plants and the seedlings under observation. Since resistance to this malady is one of the chief goals, its rapid spread is sought, to permit selection of resistant types. Where it may seem apparent that plants vary in reactions to insects, the latter pests may also be left uncontrolled. Since it is not desirable to select plants under soil conditions exceptionally favorable for growth, the use of fertilizers is restricted. Otherwise, plants are allowed to develop in a manner comparable to those in commercial yards.

Figure 6.—Experimental hop-drying chamber. The small cabinet within contains the samples of hops, placed in coarse mesh bags. The scale beam allows constant checking of moisture losses as the charge is dried. Drying temperature and heated-air flow may also be recorded.

During the growing season many types of observations are made. The development of downy mildew and the plant's reaction to it are recorded weekly for some 3,000 seedlings and foreign and domestic varieties. Data are also taken on infestations of aphids and red spider. Relative maturity, vigor, stem and leaf color, leafiness, abnormalities, and sex are also recorded in seasonal notes previous to harvest.

Late Clusters, Early Clusters, and Fuggles are grown in plots of sufficient size and number of plants to obtain information on yields. In 1934 and 1935 over 400 such plants were picked and weighed individually. Other less common varieties, such as Red Vine and Bavarian, are also grown though less extensively. Foreign strains and all promising seedlings are harvested individually but have not been grown on a comparative yield basis, for reasons indicated later. After picking, samples are dried in a small experimental drier (fig. 6) through cooperation with the Oregon station section of agricultural

engineering. The hops are then pressed into small bales resembling the commercial package except in size.

Chemical tests have been made on many samples to determine the soft-resin content as a means of obtaining some index of quality. Physical examinations have also been made for color, aroma, seed content, cone size and condition, and presence and appearance of lupulin. At present, the chemical and physical analysis of the dry hops is the ultimate test for brewing value. Actual brewing tests will be necessary to finally establish the suitability of new strains for commercial use

Breeding Objectives and Progress

In the hop-breeding project thus far, definite information has been obtained on a number of problems, and observations made since 1930, together with contacts with growers and dealers, have served to crystallize objectives.

Late Clusters, the dominant domestic sort, is normally a good yielder, has a high soft-resin content, and is otherwise well suited to brewing purposes. It is, however, quite susceptible to downy mildew, plant lice, and red spider. It is also leafy and late in maturity. Early Clusters is very susceptible to downy mildew and aside from being somewhat earlier is interchangeable commercially with Late Clusters The cones are larger and the vines a little less leafy. It is a favorite with pickers. Fuggles is resistant though not immune to downy mildew, usually making a fair crop when cluster varieties are severely injured Yields are decidedly lower than those of the Early Clusters and Late Clusters and the variety does not permit as much delay in harvest as does Late Clusters. It is also quite susceptible to red spider injury. The soft-resin content of Fuggles is usually below that of the cluster types and the commercial trade recognizes the variety as an individual class

Red Vine hops have been grown more extensively in earlier years than at present; very few uniform fields of this variety now exist. It is noted for its pleasing aroma and many growers believe a small amount of Red Vine hops adds in this respect to the quality of Late Clusters. The soft-resin content is comparable with that of Late Clusters. Chief objections to Red Vine are leafiness, many small hops—though the yield is good—late maturity, and susceptibility to aphis, which is due in part to profuse foliage.

Where suitable males are present, all of these varieties produce abundant seed, but the prevention of seeding might easily be accomplished by elimination of male plants. Inability to obtain satisfactory premiums for seedless hops has not encouraged growers on the Pacific coast to eliminate seeds.

None of 30 varietal strains introduced from other hop-growing countries has appeared to be superior or equal to those now grown on the Pacific coast. This may be comparable with the results of extensive corn trials in the United States where many varieties do well only within small areas or localities. Certain of the introduced varieties have made fair growth and several have exceeded Late Clusters in percentage of soft resins. In table 1 are given results of physical and chemical analyses of some foreign and domestic hops

TABLE 1.—*Physical and chemical analyses of hop varieties and seedlings grown at Corvallis, Oreg., 1935*

Variety or seedling	Color	Aroma	Lupulin	Cones	Total soft resin
Foreign varieties					*Percent*[1]
Landhopfen	Yellow green	Strong, pleasant	Yellow, very plentiful	Medium	20.88
Burgunder	Greenish golden yellow	Pleasant, flowery	do	Small	19.92
Bavarian[2]	Yellowish green	Mild pleasant	Lemon yellow, plentiful	do	19.17
Alsace	Pale green	Strong not pleasant	do	Medium	18.60
Golding	Greenish golden yellow	Mild, not pleasant	Yellow, plentiful	Small to medium	17.87
M 45	Yellowish green	Mild, pleasant	do	Medium	17.70
Spalter	Pale green	Excellent flowery	do	do	17.54
Elassar	Yellowish green	Very pleasant, flowery	do	do	17.54
Domestic varieties					
Late Clusters	do	Mild agreeable	Lemon, yellow very plentiful	Small to medium	19.12
Early Clusters	Golden green	Strong, pleasant	Yellow, plentiful	Medium to large	18.58
Fuggles	do	Mild, very pleasant	Lemon yellow plentiful	Medium	17.62
Red Vine	Golden yellow	Strong, not pleasant	Yellow plentiful	Large	17.11
Seedlings					
52-31	Pale green	Strong, pleasant	Lemon yellow, plentiful	Medium to large	19.71
8-12	Yellowish green	Mild, agreeable	Lemon yellow very plentiful	do	19.06
62-27	Pale green	Mild, pleasant	Yellow, plentiful	Small to medium	18.12
101-32	Bright green	Very mild, pleasant	Very plentiful	Medium to large	17.75
36-32	Pale green	Mild, pleasant	Plentiful	Small to medium	17.70
73-12	Yellowish green	Strong, unpleasant	Very plentiful	do	17.20
70-13	Pale green	Mild, pleasant	Yellow, plentiful	Medium	17.16

[1] Based on air-dry hops

[2] Of uncertain origin, possibly a domestic selection by growers

grown at Corvallis, Oreg., in 1935. Though the data are for 1 year only, the analyses are remarkably high.

The soft-resin content is based on individual determination of several resin components, which is the usual method of chemical analysis. The notes on physical characteristics of the various lots are of importance, since commercial dealers usually observe these points in trade samples Comparisons may be made between foreign and domestic varieties by reference to the table. Though all of the samples listed might be considered choice from a trade viewpoint, superiority of certain strains is indicated. In both 1934 and 1935 Landhopfen and Burgunder exceeded Late Clusters, the richest domestic variety, in percentage of soft resins. Analyses of certain of the better seedling selections indicate the possibilities for obtaining improved types in this important character.

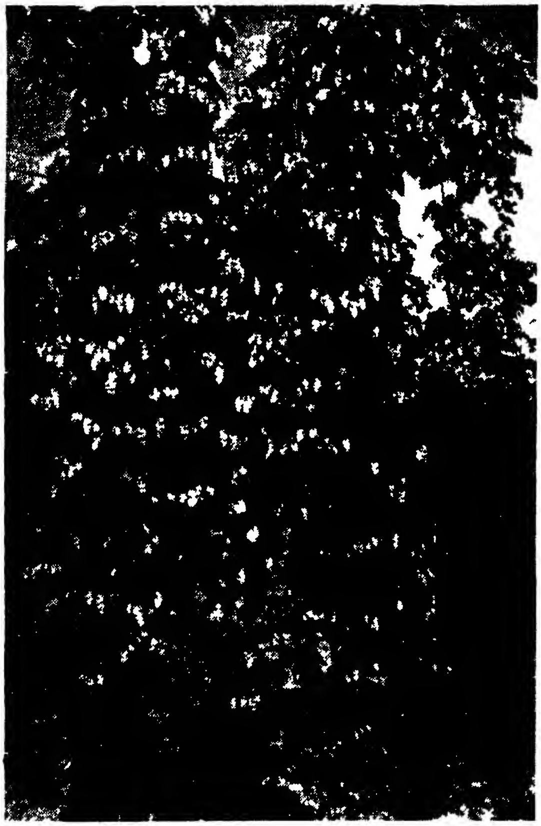

Figure 7.—A promising seedling hop plant having a cone type resembling Fuggles and leaves similar to those of Late Clusters.

Wide variations in physical traits may be noted, though soft-resin contents remain similar. Aroma particularly may vary from excellent to strong and unpleasant when other characters seem to vary but little.

Many seedlings have been grown at Corvallis since 1931. Seed has been obtained from domestic and foreign varieties from the experimental yard and from many commercial fields. These seedlings have been for the most part of inferior types. Many are male plants, others are dwarfed or otherwise undesirable, and only rarely is a plant producing "fair" hops obtained. One of the latter sorts, considerably better than usual, is illustrated in figure 7.

In the matter of soft-resin content, seedlings may vary over a wider range than varieties. In the 1933 season 29 of these varied from 9 to

17.9 percent,[7] while Late Clusters contained 17.9, and Fuggles 16.3 percent soft resins. In the crop of 1934 cones from 57 seedlings contained between 9.4 and 17.8 percent of soft resins. The percentage for Late Clusters was 17.8 and for Fuggles 14.8. Nineteen foreign varieties grown at Corvallis under similar conditions ranged from 14.2 to 19.4 percent soft resins. Similarly, the 1935 crop of 50 seedlings ranged from 11.1 to 19.7 percent; Late Clusters contained 19.1 and Fuggles 17.6 percent. Foreign varieties, 23 in number, varied from 14.1 to 20.9 in percentage of soft resins.

In aroma, many seedlings have compared to advantage with standard varieties while some are decidedly inferior.

Experience has demonstrated, both here and abroad, that plant reaction to downy mildew is difficult to ascertain. This is due to the irregularity of the occurrence and development of the disease. The nature of this problem may be indicated by the fact that one seedling of a very promising nature in the years 1931–33, free from mildew and of good agronomic appearance, mildewed severely in 1934 and 1935. Preliminary tests have shown that artificial inoculation of questionable plants by hypodermic injection of the mildew organism may be feasible. This would tend to supplement the work of nature in the development of the disease and make possible more rapid progress. Results at Corvallis offer some assurance of obtaining seedlings resistant to the downy mildew disease.

Since yields of foreign types have been obviously inferior to those of commercial varieties, comparative yield tests of the former with domestic sorts have not been made. Neither have any of the foreign varieties proved to be highly resistant to downy mildew.

Results thus far indicate that leaf, stem, cone form, and cone arrangement are fairly constant from year to year. Plants producing male or female or both types of flowers in any one year tend to be similar in other years though occasionally marked exceptions may occur.

Resistance to aphids and red spider has not been found in any varieties or seedlings observed. Though many plants have not been injured, several years' observation, as in the case of reaction to downy mildew, will be required to definitely determine the stability of this character.

In summary, of the improvements sought, agronomic characters, including high yield and desirable cone type, have proved to be the most difficult of attainment, judging from recent experience in the breeding project. Between 15,000 and 20,000 seedlings, of which approximately 3,000 have been grown to the cone-producing stage, have allowed selection of fewer than 10 with records of resistance to mildew, high resin content, and good agronomic qualities. Most of these may not survive continued tests.

It is proverbial among plant workers that varietal improvement usually requires consistent work over many years before great practical benefits can be shown. While propagation by cuttings simplifies the plant breeder's job in that plants "impure" from the hereditary standpoint may be reproduced as uniform, true-breeding commercial varieties, in the case of hops this advantage is counterbalanced by problems not usually met in such work.

[7] Based on moisture-free sample.

Large Numbers of Plants Needed for Effective Selection

Caring for large numbers of plants individually during a period of several years requires a large area and much labor. Picking and drying many samples separately and the making of chemical tests also present physical problems. All of these limitations mean that the work is necessarily slow.

Growers of the Pacific coast have shown new concern in improvement problems since 1931. Of interest in this regard also is the initiation of the varietal improvement project by the New York (State) Agricultural Experiment Station, previously mentioned.

Though European varieties have not to date proved to be adapted to conditions on the Pacific coast, the progress made in developing improved types in Europe by seedling selection offers hope for comparable progress in the United States.

Mildew Records

An obstacle common to all breeding for resistance to disease is the frequent necessity of waiting for natural development of epidemics before plant reaction can be obtained. Downy mildew appears capriciously, and 8 to 10 seasons may be required to adequately determine plant reaction to this disease. Yield and quality are variable characters requiring tests of several seasons' crops.

Methods of recording and comparing data on downy mildew reaction from season to season have presented a troublesome problem. At present such notes are taken at approximate weekly intervals while the epidemic is spreading, and plants are classified by numbers from 0 to 5 as representing progressively increasing numbers of leaves or branches infected by the disease. Comparative classifications of 2,827 plants upon which notes were taken in 1934 and 1935 are given in table 2. The differences of reaction from year to year due to variation in the development of the epidemic through the area are indicated. In 1934, for example, 294 plants were classified as no. 5 in reaction, or very susceptible. Of these, 183 failed to develop symptoms in 1935. Of the 1,788 plants classed as 0 in 1934, 1,543 did not mildew in 1935. The data show that even with downy mildew generally present, many susceptible plants may escape infection.

TABLE 2.—*Downy mildew, incidence in experimental yard, Corvallis, Oreg., 1934–35*

1935 classification [1]	Plants in each classification [1] in 1934						Total
	0	1	2	3	4	5	
0	1,543	99	304	58	62	183	2,249
1	41	2	7	3	6	10	69
2	165	8	92	22	20	60	367
3	2	0	2	4	2	2	12
4	1	0	2	1	0	1	5
5	36	3	25	15	8	38	125
Total	1,788	112	432	103	98	294	2,827

[1] 0 to 5 represents progressively increasing numbers of infected leaves or branches.

Seasonal Productivity

Various agronomic reasons for unproductive hills were suggested by Bressman (*1*), and Stockberger (*19*) indicated certain conditions influencing yields. Attempts have been made to determine the consistency of yield of hop plants (*18*) from year to year. Growers often experience unexplainable irregularity of development and production in yards usually uniform. The question has arisen also as to the possibility of continuously selecting from the most vigorous plants as a means of increasing yield by isolation of more vigorous types. Information is being sought that will answer these questions more completely.

In 1934 and 1935 hill surveys were made of 25 different marked areas of 100 hills each in some 15 yards, on several soil types in western Oregon. Plants were classed as S (strong), M (medium), W (weak), X (untrained—also a weak type) and O (indicating no plant present), at two periods in each season. A contingency table (table 3) shows the relations between 1934 and 1935 notes taken just previous to harvest. Hills designated as O in 1934 were replanted in the early spring of 1935. The data indicate unexpected irregularity in the seasonal growth and productivity of any particular class of plants. Frequently individuals classified as strong in one season may be considered as weak or even fail to produce hops the succeeding year. Continuation of records may provide information serving to throw light on such variations

TABLE 3.—*Summary comparing hill survey of plant types, commercial yards, Willamette Valley, Oreg., 1934–35*

1935 classification [1]	Plants in each classification in 1934					Total
	S	M	W	X	O	
S	390	51	216	21	95	773
M	165	4	98	9	60	336
W	85	1	91	33	227	437
X	10	0	9	6	29	54
O	45	0	27	5	51	128
Total	695	56	441	74	402	1 728

[1] S=strong, M=medium W=weak X=untrained O=no plant present

Production data add more precisely to the interpretation of this problem. Actual yields on individual plants from the experimental yard in 1934 and 1935 are available on the Late Clusters, Early Clusters, and Fuggles varieties. Correlations between yields of the two seasons are indicated in table 4.

TABLE 4.—*Yield data for three varieties of hops, 1934–35*

Variety	Plants	Mean yield		r value	P value exceeds—
		1934	1935		
	Number				
Late Clusters	104	7.9±0 50	12 14±0 49	0 19	0 05
Early Clusters	113	7.19± 40	7 94± 31	57	.01
Fuggles	125	5 60± 20	7 26± 19	.39	.01

In general a significant relation between yields from year to year is exhibited, although the correlation coefficient for Late Clusters is marginal.

Other Important Technical Studies

Analyses of the results of artificial pollination have been complicated by two major problems—(1) the slow and irregular germination of hop seeds, and (2) the doubtful results of bagging. Somewhat detailed studies have shown greatly increased and more rapid germination as a result of cold treatments. One of the best of the treatments used was placing the seeds in moist blotters in a germinator for 5 days at room temperature followed by refrigeration for 5 weeks at 5° C. Such procedure has increased germination from less than 10 to over 70 percent. Once seeds have germinated and plants have emerged, growth may be rapid. Artificial illumination has been reported by Bressman (*2*) as of value in stimulating vegetative development.

Results of bagging and subsequent pollinations have been inconclusive. Some seeds have developed within and outside of glassine and parchment bags whether or not enclosed flowers were artificially pollinated. The bags used have been tightly secured to the branches by paper clips. Flowers have been covered at various early stages of development, from the period immediately preceding the appearance of the stigmas through the time when they withered. Whether plants form seed parthenogenically, without fertilization, or whether seed obtained from bagged, unpollinated flowers will grow has not been satisfactorily determined. Thus far the possibility of incomplete exclusion of pollen from bagged flowers does not seem adequate to explain the results obtained. Winge (*20*), Howard (*5*), and others, however, have reported the failure of seeds to set when pollen was not allowed to reach bagged flowers. Relations between ability of male pollen from different plants to cause fertilization and ability of females to produce seed are also being determined. Until seed formation and germination can be more accurately controlled, the results and the value of hybridization will be uncertain.

Constancy in development among various plant characters from year to year is indicated in table 5. Fundamental information is needed in this respect to form a basis for plant selection.

TABLE 5.—*Constancy of plant vegetative characters*

1935 classification	Plants in each classification in 1934						
	Dwarfs	Dwarfed	Witches'-broom	Ragged	Russeted	Colored vines	Total
Dwarfs	2	0	0	0	0	1	3
Dwarfed	13	6	1	1	2	1	24
Witches'-broom	0	0	17	0	0	0	17
Ragged	19	17	3	65	18	66	188
Russeted	4	3	0	5	29	14	55
Colored vines	6	14	0	4	4	265	293
Total	44	40	21	75	53	347	580

Descriptive differentiation of the classifications seems unnecessary to illustrate the variations in vigor and type of growth from season to season. With the exception of colored vines, other classes are plant

weaknesses and therefore undesirable. Occasionally vigorous plants of good general type may show light russeting of leaves. Ragged plants develop torn or ragged leaves and flowering branches may be partially or entirely sterile. The type known as "witches'-broom" is apparently the sterile dwarf described by Salmon (*7*). It is possible that some of the conditions listed may be pathological while others may be due in part to genetic factors. While detailed notes are available for 2 years only, a marked constancy of growth character is evident in certain groups.

In dioecious species such as hops the expression of sex is of particular interest. Development of hop plants as to sex appears to be generally constant though infrequent, wide deviations apparently occur. It is a fairly common observation of growers that in some years more male plants appear than usual.

In approximately 1,200 seedling plants in the experimental yard upon which notes have been taken for sex, the following deviations occurred in 2 years, 1934 and 1935:

	Plants
Change from male to female	5
Change from male to hermaphrodite [8]	2
Change from female to male	1
Change from female to hermaphrodite	1
Change from hermaphrodite to male	2
Change from hermaphrodite to female	5

[8] See footnote 7, p. 1230.

Deviations may be noted in all degrees of sexual expression. Data are insufficient to justify generalizations as to which transformations occur most frequently or to suggest possible explanations. Observations of Chartschenko (*3*) in this respect are noted later. Salmon (*7*) has recorded relative frequencies of male and female individuals in seedling progenies, as well as other developmental types.

The variation to be expected in resin analysis of hops from the same plants from year to year is a factor requiring careful study. Even though individuals are harvested at as nearly the optimum time as possible and all other factors are controlled similarly, large differences may exist from season to season. This is illustrated in table 6, comparing examples taken at random from yearly analyses of individual plants.

TABLE 6.—*Soft-resin contents of hops from individual seedling plants*

Seedling no.	Soft-resin content for— [1]			Seedling no.	Soft-resin content for— [1]		
	1933	1934	1935		1933	1934	1935
	Percent	*Percent*	*Percent*		*Percent*	*Percent*	*Percent*
36-7	18.22	17.95	16 03	62-27	17.53	14.93	18.12
52-10	17.10	16.96	15.93	8-10	18.70	17.61	16.77
19-33	17.49	16.77	14 36	56-28	14.60	10.24	12.88

[1] Percentages on dry basis.

The data show the relative inaccuracy of analysis of a single year's crop as a strict indication of plant behavior, at least for some individuals. Plants might, however, be placed in general groups as good, fair, and poor, with reasonable accuracy in most instances. Increased

experience and additional care in harvesting, drying, and packaging of samples will undoubtedly decrease the errors encountered.

Contributions by Various Investigators

A brief review of investigated points of interest in hop breeding will indicate the nature of some of the problems and the facts obtained in other hop-growing countries. Though hops were investigated at an early date, comparatively little information on breeding aspects may be found in the literature. Reference has already been made to certain work. An attempt to bring together scattered supplementary facts and further outline the general background seems desirable.

It was early noted that plants from seeds were variable and most often poor (*13*). A wide range of maturity was also noted in such progenies (*15*). In addition it was recognized that new varieties might arise either from seeds or from bud variations.

Salmon (*7*) obtained the following results from seed progenies derived from controlled pollinations:

From 256 seeds 87 seedlings were produced, of which 52 plants were normal and 35 were sterile dwarfs.

From 285 seeds 67 seedlings included 66 fertile and 1 dwarf plant.

From 261 seeds 120 plants, all of normal vegetative growth, included 108 females, 111 males, and 1 hermaphrodite.

From 899 seeds 109 seedlings included 79 normal plants and 30 sterile dwarfs.

The dwarf plants made little growth compared to normal plants and failed to form flowers of any kind. Such results represent the expected appearance of many inferior plants in seed progenies, however derived. Studies of three groups of seedlings reported by Fruwirth (*4*) indicated the proportions of female plants to be 66, 77.7, and 90 percent respectively, in the progenies considered.

Pollinated cones were found by Winge (*20*) to be larger and heavier than those whose flowers were not pollinated. Unpollinated hops were observed to remain longer in the bur, and stigmas at the stem end were noted to appear first (*5*). Fertilized cones were also thought to mature earlier and resist mold to a greater degree than those unfertilized.

In order that pollination might be complete, it was recognized that male plants must shed pollen throughout the bur period of the females. Pollen from hermaphroditic plants was determined to be viable and to be capable of fertilization (*20*). Chartschenko (*3*) reported female flowers of such plants to produce viable seed.

The impossibility of crossing two female plants has been pointed out, though combinations of female varietal characters in one individual may often be desirable. In addition it seems obvious that since male plants do not bear hops, their value in use as parents must be determined with appreciable difficulty.

As early as 1894 Stambach, cited by Fruwirth (*4*), planted out seedling hops for observation. Remy, mentioned by the same writer, studied resins and tannins of seedling hops in 1898. He crossed cultivated female varieties with wild males, crossed an F_1, or first generation, male of the progeny with a cultivated female plant, and then recrossed an F_1 male of the latter progeny back to a cultivated female. This is a comparatively complicated crossing scheme but is occasionally used by plant breeders.

Reversals in the nature of the sexual character of hop plants have been reported by several workers, according to Fruwirth (*4*). Chartschenko (*3*) has given examples of sexual changes. A male plant was described as changing to a normal female in 2 years, being a hermaphrodite in the third, and a normal male again in the fourth year. In another case a cutting from a female plant produced a vine bearing male flowers. In yet another instance two female plants changed to hermaphrodites. Vegetative increase of these also gave rise to hermaphrodites.

Much interest has been shown in studying relations of numerous plant characters to the important property of resin content and other indications of quality. Fruwirth (*4*) reported high yield to be associated with inferior aroma, greater foliage production, stouter strigs (center stem of cone), and plant longevity. Chodounski, mentioned by Fruwirth, thought coarser hops to be characterized by inferior hairing, lack of uniformity in strength, abnormal structure, and other characters of the strig. Sutora, cited by the same writer, concluded that a coarser strig and darker green color of the hop is associated with a lower tannin content. According to Fruwirth, finer hops were thought by Wagner to have smaller bracts and a smaller bract area. Percival (*6*) pointed out that delicacy and weakness of cones were often met with in hops of the best quality. Salmon has indicated that a theoretically choice English hop might combine high soft-resin content with the aroma of present English or Saaz varieties (*8*). He stated that total resin contents remain fairly constant from season to season in varieties generally (*9*). Chartschenko (*3*) reported that Russian work had failed to establish any female characters as being associated with resin content. Within varieties no significant relation was found between resin content and yield of green hops or earliness of ripening, or in most cases between earliness and yield of green hops. Appreciable variation was found as to resin contents between vegetative selections within varieties. Results of analyses of male plants in which resin contents varied from 1.77 to 3.48 percent were given. Attention was directed to the importance of this in view of the fact that the male contributes half the inheritance of the progeny in this and other characters.

It has been accepted that variety has more to do with resin and oil content of hops than soil or locality. Other factors that influence these characters are climate, fertilizers, maturity, drying methods, and seed content. The aroma of certain types of American hops has been compared with the odor of turpentine, black currant leaves, onions, rue, and apples, and therefore said to be inferior to that of European hops (*8*). Resin content (*14*) and aroma (*16*) have been found to be inherited traits and progeny plants may exceed the female parent in these important attributes.

In one instance of a cross, the aroma of an Oregon female plant was exhibited by about three-fourths of its progeny. Aroma has been shown to be transmitted through the male, by the same investigator (*16*).

Characters recognized as constituting differences among varieties have included vine color and length of internodes; maturity, arrangement, and form of strobiles; color, number, and form of leaves; leafi-

ness in proportion to cones and stems; and relative dry weights of the cones. Though variation seemed less marked in males, they were found to be generally as variable as female plants (*22*).

American varieties introduced into England have proved to be unsuited there and it has been concluded (*8*) that introduction of foreign varieties has little value except for use as parents in obtaining superior seedlings. This may represent the major value of varietal introductions made into the United States.

Since the appearance of downy mildew in European hop culture, attention has been directed to varietal response to this and other diseases. Salmon (*9*) has reported many of these results, which eventually have served to classify all varieties as mildew-susceptible though in varying degrees. Saaz hops, at first thought to be immune, mildewed in 1932. Fuggles is one of the most resistant types, but both leaf and cone infection have occurred. Some strains may be resistant to cone infection. Many of the most resistant sorts are now in commercial use. Salmon (*10*) has also observed certain varieties and seedlings to be resistant to blue mold.

In England the "mosaic disease", so called because of its mottled coloring effects on the leaves, affects all hops except the varieties Fuggles, Tolhurst, and Colgate. Nettlehead and chlorotic diseases have been found only on Fuggles (*8*). In 1926 mosaic disease was serious in Yugoslavia. Mosaic disease, nettlehead, and the chlorotic diseases are virus [9] troubles not generally reported from hop-growing countries.

Crossing experiments with hops have been carried out in most European countries since 1900 Hybrids between *Humulus neomexicanus* and *H lupulus* have been reported (*11*). Imperfectly formed seeds of *H lupulus* and *H japonicus* have been obtained (*20*), but these have failed to produce plants

Cytologic investigation has received little attention to the present time, though Winge (*20*, *21*) has studied the genus *Humulus* in some detail. Chromosome numbers in *H. lupulus* have been found to be 20 in the vegetative cells (diploid). These have been designated as 18+2X in the female and 18+X+Y in the male. In *H. japonicus* 17 have been assigned to the male (14+3X) and 16 to the female (14+2X) (*21*)

Absence of more complete information on inheritance of plant characters is undoubtedly due to the sexual nature of the hop species and attendant problems in obtaining satisfactory progeny tests. As previously mentioned, the situation approaches that in higher animals.

Breeding Program Slow But Promising

Isolation of improved varieties of hops resistant to downy mildew and otherwise superior to present domestic sorts appears to be reasonably practical. Present objectives in hop breeding are well recognized and methods of reaching desirable ends are in the process of establishment. Results obtained in England indicate promise for consistent investigation. Hop breeding experiments initiated at Wye, Kent, in 1907 have resulted in significant improvements of the English crop. Salmon (*12*) has recently announced the development of two valuable

[9] An infectious principle not recognized as due to a particular organism, but capable of causing disease.

new varieties, Brewer's Favourite and Brewer's Gold. The first of these is a seedling originating in 1909 from a plant of Oregon Cluster (probably Late Clusters) introduced into England, and it has been tested extensively since that time. Brewer's Gold is also a seedling, first raised in 1919. These varieties are high yielders, producing cones rich in soft resins and otherwise acceptable to both brewer and grower.

Based upon breeding investigations with crops of other kinds as well as hops, continued experimentation will be necessary if progress is made such as has been reported in other countries. The breeding project requires observation of numerous plants in comparative field and chemical tests over a long period.

IMPROVEMENT OF FOREST TREES

ERNST J. SCHREINER, Forest Geneticist, Northeastern Forest Experiment Station, Forest Service

FORESTRY is a young profession. In comparison to agriculture, it has just been born. Under pressure of necessity, farmers were breeding crop plants long before genetics supplied the key to many of the mysteries they encountered; but the natural products of the forest were plentiful and were taken as needed, without thought of artificial replacement Until very recently, indeed, even foresters have been

Figure 1.—A "man-made forest" of slash pine in southeastern Louisiana. The artificial regeneration of cut-over lands on such a large scale emphasizes the need for guidance from sound genetics work in the improvement of forest trees.

content to utilize wild trees as they were found. This lack of interest in the improvement of forest trees has been due both to the lower unit value of the stock and to the greater difficulties involved in breeding work.

Various factors have been responsible for a gradual change in attitude within recent years. The rapid recession of the timber supply accessible to established wood-using industries; the inferior quality

of much of the second-growth wood; more stringent quality requirements in the finished product to meet the competition of other manufacturers or of substitute products, necessitating uniformity or improvement in quality of the raw wood material; the denudation of forest areas by uncontrolled commercial exploitation and the necessity for having them restocked and managed by public agencies in the public interest (fig. 1); the urgency of soil conservation on nonagricultural lands—all these have played a part in exerting pressure for a more intelligent attitude toward the forest problem as a whole, and the exploration of any possibilities that might be promising.

The tree breeder, then, has just begun to roll up his sleeves. In comparison with his confreres who deal with the older agricultural crops, his attitude is one of humility; he is only at the beginning and he has much to learn. But on the other hand, because his work is all before him, he sees infinite possibilities ahead for the improvement of forest trees by breeding and selection.

This should be kept in mind by the reader as he peruses the following brief account of the present status of breeding work with forest trees. In various parts of the world, considerable necessary spadework has been and is being done. Much of it might not be called either genetics or breeding by those who have become facile in dealing with the smaller, quicker maturing crop plants. Nevertheless, this spadework will be of great value to forest-tree improvement, and it is essential to the building up of a science of forest genetics. The appendix gives a concise summary of most of the work relating to forest-

---

UNTIL *very recently, foresters have been content to utilize wild trees as they were found. There has been a gradual change in viewpoint, brought about by the same factors that have exerted pressure for a more intelligent attitude on the part of the public toward the forest problem as a whole—the depletion of the timber supply accessible to established wood-working industries; the inferior quality of much of the second-growth wood; more stringent quality requirements in the finished product; the denudation of forest areas by uncontrolled commercial exploitation; the urgency of soil conservation on nonagricultural land. Today foresters are eager to explore any possibilities that might be promising, and tree breeding seems to be one of the most promising. In comparison with the breeder of the older agricultural crops, the tree breeder has just begun; his attitude is one of humility; but because his work is all before him, he sees infinite possibilities ahead. In various parts of the world much necessary spadework is now being done to lay the foundations of a true science of forest genetics.*

tree breeding now being carried on by public and private agencies in the United States, and some of the work being done in foreign countries.

The improvement of any wild stock should logically begin with (1) a segregation of varieties, races, and strains of the wild population. It should then proceed to (2) the evaluation of the characteristics of each group, (3) the selection of the best individuals in each of the best strains, (4) breeding and selection, which controls both parents and utilizes the best germ plasm available in these wild stocks, and, finally, (5) the production of decidedly new types by hybridization and by advantageous use of induced or natural changes in the normal number of chromosomes (polyploidy). The improvement of forest trees strictly along these lines would require extensive investigation and planting over many years. Fortunately, all five phases can well be carried on simultaneously.

STUDIES OF SEED ORIGIN—SPECIES, VARIETIES, RACES, STRAINS

For more than 60 years investigators have recognized the importance of seed origin, for which the term "provenience," meaning origin, is often used. The importance of races and strains of forest species first became apparent in Europe, where artificial regeneration of forest stands has been in progress for a much longer period than in the United States. European foresters began to realize that constant and important variations appeared between progenies from seed obtained in different regions. For example, in Sweden, Scotch pine grown from European seed often produced trees of very inferior forest form. Careful study indicated that proper selection of the seed source was necessary for the production of a desirable type of growth and an economically profitable stand. These investigations have led to fairly well controlled seed certification in some parts of Europe.

Forest research stations in the United States (fig. 2) have also been interested in this problem of seed origin (fig. 3) and experimental plantations were started over 20 years ago at several western stations. Test plots established at the Pacific Northwest Forest Experiment Station in 1915, with seed of Douglas fir, have already given valuable data on the existence and characteristics of various strains within this species. Seven apparently superior strains of ponderosa pine have been segregated at the Northern Rocky Mountain Forest Experiment Station from test plots established 23 to 27 years ago. Work at these and other stations is described in the appendix.

The establishment of the Eddy Tree Breeding Station (now the Institute of Forest Genetics, California Forest and Range Experiment Station)[1] in 1925 initiated a project for the intensive study of various problems in forest genetics. Extensive tests at the institute include 100 species and named varieties of pine (the genus *Pinus*) and innumerable climatic forms of many of these species. The seed has

[1] The Eddy Tree Breeding Station was originally founded and financed by James G Eddy at Placerville, Calif. In 1931, the station was incorporated and deeded to a board of trustees, the name being changed to the Institute of Forest Genetics Between the years 1931 and 1935 the institute received aid from the Carnegie Institution and the U. S Department of Agriculture (Bureau of Plant Industry, Soil Conservation Service, and Forest Service) On July 1, 1935, Congress granted funds to carry on work in forest genetics at the California Station and in this year the property of the institute was deeded to the Federal Government and became part of the California Forest and Range Experiment Station.

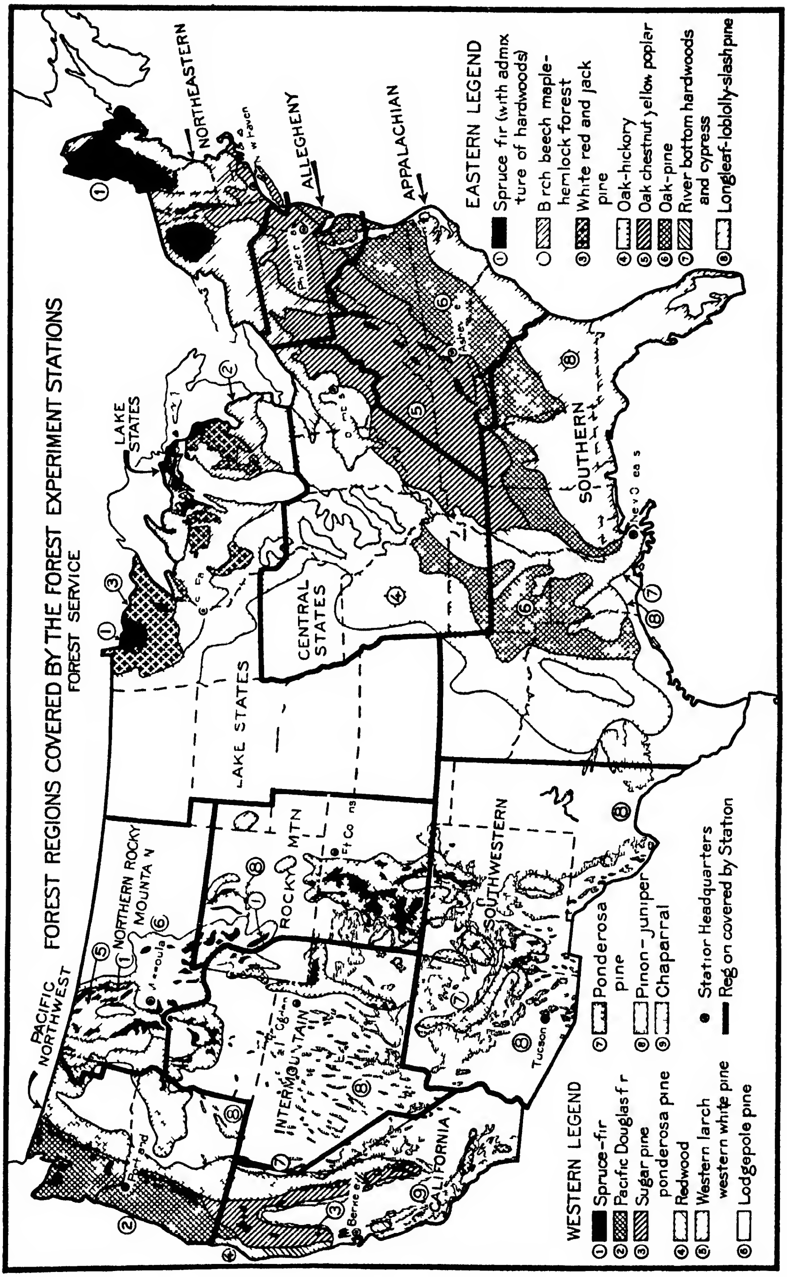

Figure 2.—Regions covered by the forest experiment stations of the Forest Service and the principal timber types of the regions.

been obtained from approximately 40 countries. In addition to the work with *Pinus*, 35 species of conifers, representing 17 genera, and 20 species of hardwood trees, representing 13 genera, have been included in this project, which at the present time is apparently the most comprehensive program of this nature in the United States. Valuable data have already been collected from these plantations,

Figure 3.—The importance of seed origin is shown by these 5-year-old Scotch pines. The tree on the left, of central European origin, has inherited rapid growth but a very poor and ultimately unprofitable growth habit. That on the right, from seed collected in Norway, has grown more slowly but will develop into a good forest tree.

and the institute will undoubtedly evaluate superior germ plasm for the breeding and selection of superior forest stocks.

Briefly stated, the investigations in connection with the problem of seed origin have shown that in many, if not all, important forest species there are rather distinct races and strains that differ in their hereditary response to a given complex of environmental conditions. Such races and strains probably have been evolved in response to the environment peculiar to their original habitat. Although the best reforestation results in any particular region can usually be expected from seed collected locally, or from a region in which the seed trees have been subjected to apparently similar environmental conditions, there are enough exceptions to this generalization to indicate that a great deal more investigation is required before the inherent adaptability of races and strains can be accurately cataloged.

INDIVIDUAL SEED-TREE PROGENY TESTS

Individual seed-tree progeny tests resulted from the realization that seed origin was of tremendous importance to the forester in considering

artificial reforestation. Observations that the individuals of the same seed origin showed marked differences in growth habit, in rate of growth, and in resistance to disease, climate, and site conditions, stimulated a further refinement in seed-selection studies. Investigations were soon started on the inherent characteristics of the progeny of individual

Figure 1. – Individuals of ponderosa pine growing in the same stands show inherent differences in vigor of growth. These two 7-year-old trees are from wind-pollinated seed collected from different seed trees in the same field plot in Eldorado County, Calif. The sister seedlings of both these trees were uniformly more vigorous than those of the slower growing pine of figure 5.

trees. Recognition of only the female parent was involved, since most of the important forest trees are wind-pollinated, and the source of the pollen that had fertilized the seed was necessarily unknown.

A number of European institutions are now engaged in individual seed-tree progeny tests. Oppermann, in Denmark, was among the first to insist on the necessity of carefully selected seed trees. Nicolai of Danzig, in particular, has stressed the importance of this problem and has started work with several forest species.

In the United States, many of the forest experiment stations have included individual seed-tree progeny tests in their research program. The Rocky Mountain Station has located individual trees of the ponderosa pine which are apparently mistletoe-resistant and has begun individual progeny tests with seed from these trees. Mistletoe infection often seriously retards the growth rate in this region and on the poorer sites often results in high mortality. Individual seed-tree progeny tests with green ash at the Lake States Station indicate that there are inherently different climatic races within this species.

An extensive progeny test was started in 1929 at the Institute of Forest Genetics with 742 individual seed trees of *Pinus ponderosa* (ponderosa pine) and its varieties *scopulorum* and *jeffreyi* (Jeffrey pine) Results to date indicate that there are apparently innumerable local strains, each with distinct morphological and physiological characteristics, and that individual trees vary strikingly in their ability to produce superior seedlings (fig. 4). This test included seed trees from 60 counties in 12 Western States and British Columbia (fig. 5). A more intensive progeny study, restricted to Eldorao County, Calif., where types with the greatest hereditary vigor seemed to occur, was started with the 1934 seed crop. The institute is also testing the individual seed progenies of 16 species and natural hybrids of walnut.

Figure 5.—This tree is typical of the comparatively slow growth of the British Columbia strain of ponderosa pine. Compare it with the more vigorous trees of the same age shown in figure 4. Racial differences are clearly indicated.

The results obtained from individual seed-tree progeny tests indicate that individual trees, growing under the same environmental conditions, vary greatly in their ability to produce good offspring and that it is therefore necessary to establish criteria for the recognition of heritable qualities. Adequate information for the description of good seed trees is not available at present.[2]

HYBRIDIZATION OF FOREST TREES

Numerous natural hybrids have been observed from time to time and the parentage of some of these has probably been accurately ascertained. Among such natural hybrids the following may be noted:

Larix eurolepis[3] (Dunkeld larch) from *L. europaea* × *L. leptolepis*
L. gmelini × *L. Kaempferi.*
Pinus sondereggii from *P. palustris* (longleaf pine) × *P. taeda* (loblolly pine).
P. halepensis × *P. pinaster.*
P. nigra × *P. sylvestris.*
P. montana × *P. sylvestris.*
P. montana × *P. nigra.*
Picea sitchensis × *P. canadensis.*
P. engelmannii × *P. canadensis.*
Salix coerula (cricketbat willow) from *S. alba* × *S. gracilis.*
Ulmus glabra × *U. montana* (Huntingdon elm).
Quercus cerris × *Q. suber* (Lucombe oak).
Royal walnut hybrids (eastern black walnut × various California black walnuts).
Poplar hybrids (Eugenei poplar, Serotina poplar, and others).

[2] Additional information on individual seed-tree progeny tests is included in the appendix.
[3] Species names have too often been applied to hybrids between tree species; in the case of poplars, to hybrid clones existing as a single sex. Hybrids are not species and naming them as such can only lead to confusion.

Many of these hybrids grow more vigorously than either of their parents, and in some instances other valuable properties or characteristics have been noted. For example, the Dunkeld larch is said to be resistant to the larch canker, and the wood of the cricketbat willow is said to be particularly well adapted to the manufacture of cricket bats.

Early Work

If possible, tree breeding should begin with stock that has been selected on the basis of its breeding quality (superior germ plasm), but since 1845 investigators have been interested in the possibilities of hybrids between species of forest trees, primarily because of the fact that species hybrids often surpass their parents in vigor of growth (so-called hybrid vigor). Klotzsch[4] is generally considered to have produced the first artificial hybrids between forest-tree species. In 1845 he hybridized two species each of pine, oak, elm, and alder, and observed that the resulting hybrids possessed growth characteristics superior to their respective parents.

Sporadic attempts to hybridize forest-tree species continued over many years. Ness, working at the Texas Agricultural College, produced a few hybrids between the live oak and the overcup oak in 1909, and a limited amount of breeding appears to have been continued at this station. Henry, working in England, produced several fast-growing poplar hybrids and in 1916 published a paper on the possibilities of obtaining rapid-growing forest stock by hybridization. Since 1916, there have been a number of publications discussing various aspects of the possibilities of hybridizing trees. The loss of our native chestnut through the introduction of the Asiatic chestnut blight stimulated interest in breeding this group, and as a result W. Van Fleet, of the United States Department of Agriculture, carried on breeding work with American and Asiatic chestnut species in an effort to produce an immune or resistant timber type.

Recent Work

The chestnut-breeding work started by Van Fleet has been continued and expanded by the Division of Forest Pathology, Bureau of Plant Industry. Selections have been made from the most promising forest strains of the Chinese hairy chestnut, *Castanea mollissima*, and of forest types of the Japanese chestnut *C. crenata*. First-generation hybrids between Asiatic and American species are usually remarkable in vigor, ordinarily excelling all other hybrids in this respect. Selective breeding has also been directed toward the development of small-sized nuts useful in mast production on trees that might be grown in soils not well adapted to either orchard or forest planting.

The first comprehensive project in hybridization within a tree genus was started in 1924 by the Oxford Paper Co., Rumford, Maine, in cooperation with the New York Botanical Garden, New York, N. Y. The primary purpose of this work was to produce new poplars valuable for pulpwood reforestation (fig. 6). This work has been highly successful. A total of about 13,000 hybrid seedlings was obtained from about 100 different cross combinations between 34 different

[4] See Bibliography, published in the Yearbook separate of this article.

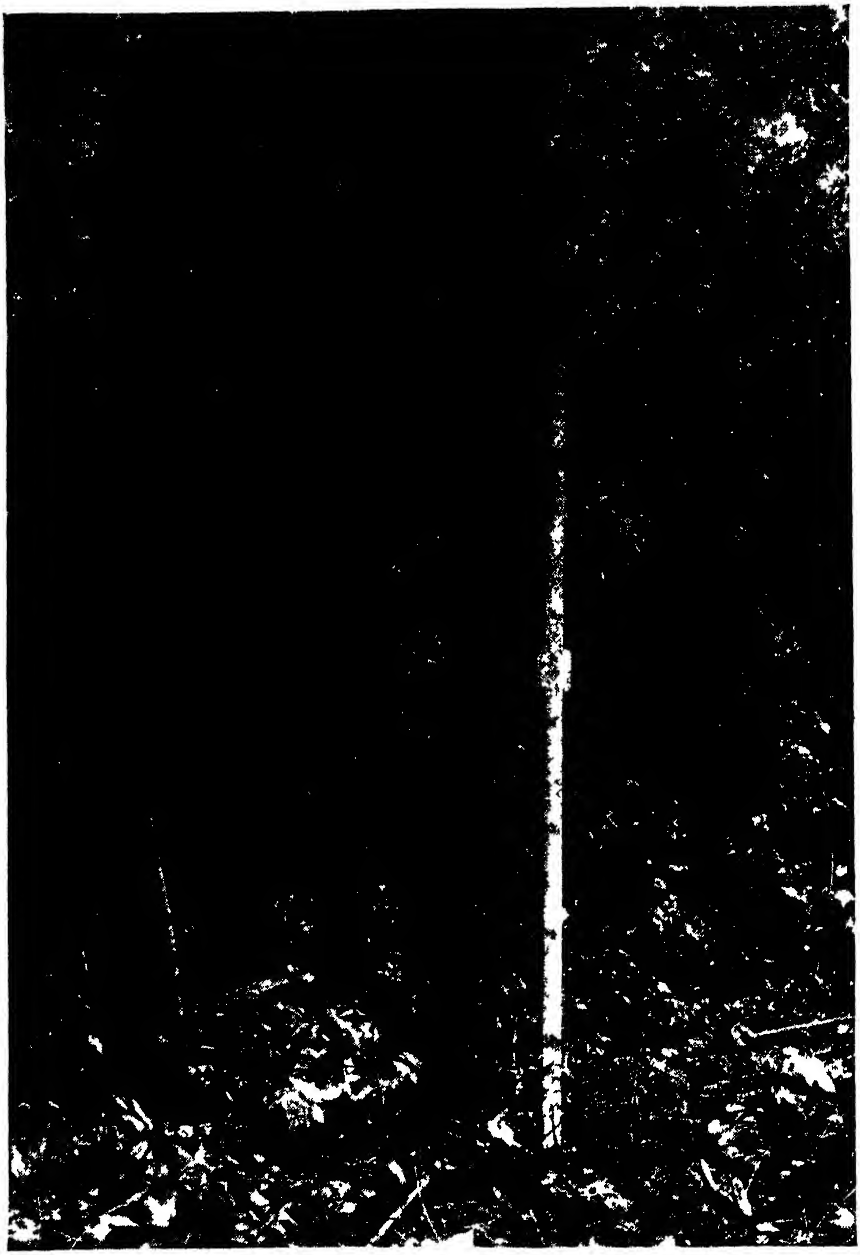

Figure 5.—The Strathglass poplar, one of the selected hybrid poplars produced by the Oxford Paper Co., after 7 years of growth in the field. This tree is approximately 7 inches in diameter and 37 feet tall. It is rather heavily branched, but the branches are small and should offer no difficulties to the use of the wood for soda pulp.

species, varieties, and hybrids of poplars. The parents included 3 white poplars, 5 aspens, 17 black poplars and cottonwoods, and 9 balsam poplars or hybrids belonging in this group. Many of the new hybrids appear especially promising because they surpass the older hybrids, at least during the first 8 years of their life, in rate of growth, resistance to disease and climatic conditions, and habit of growth (fig. 7).

Figure 7.—That well-directed breeding can produce trees immune or highly resistant to tree diseases is demonstrated by these two poplar hybrids. The picture was taken in early September. The trees at the right, without leaves, are members of a clone which is highly susceptible to *Melampsora* rust disease. The trees at the left, in full leaf, are members of a hybrid clone that is much more resistant to this disease. These hybrids are the same age and have the same female parent but different male parents.

Breeding work was undertaken at the Institute of Forest Genetics in 1925 and the institute has now approximately 60 hybrid seedlings involving 8 pine species and varieties as parents.

In 1930 the Brooklyn Botanic Garden, Brooklyn, N. Y., initiated a project for the breeding of chestnut, to produce hybrids that would combine good forest form with immunity to the chestnut blight. Some of the hybrids that have been produced give promise of excellent timber form and resistance to the disease.

The most recent large-scale breeding work was undertaken by the tree crop unit of the Forestry Division, Tennessee Valley Authority, Knoxville, Tenn., to develop trees that will combine good timber qualities with the production of annual crops of fruit (nuts, acorns, berries) of high quality and quantity. Such trees are to be used in tree-crop plantings, where the fruits will produce an annual income and the mature trees can be harvested for lumber or chemical wood.

The work of the Tennessee Valley Authority is of special interest because it aims at an annual income for the forest or wood-lot owner. For example, a stand of oak that will produce a large quantity of acorns will probably more than pay its way to maturity by the hog feed they provide, and if this production can be combined with excellent timber quality, forest planting to prevent soil erosion will

Figure 8.—Artificial hybrids between longleaf and slash pines produced at the Southern Forest Experiment Station show wide variation in susceptibility to brown spot (a needle disease of longleaf pine) in the same plantation: *A*, A 3-year-old hybrid seedling, highly susceptible to brown spot, has lost all of its older needles; *B*, another hybrid of the same age, is relatively free from the disease and shows superior growth and vigor.

be profitable to many southern hill-farmers. Improvement of our best annual-crop trees by hybridization and selective breeding will be essential to the successful and profitable combination of tree crops and forestry on marginal and nonagricultural farm lands.

At the present time the Northeastern Forest Experiment Station, New Haven, Conn., is starting a project in forest genetics directed toward the improvement of forest trees in the Northeastern region. It is expected that the program will include practical and fundamental research on seed origin, progeny tests, selective breeding, and hybridization.

Numerous other investigators in recent years have hybridized species of forest trees to a limited extent. At the Southern Forest Experiment Station, New Orleans, La., hybrid seedlings of *Pinus palustris* × *P. caribaea* (longleaf and slash pines) were obtained in 1929 (fig. 8), and also hybrids between *P. sondereggeri* (itself a hybrid)

and *P. palustris* and *P. taeda*, respectively. Workers at the Rocky Mountain Forest and Range Experiment Station, Fort Collins, Colo., have successfully crossed individuals of a strain of ponderosa pine that is apparently immune to mistletoe. At the Petawawa Forest Experiment station, Petawawa, Ontario, Canada, red spruce and Norway spruce were successfully hybridized in 1932, and in 1936 *Populus canescens* was crossed with *P. tremuloides* in an effort to obtain a hardy aspen hybrid combining the wood characteristics required for match and veneer wood with resistance to heart rot.

Breeding of forest trees is also being stressed in Europe. Larsen, in Denmark, has been carrying on rather extensive breeding studies, especially from the standpoint of self-pollination, and has published his results in some detail. Von Wettstein, in Germany, has been interested in the hybridization of poplars, particularly for the production of trees especially suited to matchwood production. He has developed and described a method for the maturation of hybrid seed in artificial nutrient media. Liese, at Eberswalde, Germany, working with *Pinus montana* (Swiss mountain pine) and *P. sylvestris* (Scotch pine) failed to obtain hybrid seed between these species, which are considered to produce natural hybrids quite frequently. This failure, he concludes, may have been due to lack of "crossibility" between the particular strains used, and the use of other individuals might give positive results.

In addition to these strictly forest species, considerable breeding work has been done with various nut trees, such as the walnut, of which exceedingly vigorous hybrids are now in existence. This work is described in the article on nut-tree breeding elsewhere in this Yearbook.

The outstanding improvement apparent in natural and artificially produced hybrids between forest-tree species amply justifies particular effort in this direction.

VEGETATIVE PROPAGATION

Vegetative propagation will be of great value for the immediate utilization of exceptionally promising natural or artificially produced forest trees. The rapid improvement of horticultural trees has been possible because any new and improved type, hybrid or otherwise, could be immediately multiplied as a clone by grafting, budding, or other forms of vegetative propagation. With forest trees such as the poplars and willows, which can be propagated by cuttings, the tree breeder can utilize exceptional hybrids immediately with the assurance that the individual members of such a vegetative clone will exhibit the same inherent characteristics as the original tree, except for mutations in the body cells of various parts of the tree. These ordinarily occur so rarely that from a practical standpoint they are unimportant. By such methods it is possible to retain any excellent characteristic such as hybrid vigor—the exceptionally rapid growth often inherent in first-generation hybrids—or any new character that is due to an unfixed combination of complementary genes. Few forest trees, however, can be commercially propagated by cuttings, and although many species can be propagated vegetatively by grafting, budding, or layering, these methods are not feasible at present because of their comparatively high cost. It is essential to find cheaper

methods of vegetative propagation if select hybrids or strains are to be multiplied and utilized immediately for forestation planting.

A POSSIBLE APPROACH TO THE IMPROVEMENT PROBLEM

Seed Origin and Individual Seed-Tree Progeny Studies

A search of the literature may leave the impression that investigations in the past have too strongly stressed the subject of seed origin and seed-tree selection, and that the improvement of our forest trees along these lines will be exceedingly slow. But from the standpoint of immediate reforestation requirements, seed-origin and progeny studies are of the greatest importance if the errors responsible for the poor quality of many of the early European plantations are to be avoided. According to Baldwin, approximately 25 percent of the forest stands in Germany are inherently so poorly adapted to their environment that the Government has ordered clear cutting to prevent their regeneration.

A program for the improvement of our forest trees that is concerned with the immediate needs of general forestry may well contemplate studies on seed origin, delineation of races and strains of species and varieties, individual seed-tree progeny studies, and adaptability of exotics on a larger and more intensive scale than in the past. Although such studies are especially necessary to determine the best races or strains for forestation, the data derived from them will also be of great value for improving the inherent qualities of natural forest stands by silvicultural methods. Criteria for the selection of good breeding stock, that is, for differentiating environmental and hereditary characteristics, are essential to good silvicultural practice in our natural stands. Improvement cuttings, thinnings, and especially selective logging, are probably the forester's best approach to mass selection, which will improve the inherent quality of our wild forests in direct proportion to the ability of the silviculturist to identify the select stock and leave it for seed purposes.

There is evidence that in our forest trees many valuable inherent characteristics are still to be discovered and isolated. A list of characters in which differences between individual trees of the same species have been reported as apparently hereditary is included at this point, because it indicates the range of hereditary variation and the possibilities in selection from our present wild stocks.

Rapidity of growth.
Growth habit.
Crown and stem form.
Leaf size, form, and color.
Growth periods.
Nut qualities and length of catkin.
Yield and composition of resin.
Proportion of resin adhering to faces as "scrape."[5]
Color and correlated quality of wood.
Fiber length in wood.
Physical and chemical properties of wood.
Twisted grain in wood.
Resistance to frost, heat, light, and snow.
Resistance to disease and mistletoe.
Resistance to insects.

[5] This refers to the gum adhering to the wood exposed in turpentining, reducing the final yield appreciably.

These characters include not only those that are desirable from the standpoint of the forester (the producer), such as rapid growth and resistance to climatic conditions, disease, and insects, but also qualities important to the consumer, such as straightness of trunk and properties of the wood. Selection must be based on the requirements of the grower and the requirements of the user—so-called forest requirements and use requirements, respectively.

The silviculturist must look to the forest geneticist for possible correlations between readily recognized characteristics of the individual tree and its capacity for producing desirable progeny. Such correlations, even though they are only approximate, will be of great immediate value. This is especially true because the forester, managing a natural stand under a proper selection system, usually has an overabundance of seedlings, only a small percentage of which will be brought to maturity. If selection is for vigor of growth, the inherently vigorous individuals will normally take the lead and should make up a large proportion of the final crop. If other characteristics or qualities are desired, the forester using a selection system has opportunity to rogue his stand with each cutting or thinning, and undesirable individuals can be eliminated as their mature qualities become apparent.

Since the recognition of inherent quality is a key to the improvement of vast forest stands which for various reasons, such as inaccessibility or difficult environmental conditions, are not adapted to intensive forestry, well-planned investigations on this problem are justified. Much of the groundwork will not be strictly genetics. It will first be necessary to define clearly the desired characteristics or qualities. The relative desirability of particular qualities or characteristics will depend upon many things, including the species; the locality where it is to be grown; the purpose for which it is grown—watershed protection, soil-erosion control, tree crops or wood; and probable utilization—lumber, chemical wood, etc.

After the desired characteristics have been defined, methods for their accurate description or measurement must be devised. If measurement is not possible, then descriptions that will adequately bring out existing differences should be available. Rapidity of growth, usually a most important consideration in forestry, is easily measured. Measures for resistance to disease, insects, and climatic conditions will be fairly easy to develop. On the other hand, tree form or branching habit, very important from the standpoint of lumber quality, has been much debated but seldom adequately described or measured. Wood quality is even more elusive; "test-tube" methods for determining the physical and chemical qualities of wood are urgently needed. Tests that require cutting down the tree cannot be used to advantage by the forest geneticist, since a felled tree obviously cannot be used in breeding.

The progeny test is the generally accepted measure of inherent (breeding) quality. As applied to forest trees the method usually involves knowledge of the female parent only, since the seed is set by open pollination. Seed is collected from selected seed trees and the performance of the progenies of the individual seed trees is used as a criterion of breeding quality. This method eliminates the expense and

time involved in making controlled pollinations (fig. 9), but since the male parent is unknown the results must be interpreted with caution and can never provide exact genetical data on the mode of inheritance. This one-parent method may provide partially correct answers somewhat earlier than more exact methods, but a careful analysis of individual seed-tree progeny tests, which have been under way for a period of

Figure 9.—Controlled pollination technique developed for work with pines at the Institute of Forest Genetics. A finely woven canvas bag with transparent window is placed over the flowering branches before the female flowers come into bloom. The sulphurlike pollen of the desired species of pine is placed in the barrel of a hypodermic needle and injected into the bag containing the ovulate flowers. The transparent window in the bag enables the operator to determine when the flowers are in the receptive stage and ready to receive the pollen.

years, will be highly desirable before further extensive trials of this kind are started.

Progeny tests involving full control of parentage are required to provide accurate data on heritability and mode of inheritance of particular characteristics. With this method both the male and the female parents are known. Self-fertilization, where possible, will be the quickest method of evaluation, but it is to be recognized that selfing in plants that naturally cross-breed often leads to degenerate lines, with loss of vigor. This must be considered in pure line breeding with forest trees which are apparently continually cross-pollinated.

Selective Breeding and Hybridization

Improvement by selection of the best individuals or strains from the wild stock is limited in scope. This procedure can hardly result in improvement of our best forest trees in the strict sense of the word, since the essence of the selection process is a sifting out of undesirable types and a segregation of the best strains already in existence.

Hybridization and selective breeding aim beyond this point and attempt to develop new types, which combine the desirable characteristics present in two or more individuals often widely separated geographically and sometimes racially. This possibility can be demonstrated in the hybrid progeny of a controlled cross-pollination, carried out at the Institute of Forest Genetics, between *Pinus atten-*

Figure 10. Hybrids of knobcone and Monterey pines combine the frost resistance of one species and the vigor of the other. The short tree on the right represents the hardy but slow-growing knobcone pine. Beyond it are two trees of the badly frosted but rapid-growing Monterey pine. On the left are three hybrids of these two species. They have about the same vigor as their pollen parents, the Monterey pine, and are practically as hardy as their seed parent, the knobcone pine. All trees are 4 years old from seed.

uata (knobcone pine) and *P. radiata* (Monterey pine), which combine the rapid growth of the pollen parent with the frost resistance of the seed parent (fig. 10); or in the Dunkeld larch, which is said to combine the excellent growth qualities of the European larch with the resistance to larch canker inherent in its Japanese parent. Cross-breeding may also result in the creation of entirely new characteristics, the expression of combinations of genes that would never occur under natural conditions. As has already been said, hybridization and breeding have infinite possibilities, but they are only at their beginning in forestry.

A proper appreciation of breeding methods must be based upon the realization that the plant breeder is concerned with individual plants; that particular characteristics or qualities of the individual are of primary importance; and that the factors or combinations of factors in the germ plasm, which are responsible for the particular characteristics, are the raw materials that the breeder must shape into his ideal plant. With this in mind it is obvious that the most rapid progress in forest-tree improvement necessitates accurate information on the expression and behavior of the hereditary units in our various forest-tree species.

Mass Selection

In mass selection, groups of plants with more or less uniform characteristics are permitted to intercross. Close control of parentage is impossible, and gradual improvement results from continued selection of breeding stock on the basis of apparent quality. Improvement is

usually rather slow and the method does not provide accurate data that can be utilized for further breeding. The results attained depend to a considerable extent on the judgment of the breeder in selecting seed plants, and especially on his ability to distinguish between the effects of heredity and of environment. As noted previously, for the present this method seems best adapted to the improvement of natural stands that are to be handled under a selection system.

One-Parent Progeny Tests

The evaluation of the inherent quality of an individual tree on the basis of the progeny derived from uncontrolled pollination has already been discussed. The fact that only the female parent is known and that the unknown male parent has contributed half the germ plasm of the progeny considerably restricts any interpretation of the results. The method can probably be recommended only for preliminary survey purposes or where personnel is inadequate for the application of a more accurate procedure.

Pedigree Breeding Within and Between Varieties, Species, and Genera

Pedigree breeding with full control of parentage has been described in many of the articles in this and the 1936 Yearbook of Agriculture. Here both parents are known, and the progeny derived from selfing and from well-planned crosses provide an accurate measure of the respective parental germ plasm. Investigation by this method will not only determine which characteristics are inherent, but will also indicate the mode of inheritance—information that is indispensable for far-reaching improvement by intensive breeding and hybridization. The following discussion indicates pedigree methods applicable to forest trees.

Pure-line breeding, by selfing, is usually the most rapid method for the evaluation of hereditary characteristics. This will be possible only with trees that are hermaphrodite and self-fertile. In breeding trees that produce male and female flowers on separate individuals, or hermaphrodite trees that are self-sterile, crossing between selected individuals is necessary. With trees of this nature the nearest approach to pure-line breeding is to cross parents possessing the same characters, that is, breeding within a strain, variety, or species. Pure-line breeding and cross-breeding within a variety or strain will provide fundamental genetical data for the evaluation of inherent quality and the mode of inheritance, and may also provide superior races and strains for forestation. These superior types will be a source of superior germ plasm of known breeding value for further hybridization and breeding.

Combinations of desirable characteristics and modifications or new expressions of characters, due to new combinations or rearrangements of the determiners of heredity, are possible by cross-breeding between pure lines or varieties (intervarietal or intraspecific hybridization). Intervarietal crosses ordinarily represent the least difficult kind of hybridization. Varieties usually cross quite readily and produce fertile offspring. Valuable results may be apparent in the F_1 or first hybrid generation, and segregation in the F_2 or second generation (F_1 plants selfed or crossed) will produce new combinations from which the best individuals can be chosen for further selective breeding.

Crosses between different species of forest trees—a more remote relationship than between varieties—offer interesting possibilities. Such interspecific hybridization is often complicated by the fact that two species are difficult to cross, or by the partial or complete sterility of the resulting hybrids. If two species cannot be crossed directly it is at times possible to include them in the parentage of the final hybrid by breeding through a third species. In fact the utilization of three or more species in the breeding of daylilies has produced particularly valuable hybrids.

The first-generation hybrids of two forest-tree species are often quite uniform and more or less intermediate between the parent species. Segregation and recombination of characteristics occur in the second generation, and it is this generation that provides a very wide diversity of material for selective breeding. The procedure indicated is, therefore, (1) a small first-generation population, but (2) a large second-generation population, with (3) selective breeding continued with the most promising individuals of the second generation.

Interspecific hybridization of our forest trees is entirely justified, because it offers immediate improvement by combinations of desirable characters and the possibility of entirely new characteristics or qualities resulting from combinations of determiners that have never before been combined in any germ plasm. Many first-generation hybrids are more vigorous than either of their parents. This so-called hybrid vigor and any other valuable character can be maintained and utilized immediately if vegetative propagation is possible. Hybridization followed by polyploidy has also created individuals with unusual chromosome numbers that are superior to their parents and have their characteristics "fixed" so that they come true from seed.

Genera are, of course, even more distantly related than species. The comparatively few intergeneric plant hybrids that have been produced up to the present time have not been of practical value. Intergeneric hybridization is very greatly limited by specific differences in the requirements for fertilization inherent in distantly related plants. Furthermore, the progeny are seldom fertile. In spite of the difficulties involved, crosses between different genera may lead to valuable results, and excursions in this direction are warranted.

The Time Element in Tree Breeding

The improvement of forest trees by breeding and selection might appear, at first sight, to require centuries for completion. But although the work often requires a considerably longer time for the successful production of improved stocks than similar work with annual plants, various short cuts are possible.

The time element in breeding is dependent among other things on the relative age at which the individuals begin to bloom. Many trees produce flowers early in life —7-month-old chestnut seedlings occasionally bloom in nursery beds; fruit is often produced on chestnut trees before they are 5 years old; 4-year-old pines have been observed to mature cones; first-generation poplar hybrids 7 years old from seed have produced flowers and fruit. The blooming of more slowly maturing trees can usually be hastened by top-working or grafting on closely related mature individuals, and possibly in some species by

ringing, a light girdling of the trunk. Further work to determine the possibility of lowering the blooming age would be well worth while, since early blooming permits further cross-breeding or inbreeding and eventually speeds up the entire improvement program.

In order to take advantage of early blooming, correlations between juvenile and mature characteristics must be discovered. The fact that a tree blooms at an early age is of no value unless its characteristics at maturity can be predicted with fair accuracy. Such qualities as resistance to disease and winter hardiness can usually be determined with young trees, but in breeding for good forest form (habit of growth) it will be necessary to recognize and select for further breeding the young individuals that will develop good form at maturity.

The possibility for early results is indicated by the fact that selective breeding with daylilies, based on a knowledge of the mode of inheritance within the group, has fixed new combinations of germ plasm, derived from as many as four distinct species, into new types in five generations (Stout, 1936).[6]

Increased Chromosome Numbers, Polyploidy, Aneuploidy, and Mutations

Many valuable types of cultivated plants have arisen through an increase of chromosomes, originating in the somatic (body) cells, in the germ cells, or in the earliest divisions of the fertilized egg. The increase may consist in the duplication of a single chromosome, an unbalanced condition referred to as aneuploidy; or the chromosomes may be duplicated in multiples of the basic number (polyploidy). There may be multiplication of the chromosomes of a single individual (autopolyploidy), or a multiplication of both of the parental chromosome complements of a hybrid (allopolyploidy). Individuals with unbalanced chromosome complements may be maintained and multiplied as clones if vegetative propagation methods can be used.

There is evidence that merely a quantitative increase in chromatin material may be responsible for wide differences in characters that are of great practical value, and that polyploidy in hybrids, involving a quantitative increase in the chromatin material received from both parents, can produce new types as distinct as many of our present species. Polyploidy may result advantageously in (1) increased vigor; (2) increased variation; certain types of polyploidy may also give (3) increased fertility; (4) stability—that is, new types may breed true. On the other hand, polyploidy is sometimes directly responsible for increase in cell size, a contingency that is of particular significance since the chief product of forest trees is wood. An increase in the size of the wood fibers would be detrimental to the physical properties of some woods and would limit the use of others now used in the manufacture of particular grades of paper.

Of especial interest to forest-tree breeders are the facts that polyploidy has been induced by physical treatment of both somatic (body) and germinal tissue and by hybridization, and that balanced polyploids may breed true. If a superior self-fertile individual of this nature can be developed by physiological methods or by hybridization, it can immediately be propagated by seed. Such a strain

[6] See Bibliography, published in the Yearbook separate of this article.

would probably not cross readily with the native species and might thus maintain itself unmixed (homozygous) under natural conditions. The possibilities justify intensive effort directed toward the creation of polyploid strains.

New variations of the nature of mutations and bud sports, involving basic changes in the chromosome complement other than those due to duplication, occur occasionally in forest trees. The Lombardy poplar is said to be a mutant form of the European black poplar (*Populus nigra*) and the weeping beeches and birches are probably of similar origin. Although such variations have been primarily of value as ornamentals, it is possible that individuals of particular value for forestation purposes may be discovered.

Advantages in the Use of Vegetative Propagation

If vegetative propagation is feasible, any superior individual can be multiplied immediately and its characteristics perpetuated by the establishment of a clone By vegetative propagation the breeder can

Figure 11.—One season's growth from roots of poplar hybrids cut back annually for the production of cuttings. The measuring rod is 9 feet high.

take advantage of the excellent individuals that may be produced at any stage of the breeding work, and since the components of the germ plasm are maintained in the somatic condition, the difficulties due to segregation of superior chromosome combinations are eliminated. Many so-called species are actually clones, and the uniformity among the individuals is due to the fact that the genetical complex is always passed on exactly as it was in the original plant.

Vegetative propagation does not lead to degeneration in clones. Investigations on cases of supposed senescence in clones have proved

that outside agencies such as environment or disease-producing organisms have been responsible.

The most promising hybrids produced in connection with the breeding project of the Oxford Paper Co. have been rapidly multiplied from cuttings at a unit cost lower than that of northern-grown nursery stock. Some idea of the rapidity of propagation by means of dormant cuttings may be gained from the fact that in Maine, with a comparatively short growing season, a 1-year-old poplar hybrid will produce 10 to 20 cuttings, at 2 years, 40 to 60 cuttings, and that after 3 years it will continue to produce 100 to 200 cuttings annually (fig. 11). If necessary, the rate of multiplication can be further increased by propagation from softwood cuttings. By this method small twigs 4 to 6 inches in length, cut from the mother plant throughout the growing season, are rooted in shaded, moist sand beds.

Figure 12.—Controlled hybridization in pines involves physical difficulties. This 77-foot ponderosa pine has 100 bags protecting the ovulate flowers from wind pollination.

Intensive investigation to develop a cheap method for the vegetative propagation of forest species that cannot now be economically reproduced in this way is fully justified; the best of our present wildlings and the elite individuals produced through breeding can then be utilized without further delay.

Need of Developing Technique

As in every new line of research, technical difficulties must be overcome before extensive breeding work can be undertaken. The breeder of forest trees is not only faced with the physical difficulties incident to the necessity of working with flowers at the tops of large trees (fig. 12), and often on the outside branches, but he is also handicapped at the present time by lack of accurate information essential to his work. Practically nothing is known of flower behavior, pollen-storage possibilities, artificial pollen-germination methods, sterilities, and incompatibilities in forest trees, and the affinities between species.

Accurate and detailed data on the flowering period of parent trees are essential for the successful planning of a breeding project. Information on blooming dates is not always sufficient; the receptive period of the female flowers is of vital importance in breeding. Where dichogamy, or the ripening of male and female organs at different times, occurs, it often necessitates storing pollen until it can be used, and since pollen viability in different species is known to vary from a few days to over a year, data on this point should be available. Assuming that the pollination has been made with viable pollen at the proper time and under favorable climatic conditions, incompatibilities or sterilities may still cause failure, and success can be attained only through a thorough understanding of such conditions.

The breeder of agricultural plants usually has more or less proven varieties and strains available that can be grown in adjacent plots in his experimental grounds. The breeder of forest trees must work with a wide diversity of species and varieties and often with widely scattered parent stocks—desirable parent types may be located hundreds of miles apart, and at best they are seldom within walking distance. Crossing such trees often requires the development of a new technique.

FUNDAMENTAL INVESTIGATIONS[7]

FUNDAMENTAL genetical studies should certainly be started with forest trees. Chromosome studies and other cytological work necessary to a thorough understanding of the particular physical process involved in the transmission of hereditary characteristics in trees will be indispensable to the tree breeder. Cytological data will be an immediate necessity for effective work directed toward the compounding of polyploids. The solution of many problems will require the combined efforts of the geneticist, the cytologist, and the physiologist.

The forest geneticist should lay a broad foundation for such fundamental studies, but in doing so he should not overlook the fact that much of his early work must of necessity be more or less empirical in nature. It is generally recognized that the mode of inheritance of any particular character can seldom be predicted from a cytological study of the parents used; only actual crossing can supply the answer. It will be largely on the breeding work of the forest geneticist of today that the forest geneticist of tomorrow can safely continue his fundamental research, with the assurance that his line of attack is in the right direction.

A questionnaire on the subject of improvement in forest trees, which was submitted in connection with this Yearbook to various individuals and organizations both in the United States and abroad, asked for an opinion on the outstanding technical and practical problems that remain to be solved. In order to present the views of individual workers in various parts of the country with respect to their particular problems, it seems advisable to include their recommendations on genetical problems verbatim.

---

[7] The following section is intended primarily for students and others professionally interested in breeding or genetics.

Lloyd Austin. California Forest and Range Experiment Station, Institute of Forest Genetics, Placerville, Calif.

Adaptability of selected strains and progenies.—While quite a little preliminary work has been done by the institute and other organizations in testing in a general way the adaptability of various forest species, only a bare beginning has been made in the formidable task of adequately testing and retesting the various selected strains and progenies of these species that are gradually being discovered. There can be no one best strain for all localities, and, as superior types are isolated by progeny tests and other methods, it will become imperative to try these out in a comprehensive way and under various climatic and soil conditions, so that eventually the best forms for each locality will be definitely known.

Hybridizing within species to combine vigor and cold-hardiness.—The institute's results seem to indicate that, at least in the case of *Pinus ponderosa,* most of the seed trees having the greatest inherent vigor will probably be found at relatively low elevations. Although proof is not yet available, it seems highly probable that these low-altitude forms will lack the degree of inherent cold-hardiness possessed by the forms from the higher elevations where much lower temperatures are encountered. This opens up a most promising line of genetical research in which artificial crosses would be made between low- and high-altitude strains, utilizing as parents in both cases the individual seed trees that the progeny tests show to be hereditarily superior. In this way it should prove possible to combine the rapid growth rate of one form with the desired cold-hardiness of the other, and thus greatly increase the adaptability and usefulness of the vigorous types. The institute has already accomplished practically this same combination of characters in the case of its cross of *P. attenuata* and *P. radiata,* and it should prove much easier to cross different altitudinal forms of *P. ponderosa* than to cross distinct species, which is nearly always difficult of accomplishment.

Improving the quality of seed from selected native seed trees.—Another promising line of genetical inquiry well worthy of investigation would consist in making tests in relatively isolated field plots to determine the practicability of using a carefully regulated thinning to improve the quality of the seed from the germinally superior individuals. The plan would be to cut out all those seed trees that the progeny tests show to be inferior. In this way subsequent natural cross-pollination would take place largely between the better types and seed with improved heredity should result. Such seed would be highly valuable for actual work in reforestation.

Roy L. Donahue. Mississippi State College, State College, Miss.

I would say that the needs for this region in particular with reference to forest genetics should include a testing of the various strains of black locust, especially different strains varying as to seed source.

Another type of research needed in Mississippi as well as throughout the entire South is in relation to the selection and breeding of a first-class Christmas tree. At the present time Christmas trees of excellent quality are imported from as far away as the West coast.

Duncan Dunning. California Forest and Range Experiment Station, Berkeley, Calif.

Studies should be made of the heritability of crookedness, excessive branching, spiral grain, and susceptibility to diseases.

Arthur H. Graves. Brooklyn Botanic Garden, Brooklyn, N. Y.

The most important of these requirements for rapid progress in forest tree improvement is reproduction by asexual methods cutting, layering, budding, and grafting.

C. Heimburger. Petawawa Forest Experiment Station, Chalk River, Ontario, Canada. Urgent research problems:

The finding of a suitable strain of Norway spruce for pulpwood production, especially for the spruce regions in eastern Canada.

The finding of suitable strains of Scotch pine to replace jack pine, on sites not suitable for other more valuable native pines.

The production of a fully hardy rapidly growing aspen hybrid, combining the useful characters of the native aspens with added resistance to heart rot and better wood quality for the production of match stock and veneer.

A suitable propagation method for aspen poplars and their hybrids, better than the usual root-cutting methods.

Richard E. McArdle. Rocky Mountain Forest and Range Experiment Station, Fort Collins, Colo.

Other practical problems which demand solution involve the development or isolation of drought-resistant strains of native species (particularly ponderosa pine) for planting in the sand hills of the Plains States and in the high plains dry-land country immediately east of the mountains; determination of the best strains of Engelmann spruce and possibly other species for planting on denuded subalpine sites in the spruce type in Colorado, also in the bristlecone pine and limber pine types where administrative restrictions have been imposed upon the planting of native soft pines because of the blister-rust menace; improving lodgepole pine from a pathological standpoint to cut down losses in merchantable stands. While these problems are practical in their scope, their solution can follow only along highly technical lines of approach. This will require, therefore, the solution of technical problems either directly or under the supervision of qualified geneticists.

T. E. Maki. Intermountain Forest and Range Experiment Station, Ogden, Utah. Urgent research problems:

Determination of the inherentness of heavy or light seed producers.

Determination of vigor, natural pruning habit, etc., of progeny from different tree and age classes.

F. I. Righter. California Forest and Range Experiment Station, Institute of Forest Genetics, Placerville, Calif.

Breeding with polyploids.—In pine breeding projects the problem of inducing tetraploidy in hybrids may well be regarded as second to none in importance. The production of such forms, which, having their origin in hybridization, are yet something more than hybrids—namely, amphidiploid hybrids—will yield the following advantages: (1) Prolonged and costly selection tests of the F_2 and succeeding generations would be avoided; (2) such forms often are more vigorous than the parental species; (3) they are endowed with higher degree of fertility; (4) insofar as practical purposes are concerned, they breed true; and (5) when they, in turn, are hybridized the F_2 generation will consist of greater varieties of new forms for investigation than does the F_2 of the ordinary species or varietal cross.

Polyploidy has not been reported for the pines, and it probably will be necessary to induce tetraploidy before any further breeding with polyploids will be possible; however, the tetraploids should constitute sufficient justification in themselves for work in this field. The possibility of realizing the benefits which may be expected from the production of amphidiploid hybrids is not more remote than is that of achieving comparable results through selection tests subsequent to hybridization. In fact, the latter method of proceeding may well be regarded as the last desperate resource in the field of hybridization with pines, whereas the former offers such valuable results that its immediate adoption is fully justified.

Tetraploidy has developed in sterile species hybrids spontaneously but such appearances have been so rare that it will not be practicable for the pine breeder to rely on the production of such forms through the operation of Nature alone. Artificial means are practically a requisite for such work. Fortunately, means of inducing tetraploids have been developed. The chief method developed thus far consists of subjecting the zygote to heat treatments during the first few cell divisions following fertilization. Under the influence of such treatments a newly formed embryo may undergo nuclear division without the laying down of a dividing wall. This process results in the formation of a cell having the double number of chromosomes. The further growth of the embryo results in an individual that is entirely tetraploid. Attempts to induce tetraploids in hybrids may prove difficult at first, because of the difficulty of ascertaining when fertilization occurs,

for in most of the pines fertilization occurs about a year after pollination; however, the problem should yield to the combined attacks of the geneticists, the cytologist, and the physiologist.

Cytological, taxonomical, and physiological studies.—Cytological, taxonomical, and physiological studies of the genus *Pinus* will contribute immeasurably to the progress of the work of breeding superior timber trees, because they ramify into all phases of the work. Such studies will be started in the near future.

Paul O. Rudolf. Lake States Forest Experiment Station, St. Paul, Minn.

As far as forest genetics goes, the field has barely been scratched. So many problems remain to be solved that it is difficult to know where to begin in listing what remains to be done.

From the practical standpoint it seems desirable to extend source-of-seed tests to include all species used in forestation work to indicate within what limits seed can safely be used in other than native localities for various species. The selection of individual trees and stands of particularly desirable characteristics, followed by the determination of the extent to which these characteristics are heritable by their progeny, is another useful field of investigation. Cross-breeding and hybridizations which have been begun with certain early-maturing species of *Populus*, *Salix*, and *Larix* here and abroad might well be extended to other species in general although the immediate practical value may not be as great as for other studies.

In the field of pure genetics much of value might be accomplished by a study of the mechanics of inheritance for important tree species particularly with a view to determining how certain desired characteristics are transmitted and to what extent such functions may be modified or controlled.

Philip C. Wakeley. Southern Forest Experiment Station, New Orleans, La.

Further work upon the pines (to say nothing of the hardwoods) is urgently needed in:

a. Effect of climatic-zone source of seed.
b. Effect of major soil type source; e. g., deep sands.
c. Effect of female parent source alone on progeny (of direct application in seed collection).
d. Effect of both parents upon progeny (of direct application in marking for natural reproduction cuttings).
e. Development of very tall strains for high yields, structural timber, and piling.
f. Development of strains high in naval stores yield.
g. Development of brown spot-resistant *P. palustris*, windfirm *P. caribaea*, and tip moth-resistant *P. taeda* and *P. echinata*, for artificial reforestation.

APPENDIX

As a part of the cooperative survey of plant and animal improvement, a comprehensive questionnaire requesting information on investigations pertaining to improvement in forest trees was sent to approximately 150 institutions and private agencies in various parts of the world. Summaries of the reports received from those organizations or individuals engaged in work of this nature are included here. The replies received present a rather complete account of forest-tree improvement work in progress throughout the United States, but the replies from foreign sources are rather limited.

United States—Federal Agencies

Bureau of Plant Industry, Division of Forest Pathology

3. Hybridization

Progeny of the following crosses, being grown for forest-tree improvement, are under observation:

Castanea mollissima × *C. dentata*, 272 seedlings 1 to 8 years old.

C. crenata (forest types) × *C. dentata*, 33 seedlings 1 to 4 years old.

C. crenata (forest types) × *C. mollissima*, 44 seedlings 1 to 5 years old.
C. mollissima × *C. henryi*, 16 seedlings 1 to 9 years old.
C. crenata (forest types) × *C. henryi*, 3 seedlings 1 to 2 years old.

In general, hybrid vigor is present in these first-generation trees in the order as listed.

Progeny of the following crosses apparently should be valuable in the production of mast crops and for soil conservation planting:

C. pumila × *C. seguinii*, 21 seedlings 1 to 5 years old.
C. mollissima × *C. seguinii*, 19 seedlings 3 to 6 years old.
C. crenata × *seguinii*, 24 seedlings 1 to 6 years old.

Reciprocal crosses are usually made as a matter of routine. From the genetic viewpoint no significant differences have been found in their progeny. Seedlings of crosses with a dwarf Chinese chestnut, *C. seguinii*, tend to be everblooming in habit, a dominant character inherited from that species. Additional crosses are being made between the several American chinquapins and the various true chestnuts from Asia. Here again selections will be made of individuals suitable for mast-crop production and soil-conservation planting, but such selections are not expected to carry the everblooming habit.

Present work is now largely confined to the production of second-generation stock and incidentally to the study of genetic phases of the problem with special regard to the inheritance of resistance to the chestnut blight.

Forest Service, Appalachian Forest Experiment Station [8]

1. Seed Origin

Robinia pseudoacacia (black locust)

One-year-old seedlings from seed collected from seven Appalachian sources (West Virginia, Virginia, North Carolina, 1,800 to 3,000 feet elevation) were set out in test plantations at Bent Creek in 1935. Seed from an additional five sources (three foreign, two American) was used to establish test plots in South Carolina, West Virginia, North Carolina, and north Georgia in 1936. In both experiments significant differences between the average height of seedlings from different sources were observed at the end of the first season's growth. Some difference was also indicated in form of bole.

In the fall of 1935, 20 superior and 20 average seedlings were selected in each of 10 nurseries (in North Carolina, South Carolina, Tennessee, Mississippi, Virginia, and West Virginia). These were planted in test plots in the Bent Creek Experimental Forest in 1936 to determine the possibility of selecting superior strains from 1-year-old seedlings.

2. Individual Seed-Tree Progeny Tests

Pinus taeda (Loblolly Pine)

Seedlings from 122 individual seed trees were out-planted in 1936 for progeny study. The purpose of this experiment is to determine the effect of the female parent on the germination and growth of seedlings, with the ultimate aim of determining the desirable characteristics of loblolly pine seed trees.

California Forest and Range Experiment Station, Institute of Forest Genetics

1. Seed Origin

Extensive tests of species and geographical races are well under way. The arboretum contains approximately 100 species and named varieties of the genus *Pinus* and innumerable climatic forms of many of these species; seed has been obtained from 40 countries. Growth records, taxonomic records, phenological records, injury records, and seed, sowing, and germination records are taken on all of these test trees, which range in age from 4 to 15 years. Among the fastest growing species so far tested are *P. radiata* (Monterey pine), *P. pinaster* (cluster pine), *P. taeda* (loblolly pine), *P. coulteri* (Coulter pine), *P. patula* (Toluca pine). In most tests *P. radiata* has surpassed all other species in rate of growth, particularly in height growth.

The great majority of all the pine species tested have possessed sufficient cold-hardiness to enable them to survive at the institute at Placerville, Calif., where

[8] At Asheville, N. C.

the lowest temperature on record is 16° F. Exceptions have occurred in the case of certain tropical species, such as *Pinus tropicalis*, *P. insularis*, *P. canariensis*, and *P. merkusii*. These species do not seem to possess enough inherent resistance to cold to be of practical value in any of the important forest regions of the United States, but they are of interest to tree breeders who may wish to hybridize them with hardier species.

Tests with approximately 30 species of pine are under way in cooperation with numerous organizations (31 in the United States and 1 each in England, Scotland, and Denmark) to determine the adaptability of the various native and foreign species.

In addition to the work with pines, 35 species of conifers, representing 17 genera, and 20 species of hardwood trees, 13 genera, are included in the arboretum.

These investigations will eventually indicate the value and adaptability of geographic races and strains of many important timber trees, and the arboretum will be a source of superior germ plasm for future selection and breeding work.

2. Individual Seed-Tree Progeny Tests

Progeny tests have been undertaken with 10 species and varieties of pines. All seed is collected from tagged seed trees, which are fully described and have their location recorded in map form. Seed has been gathered from a total of 2,609 separate trees located in 289 field plots. Many thousands of seedlings have been grown in the nursery and of these 1,843 progeny trees have appeared worthy of further trial in forest plantations to test the permanence of the early differences apparent in the nursery.

As rapidly as the desirable seed trees are discovered, they become for many years potential sources of relatively large quantities of superior seed for practical reforestation. Trees selected in this way are also valuable for use in breeding experiments designed to develop still better types.

P. ponderosa (ponderosa pine)

The largest single progeny test was started in 1929 with seed from 742 individual trees of this species and its varieties *scopulorum* and *jeffreyi*. (*Pinus jeffreyi* is considered a separate species by Sudworth in his Check List of the Forest Trees of the United States.) The seed trees represented in this test are scattered over 60 counties in 12 Western States and British Columbia.

Results already indicate that within this species and its varieties there are innumerable local strains, each with distinct morphological and physiological characteristics. Even within a local geographical strain, individual seed trees vary strikingly in their ability to produce seedlings that are superior in vigor and in habit of growth.

Although the hereditary vigor of ponderosa pine in the central Sierras of California tends to decrease markedly with an increase in the elevation of the seed source, certain individual seed trees have been found at relatively high elevations which, contrary to the general tendency, have high inherent vigor. These are of outstanding value since they probably have the ability to produce offspring that will be both fast-growing and cold-hardy.

Eldorado County, Calif., seems to be about the center of the optimum belt for ponderosa pine, and an intensive progeny test is to be started in the spring of 1937 using seed already collected from about 1,000 trees growing in this county and closely adjoining areas. Seed-collection activities have been so directed that there has resulted a relatively complete sampling of the local strains within this limited area. The field plots are distributed over an altitudinal range of more than 8,000 feet, extending from an elevation of 150 feet up to 8,400 feet.

It is hoped from these various progeny tests to determine whether or not there are any correlations between the visible characters of the seed trees and the nature of their progenies, and to ascertain any relationships that may exist between the environment of a seed tree and the growth, hardiness, etc., of its progeny.

Juglans (walnuts)

Walnuts are being studied primarily from the point of view of developing superior timber trees, and their nut-producing characteristics are a secondary consideration in these experiments. Tests have been undertaken with the progenies of 272 individual trees of 16 species and hybrids of walnuts. After growing the progenies for 2 years in the nursery, 421 seedlings were selected and

set out in permanent plantations. There have been marked differences in the growth of the different progenies.

In some cases natural cross-pollination between species apparently took place during the spring prior to the collection of the nuts, for certain nonhybrid seed trees yielded progenies that were partly hybrid in nature. The nuts were graded into three sizes before sowing, and it was later discovered that most of the hybrids, some of which were very vigorous, came from the large nuts. Hybridization apparently stimulated the development of the nuts, and this may provide a simple method for selecting a high proportion of naturally hybridized nuts from walnut trees exposed to pollen of other walnut species.

3. Hybridization

Controlled hybridization has been a very important part of the work carried on at this station.

Progeny of the following artificial crosses (made at the institute) are under observation:

P. attenuata (knobcone pine) × *P. radiata* (Monterey pine). Hybridity certain. Progeny, 8 years old, shows rapid growth of pollen parent combined with frost resistance of seed parent. Appears to be weakly fertile. Twenty-eight trees.

(*P. attenuata* × *P. radiata*) × self. (F_2) hybridity certain. Progeny 3 years old. Five trees.

P. caribaea (slash pine × *P. taeda* (loblolly pine). Hybridity probable. Progeny 3 years old. Ten trees.

P. echinata (shortleaf pine) × *P. taeda*. Hybridity probable. Vigor of 2-year-old progeny exceeds that of seed parent. Fourteen trees. Seedlings now 3 years old.

P. ponderosa var. *jeffreyi* × *P. ponderosa*. Hybridity certain. Vigor of 3-year-old progeny greatly exceeds that of seed parent. A potentially valuable cross.

P. rigida (pitch pine) × *P. taeda*. Hybridity probable. Four trees. Age 3 years.

The following artificial crosses were made with various species and varieties of *Juglans* in 1927:

J. hindsii × Royal hybrid; 12 hybrid seedlings obtained.
Royal hybrid × Royal hybrid; 7 hybrid seedlings obtained.
Royal hybrid × *J. mandshurica:* 1 hybrid seedling obtained.
Royal hybrid × *J. regia;* 3 hybrid seedlings obtained.
J. hindsii × *J. hindsii;* 3 seedlings obtained.
Royal hybrid × *J. hindsii;* 1 hybrid seedling obtained.

Central States Forest Experiment Station[9]

1. Seed Origin

Robinia pseudoacacia (black locust)

Experimental work was started in 1935 with approximately 22 strains of black locust, including the shipmast locust (var. *rectissima*), in a search for strains resistant to locust borer.

Yellow pines

Work of a minor nature is in progress with local strains of shortleaf, pitch, and Virginia pines.

Intermountain Forest and Range Experiment Station[10]

1. Seed Origin

Pinus ponderosa (ponderosa pine)

Some experimental work on importance of seed origin is being carried on but work is too recent for definite observations.

Future plans call for investigations on regional and altitudinal strains of this species.

[9] At Columbus, Ohio.
[10] At Ogden, Utah.

Lake States Forest Experiment Station [11]

1. SEED ORIGIN

Pinus resinosa (Norway pine)

Three plantations each containing progeny from 154 seed sources (Lake States, Pennsylvania, New York, New England, Quebec, Ontario) were established in 1931 and 1933. Seed collection was mostly from "individual tree" or "small group" but some "limited locality" and general collections are also represented. Differences are already apparent in vigor, winter hardiness, and drought resistance.

Pinus sylvestris (Scotch pine)

Progeny from 27 seed sources (United States and foreign) were included in the plantations of Norway pine (1931 and 1933). Differences have been observed in the nursery and in the field between northern and southern stocks in size of seedlings and color of foliage—stock from southern sources is larger and tends to have darker green foliage Northern stocks showed markedly superior winter resistance, 1935–36.

Picea (spruce)

In a search for fast-growing spruce for pulpwood, plantations of nine different spruces were established in 1936. The following species were used: *P. glauca* (white spruce) six seed sources; *P. excelsa* (Norway spruce) six sources, mostly from the Union of Soviet Socialist Republics; *P. rubra* (red spruce) two sources; *P. glauca albertiana* (Alberta spruce); *P. mariana* (black spruce); *P. glehnii* (Sakhalin spruce); *P. orientalis* (Oriental spruce); and *P. omorika* (Serbian spruce) Seed of the last five each from one source.

2. INDIVIDUAL SEED-TREE PROGENY TESTS

Fraxinus pennsylvanica lanceolata (green ash)

Progenies of 83 individual trees (from North Dakota, South Dakota, Iowa, Nebraska, Kansas, and Oklahoma) were grown in two nurseries (York, Nebr., and Denbigh, N. Dak.). Variations between individual progenies were apparent in the nursery; seed from the northern area exhibited slow germination and growth. Seedlings from northern stock were much smaller, with smaller, darker green leaves, and shorter growing periods than southern stock. Transplants of the York stock were field-planted in Nebraska in the fall of 1936, but are insufficient in number to give conclusive results.

Artificial drought tests indicated a definite decrease in drought resistance from north to south and from west to east (definitely correlated with climate). The greatest difference was observed between plants from the northwest portion of North Dakota and the eastern portion of Nebraska, Kansas, and Oklahoma. The evidence indicates that there are inherently different climatic races. Local variations within a single subdivision of the plains region were also observed.

Pinus resinosa (Norway pine)

Approximately 100 of the 150 seed lots mentioned under Seed origin were from individual seed trees. A few of the individual progenies are sufficiently outstanding to indicate that selection and breeding might produce a superrace of Norway pine.

Pinus sylvestris (Scotch pine)

Some 20 of the 27 seed lots obtained for provenience study were from individual seed trees growing in the Lake States. No significant differences have been observed to date.

Northeastern Forest Experiment Station [12]

1. SEED ORIGIN

Pinus sylvestris (Scotch pine)

Two-year-old seedlings of two strains of Scotch pine, Riga and Austrian, were outplanted in 1925 on the Mount Toby Demonstration Forest in Massachusetts After 11 years the Austrian Scotch pine has made 2 to 3 feet better height growth

[11] At St Paul, Minn.
[12] At New Haven, Conn.

and greater diameter growth than the Riga strain, and it appears to have a superior stem form.

Studies are under way to determine whether a single vigorous stock of Scotch pine is suitable for planting in all parts of the Northeastern region. In 1932, 2–2 planting stock from a single seed source (Booneville, N. Y.) was planted in 10 test plots of 1,200 trees each throughout the Northeastern States. Additional plantings were made in 1934 using 1–2 and 2–0 stock from the same source. No significant results have been noted up to the present time.

A rather comprehensive forest-genetics project is now being started. It is anticipated that this project will include practical and fundamental research on seed origin, adequate progeny tests, selective breeding and hybridization. Although the primary emphasis will probably be placed on deciduous forest trees, some work with conifers, particularly with reference to disease and insect resistance of native species, will undoubtedly be advisable. The station also expects to cooperate with the Oxford Paper Co. in continuing the valuable hybridization work with poplars started by that organization in 1924.

Northern Rocky Mountain Forest and Range Experiment Station [13]

1. Seed Origin

Pinus ponderosa (ponderosa pine)

Twenty-two experimental plots in northern Idaho contain progenies from seed collected in 22 geographic localities in Oregon, California, Idaho, Washington, Montana, South Dakota, Colorado, Arizona, New Mexico, and Utah. The trees are now 23 to 27 years old from seed

Figure 13 —Racial differences in ponderosa pine: *A*, The open, plumelike arrangement of long, slender needles of the North Pacific and Northern Rocky Mountain races is easily distinguished from *B*, the compact and bushlike growth of short, stout needles of races from the east slope of the Rocky Mountains.

[13] At Missoula, Mont.

A number of distinct races have developed under natural conditions in ponderosa pine, which is widely distributed throughout the Western States and is subject to a great diversity of environmental conditions (fig. 13). Progenies from sources west of the Continental Divide in the North-Pacific and Northern Rocky Mountain regions have long, slender, flexible needles with slight to moderate thickening of the hypoderm cell walls, prevailingly in three-needle fascicles (fig. 14, *A*). Trees from east of the Continental Divide and in Colorado and Utah have foliage prevailingly in two-needle fascicles with short, thick, stiff needles with extremely thick hypoderm tissues (fig. 14, *B*) Trees from the Arizona-New

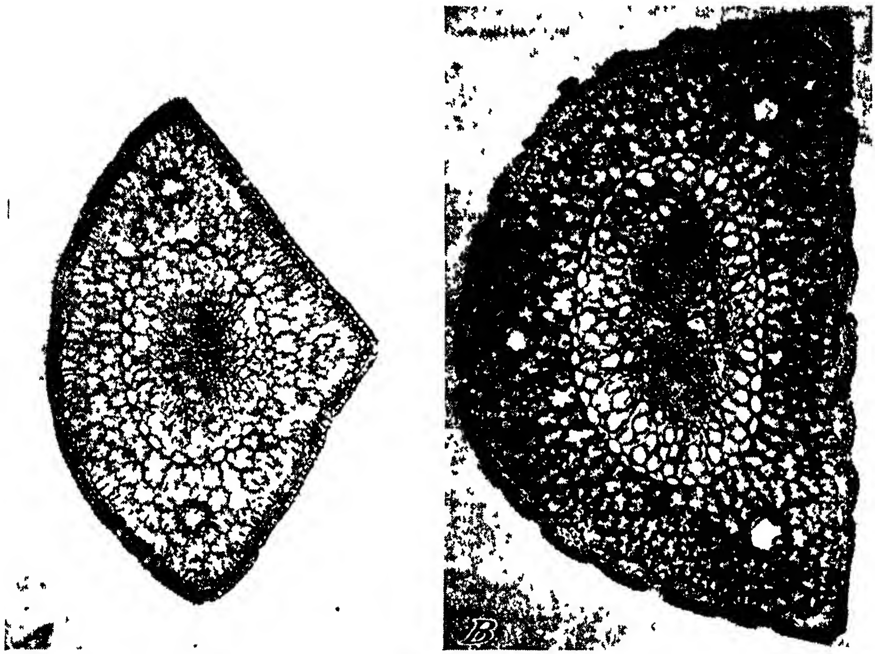

Figure 14.—Races of ponderosa pine show inherent differences in needle structure: *A*, An example of the thin hypoderm layer and lack of stomatal depressions of the long-needle type shown in figure 13, *A*; *B*, thicker hypoderm layer without stomatal depressions, characteristic of the short-needle type illustrated in figure 13, *B*.

Mexico Plateau have preponderantly three-needle fascicles, with moderate length and slenderness of needles, but with thick hypoderm structure. As these pronounced differences in foliage were found to be the same in trees of the parent localities, the conclusion is that these characteristics are strongly heritable.

Progenies that originated in localities within the northern Rocky Mountains, where the climate was similar to that of the experimental site, have made the greatest growth in height and diameter. Those from regions of more severe climates in Colorado, Utah, Arizona, and New Mexico have made the least. The slowest growing progenies in the experiment have reached an average height and diameter only half that of the fastest growing offspring. Comparison of progenies with trees growing in parent localities shows strong inheritance of growth rate in the new environment, except that the tendency is less marked where the progeny came from a region of more favorable climate.

Relative degree of hardiness was revealed by a sudden steep drop in temperature of 57° F. on December 15, 1924. Two progenies from the mild Pacific coast region were practically eliminated. The progenies from regions of the most rigorous winter climates suffered little or no loss by this freeze.

The results to date indicate that the most suitable seed source for planting in northern Idaho is from Republic, Wash., to the Continental Divide and from the Salmon River to the Canadian boundary. Introductions from the mild climate of the Pacific coast are subject to loss from sudden and severe temperature changes, which may occur periodically in Idaho. Although an introduced tree may be perfectly adaptable to the climate, it may, because of slow growth, be decidedly unsuitable for timber growing in northern Idaho. On this basis seed from Black Hills and southeastern Montana sources would be unsatisfactory, and Colorado seed would prove decidedly so.

Pacific Northwest Forest Experiment Station [14]

1. SEED ORIGIN

Pseudotsuga taxifolia (Douglas fir)

Five replicative plantations were established in 1915 with seed from 13 localities (northwestern Washington to central-western Oregon, 100- to 3,850-foot elevations) to study climatic and geographic races within the Pacific coast form. Progenies from individual trees representing variations in age, form, infection by wood-rot fungi, and site conditions were planted under separate pedigree numbers. No gross differences have been observed in morphological characteristics (leaves, crown, stem, flowers) between progenies from different seed sources. A significant and constant difference was observed in the relative time at which the various progenies burst their buds in the spring. Different progenies also varied in their susceptibility to late-spring frost injury. The progenies of certain individual parents were significantly taller than those from other parents growing in the same locality. The progeny from two of the seed-source localities made outstandingly good height growth on every plantation.

Pinus ponderosa (ponderosa pine)

Plantations were established in 1926 for a study of geographical races of this species. Results indicate that local stock is doing best in growth and survival. Progenies from different seed sources are already beginning to show rather distinct variations in the appearance of the foliage.

Rocky Mountain Forest and Range Experiment Station [15]

1. SEED ORIGIN

Pinus ponderosa (ponderosa pine)

Test plantations were established at Fremont in 1915 and 1916 with seed from seven sources (five Colorado, one Wyoming, and one South Dakota). Altitude range of seed sources was from 5,200 to 9,000 feet. A second test plantation was established in 1920 with seed from eight sources (one each from Montana, Arizona, California, Oregon, South Dakota, and three from Colorado). Data are available on survival, height, and form. The results from the standpoint of survival, rate of growth, and winter-hardiness point conclusively to the futility of using any but Colorado (not including southwestern pine type) and possibly Black Hills seed.

Test plantations were established in the Nebraska National Forest (1926) with seed from eight sources (Nebraska, South Dakota, Colorado, Arizona, New Mexico). The results indicate the superiority of local Nebraska seed. Southwestern and central Rocky Mountain stocks have been extremely susceptible to tip-moth attack. A segregated seed area has been established.

Pinus contorta (lodgepole pine)

A plantation at Fremont now 21 years old includes trees from seed collected from nine localities in Wyoming and Colorado. There is also a 17-year-old plantation, established with stock from 14 sources from approximately the same general region. In general the nearest seed sources have given the best results, but the extent of variation within a seed progeny largely eliminates the significance of the group performance.

A test planting in the Medicine Bow Forest, Wyo., is now 17 years old; seed from three sources (local, southern Wyoming, western Colorado). The relative survival and performance have been in inverse ratio to proximity of the seed source to the experimental area.

[14] At Portland, Oreg.
[15] At Fort Collins, Colo.

Pseudotsuga taxifolia (Douglas fir)

A 20-year-old plantation at Fremont includes stock from 11 national forests (6 in Colorado, 5 in Wyoming) and 15 climatic sources. Last observations (1923) indicate that local stock is decidedly superior in survival and height growth. Wyoming stock failed completely.

Picea engelmanni (Engelmann spruce)

A plantation on the east slope of Pike's Peak (elevation 10,500 feet), 24 years old, contains 10 climatic strains from 6 Colorado National Forest seed sources. Results are not conclusive.

2. Individual Seed-Tree Progeny Tests.

Pinus ponderosa (ponderosa pine)

Test plots were established in 1932 at elevations of 7,200 feet and 9,100 feet in the Pike's Peak locality with progeny from eight individual parent trees representing a 2,000-foot altitudinal range within the same locality. The lower plantation was eliminated by drought. In the upper plantation survival shows a fairly regular increase from low to high elevation sources.

Progeny from individual mistletoe-susceptible and presumably mistletoe-resistant trees are being tested in two 4-year-old plantations at Fremont station.

Three plantations (3, 4, and 6 years old) in the Nebraska sand hills include progeny of individual trees selected because of superior development and freedom from Peridermium.

Pseudotsuga taxifolia (Douglas fir)

Progeny of individual parent trees possessing peculiar branching habits are under observation in two plantations at Freemont (6 and 8 years old).

3. Tree Breeding

Artificial crosses between individuals of an apparently mistletoe-immune strain of *Pinus ponderosa* (ponderosa pine) have been successful. Seedlings are now 4 years old.

Southern Forest Experiment Station [16]

1. Seed Origin

Pinus taeda (loblolly pine)

Test plots were established in 1927 at Bogalusa, La., with trees from seed collected in Louisiana, Texas, Arkansas, and Georgia. Observation in the spring of 1936 (trees 9 years in field) showed local Louisiana seed definitely superior in growth rate. Other significant differences may exist.

Pinus palustris (longleaf pine), *P. caribaea* (slash pine), *P. taeda* (loblolly pine), *P. echinata* (shortleaf pine)

Test plantations were started on the Palustris Experimental Forest (1935–36) with stock from seed of various geographic sources. The following species were used: *P. palustris* (eight sources), *P. caribaea* (nine sources), *P. taeda* (two sources), *P. echinata* (two sources).

Seed of the following four species was obtained from 40 different sources in 1935: *P. palustris* (11 sources), *P. caribaea* (7 sources), *P. taeda* (12 sources). *P. echinata* (10 sources). Seedlings from seed of practically all sources for each species were grown at or near each point of origin, for planting during the 1936–37 planting season. The purpose of this is to test every geographic strain both in its own locality and in every other locality included in the study of that species. In at least one nursery distinct differences in size and in rate of maturing were apparent in the fall of 1936, the most conspicuous being between shortleaf pine seedlings from Pennsylvania and from Texas seed.

2. Individual Seed-Tree Progeny Tests

Pinus palustris (longleaf pine)

A test plantation was started in 1936 with 300 seedlings from parents high in naval stores yield and from parents low in yield.

[16] At New Orleans, La.

3. Tree Breeding

Pinus palustris x *P. caribaea*, hybridized in 1929, produced approximately 24 hybrid seedlings intermediate between the parents in stem, foliage, and bud characteristics, growth habit, and rate of growth. X *P. sondereggeri* (F_1) was crossed with *P. palustris*, *P. taeda*, and X *P. sondereggeri*. A few seedlings were obtained from each of these crosses and were planted out in 1933.

Southwestern Forest and Range Experiment Station [17]

1. Seed Origin

Pinus ponderosa (ponderosa pine)

Tests of climatic races are under way at the Fort Valley station. Results indicate that seed from California and the northwest portions of the United States invariably germinate less rapidly and produce larger, more succulent, but noticeably less hardy seedlings than local seed. Seed from Colorado, Utah, and Black Hills produce plants much like those from local seed, but Black Hills seedlings always show characteristic differences in color and form, and 20 years after planting are beginning to show signs of decline.

Tennessee Valley Authority, Forestry Division [18]

2. Individual Tree Selection

The tree crop unit of the Forestry Division has been interested in the selection of individual forest trees that combine desirable timber quality with production of high quality and quantity of fruit (nuts, acorns, berries). This work has been carried on through prize contests and through direct scouting. Up to the present time, one black walnut, two black locusts, two honey locusts, one ash, one hickory, and two oaks have been discovered which appear to merit special study. These individuals are being multiplied vegetatively by grafting and budding.

3. Tree Breeding

The tree crop unit initiated a project in hybridization and breeding in the spring of 1936. During this first year, a total of approximately 5,000 artificial pollinations were made with 72 species, varieties, and clones of the following 10 genera: *Juglans* (walnut), *Hicoria*, syn. *Carya* (hickory), *Corylus* (hazel), *Castanea* (chestnut), *Quercus* (oak), *Asimina* (pawpaw), *Amelanchier* (serviceberry), *Gleditsia* (honeylocust), *Robinia* (black locust), and *Diospyros* (persimmon).

The purpose of this breeding work was to produce trees combining high productivity and high quality of fruit (nuts, berries, acorns, pods) with desirable timber qualities. Such superior trees are needed for tree-crop planting and will, before maturity of the timber crop, pay their way by the annual production of food for man, stock, or game.

The severe spring drought in eastern Tennessee resulted in the loss of a considerable portion of seed that had originally set to cross-pollination.

United States— State, Private, and Endowed Agencies

Brooklyn Botanic Garden [19]

3. Tree Breeding

Controlled breeding experiments were undertaken in 1930, to produce a chestnut with inherently good timber form and high resistance to or immunity from the chestnut blight disease. The work was started with Japanese and American chestnuts, but in recent years additional species, varieties, and hybrids have been used as parent stocks. Some of these hybrids are now 5 years old. Up to the present time, the following *Castanea* hybrids have been produced ((R) indicates reciprocal crosses between the parents):

C. crenata (Japanese c.) × *C. dentata* (American c.)
C. mollissima (Chinese c.) × *C. dentata* (R)
C. S8 × *C. dentata* (R)
C. S8 × *C. crenata* (R)
C. crenata × (*C. crenata* × *C. dentata*) (R)

---
[17] At Tucson, Ariz.
[18] At Norris, Tenn.
[19] At Brooklyn, N. Y.

(*C. crenata* × *C. dentata*) × *C. mollissima* (R)
(*C. mollissima* × *C. pumila* (chinquapin) × *C. dentata*
C. crenata × *C. seguinii* (Chinese chinquapin)
C. mollissima × *C. seguinii*
(*C. crenata* × *C. dentata*) × *C. dentata*
(*C. crenata* × *C. dentata*) × (*C. crenata* × *C. dentata*)

(NOTE.—S8 is apparently a combination of *C. crenata* and *C. pumila;* made by Walter Van Fleet, U S. Department of Agriculture.)

Many of the *C. crenata* × *C. dentata* hybrids give promise of timber types and appear to be resistant to chestnut blight. So far, they have been subjected only to natural infection, but in 1936 all hybrids were artificially inoculated. It is too early to determine the results of these inoculation tests. Some of the hybrids bloomed at 3 years of age; these were immediately used for further hybridization.

Fox Research Forest [20]

1. SEED ORIGIN

Investigations originally started by the Brown Co. are being conducted with Scotch pine, Norway spruce, and European larch. The purpose of these experimental plantations is to determine the most desirable proveniences for reforestation in New Hampshire. Most of the plantations are too young to provide pertinent information.

New York State Conservation Department, Bureau of Investigation [21]

1. SEED ORIGIN

Pinus sylvestris (Scotch pine)

Four generations, ranging in age up to 30 years, are now available for study. Observations to date indicate the possibility of rust-resistant strains and two apparently inherent growth forms; a straight-boiled, small-limbed type with small pointed crown, and a fairly straight-boled, large-limbed type with large bushy crown.

New York State College of Forestry [22]

2. SEED ORIGIN

Investigations with climatic varieties of two species of *Picea*, five species of *Pinus*, and two species of *Larix* have been started on the Pack Demonstration Forest, Warrensburg, N. Y.

Oxford Paper Co. in Cooperation with the New York Botanical Garden [23]

3. TREE BREEDING

A breeding project was initiated in the spring of 1924 to develop new hybrid poplars of particular value for pulpwood reforestation in Maine (Stout and Schreiner, 1933).[24] A total of approximately 13,000 hybrid seedlings was obtained from 99 different cross combinations between 34 different types of *Populus*, as follows:
The parents are arranged in alphabetical order within the main groups of poplars, and the extent to which each was used in hybridization is indicated by the use of the numbers assigned in the sequence. The number of seedlings grown for each cross is indicated in italics under the female parent. Thus in the cross *P. alba* × *P. alba nivea* 67 seedlings were grown.

A. The white poplars.
  1. *Populus alba* ♀ ×2 (*67*); 3 (*8*); 4 (*34*); 6 (*22*); 7 (*16*).
  2. *P. alba nivea* ♂ ×1.

32. *P. simonii* ♀ ×5 (*32*); 12 (*99*); 16 (*75*) 21 (*176*); 22 (*1*); 25 (*155*); 26 (*189*); 34 (*44*). ♂ ×17, 23.
33. *P. tacamahacca candicans* clone Balm of Gilead ♀ ×10 (*6*); 21 (*40*); 26 (*82*); 28 (*6*).
34. *P. trichocarpa* ♂ ×9, 10, 13, 15, 17, 18, 19, 23, 26, 29, 31, 32.

Approximately 700 hybrid seedlings were originally selected for intensive study and evaluation, and of this number 69 are still under close observation. Descriptions have been published of 10 of these hybrids that appear particularly promising for use in reforestation.

Propagation of the new poplar hybrids has been entirely vegetative, by cuttings. Many of the hybrids have so far indicated greater growth vigor than any previously known poplar species or hybrids. Some have been practically immune to certain diseases, particularly *Melampsora* rust and *Fusicladium* twig disease. Selections have included frost-hardy types with good forest form that grow vigorously from cuttings. There is evidence that the wood of many of the fast-growing hybrids will be denser, and will produce somewhat longer fibers, than the aspens now used for pulpwood. Most of the original hybrids are growing in plantations (now 9 and 10 years old) and many have begun to bloom; some individuals flowered at the age of 7 years.

Foreign Agencies

Austria, Forstliche Bundes, Versuchsanstalt, Mariabrunn

1. Seed Origin

Considerable research has been carried out on climatic races and on the importance of the seed origin of forest trees. This work was started previous to 1900. The progress of the work has been reported in publications by Cieslar, Tschermak, and Oehm.

Canada, Petawawa Forest Experiment Station,[25] *Ontario*

3. TREE BREEDING

Crosses between black spruce and Norway spruce, attempted in Canada in 1934, were unsuccessful. In 1936 *Populus canescens* was crossed with *P. grandidentata*, and *P. tremuloides* was crossed with *P. grandidentata*, in an effort to obtain a hybrid combining the wood characteristics required for match and veneer wood with resistance to heart rot.

C. Heimburger of this station reports that in 1932 he crossed red spruce with Norway spruce while working in New York State. Good seed was produced, and the seedlings are now being grown by the New York State College of Forestry.

Denmark, Royal Veterinary and Agricultural College, Copenhagen

3. TREE BREEDING

In the spring of 1924, *Abies concolor lowiana* (Pacific white fir) was successfully crossed with *A. grandis* (lowland white fir), and the hybrids are under observation at the present time. In 1929 *Juglans sieboldiana* (Japanese walnut) was successfully crossed with *J. cinerea* (butternut). Reciprocal crosses have been made between *Larix leptolepis* (Japanese larch) and *L. decidua* (European larch). Rather extensive self-pollinations have been made by covering portions of large trees, or entire smaller trees, with closely woven canvas. A tree of *Chamaecyparis* sp. was selfed by covering its top. A larch (7.1 m tall) thought to be a hybrid between *Larix gmelini* and *L. leptolepis* was tented and self-fertilized. A small Japanese larch was also selfed by potting and transferring it to a greenhouse.

Germany, Botanisches Institut der Forstlichen Hochschule, Eberswalde

1. SEED ORIGIN

Studies are now under way on climatic races of *Pinus sylvestris* (Scotch pine) and *Pseudotsuga taxifolia* (Douglas fir). Progenies of Douglas fir from 19 different seed sources are growing in the vicinity of Eberswalde. Particular emphasis has been placed upon the possible selection of Douglas fir races that are highly resistant to *Rhabdocline* leaf disease. Results to date indicate that in general the American coastal forms, although not entirely immune, are sufficiently resistant to warrant further use in forest planting; that the mountain forms are slower growing, more susceptible to the disease, and cannot be recommended; and that certain types should be discontinued entirely.

3. TREE BREEDING

Reciprocal crosses between *Pinus montana* and *P. sylvestris* have apparently been unsuccessful. Since natural hybrids between these species have been reported, it is possible that the negative results may have been due to lack of "crossibility" of the strains that were used.

Germany, Forstbotanisches Institut, Technischen Hochschule, Dresden (Forstliche Abteilung Tharandt)

1. SEED ORIGIN

Seed origin investigations of a large number of forest trees, including pine, spruce, larch, oak, beech, aspen, alder, ash, and maple, are under way at this station. In addition to the above the following species of most diverse seed origin are also being tested in experimental plots: *Pseudotsuga taxifolia, Betula verrucosa, Pinus murrayana, Abies cilicica, Pinus armeniaca, P. peuce. Picea engelmannii, P. sitchensis, Chamaecyparis lawsoniana.*

Great Britain, Forestry Commission of Great Britain, Research Division[26]

1. SEED ORIGIN

Investigations on climatic races of *Pseudotsuga taxifolia*, two species each of *Larix*, *Picea*, and *Quercus*, and four species of *Pinus* are under way. This work was started in 1925 and it is too early to draw any conclusions. The investigations will include a study of growth and form, frost-hardiness, and resistance to fungus and insect attacks.

[25] At Petawawa, Ontario.
[26] At London.

Switzerland, Eidgenössische Zentralanstalt für das Forstliche Versuchswesen, Zürich

1. Seed Origin

Studies on site races, form races, and so forth, were started in 1898 with two species each of *Pinus* and *Quercus*, one species each of *Picea, Abies, Larix, Fagus, Acer,* and other important tree species. These studies include the influence of geographical location, latitude, altitude, soil, precipitation, form, age, and position of the parent tree in the stand. Results indicate that the following characteristics are inherited: Color and size of needles and leaves, crown form, stem form, increment, growth periods, and resistance to frost, heat, light, snow, fungi, and insects.

These investigations are of great importance since they are to be applied to protection forests in many of the regions where natural regeneration is practiced. Results have been published by Engler, Nageli, and Burger.

BIBLIOGRAPHY

A bibliography for this article, including over 300 references related to forest tree breeding, will be published in the 1937 Yearbook Separate containing the text of the article.

BREEDING PROBLEMS WITH ANGORA GOATS

W. V. LAMBERT, Senior Animal Husbandman, Animal Husbandry Division, Bureau of Animal Industry

SINCE its domestication the goat has served man well. As a source of milk, meat, mohair, and skins it has furnished him both food and clothing, and because of its brush-eating proclivities, has spared him untold amounts of hard labor with the brush hook.

Since 1900 the Angora goat industry in the United States has undergone rapid expansion. At present it is confined largely to the Southwestern States, nearly 90 percent of all Angoras being produced in Texas, New Mexico, and Arizona. The estimated average yield of mohair per goat in 1935 was 4.4 pounds although the average yield in some of the better flocks was probably twice as great. Practically all improvement has come about through practical breeding. In comparison with other farm animals, little in the way of scientific research has been done with the Angora goat. The Texas Agricultural Experiment Station is the only place in the United States where experimental work is now known to be conducted with this breed. Research is badly needed on problems pertaining to the development of strains yielding larger amounts and a better quality of mohair. Techniques have been developed for the study of mohair that, combined with the proper genetic research, offer possiblities of improvement yet unrealized.

It is quite certain that the goat was one of the first domestic animals. In all probability, it was first domesticated in western Asia, and from there it was brought into Africa and other countries. After centuries of selection, the domestic goat is very different from its wild ancestor.

The goat is probably descended from the pasang or Grecian ibex (*Capra hircus aegagrus*), a species of wild goat found in Asia Minor, Persia, and contiguous countries. It appears unlikely that any wild species other than the pasang had an appreciable part in the ancestry of the domesticated goat, although for some breeds, as the Malayan, Cashmere, and Angora goats, the evidence is not so convincing that this form was the sole ancestor. It is possible that the ibex and markhor may have been represented in the ancestry of these breeds, for Lydekker (*9*)[1] states that both of these forms will breed readily in confinement with domesticated goats.

The development of the long-haired type of goats was accomplished centuries ago, principally in Asia Minor, where the Province of Angora gave its name to the best known of such breeds. How the short hair of the pasang and other possible ancestral forms developed

[1] Italic numbers in parentheses refer to the Bibliography p. 1292.

into the long hair characteristic of the Angora goat is not clear, but it seems most likely that it was simply by the selection of animals with variations in length of hair. Whether a single major mutation accounted for the change, as appears probable for long-haired types in the rabbit and the guinea pig, is unknown, but it would seem certain that the selection of minor variations in length of hair has modified the character in the desired direction.

According to Willingmyre, Window, Spencer, and others (*20*), the original Angora goat was described as a comparatively small animal with a fine lustrous, silky fleece that hung in ringlets and attained a length of 8 to 10 inches. In the early part of the nineteenth century the demand for raw mohair became so great that the Turks, who were the original breeders of the Angora, were unable to increase their herds rapidly enough to meet the demand. This resulted in hybridization of Angora bucks with common Kurd does in an effort to increase the number of mohair-producing animals quickly by grading up the common goats of the region. This practice became so prevalent that purebred Angora goats were practically eliminated. However, the new type of Angora developed from these cross-breds is a larger and hardier animal that yields a heavier though somewhat coarser fleece than the original Angora.

THE DISTRIBUTION OF ANGORA GOATS FROM ASIA MINOR

ALTHOUGH the Angora goat was developed in Asia Minor centuries ago,[2] its spread into other portions of the world is relatively quite recent. The first European record of the Angora goat appears in 1554 when, according to Cronwright Schreiner (*2*), the Dutch ambassador at Constantinople procured a pair of Angoras and sent them to the Emperor, Charles V. However, mohair yarn was known before this date in Europe. Following this early importation of Angora goats

[2]The use of mohair can be traced to the time of Moses. The Bible records that Moses commanded the children of Israel, after being delivered from slavery in Egypt, to bring white silk and goats' wool to weave altar cloths for the tabernacle (*20*).

ONE *of the most urgent needs for breed improvement in all branches of livestock, including mohair goats, is the development of more and better criteria for the selection of breeding animals. Too generally, selection is based solely upon the animal's appearance, or phenotype, and it is a well-known fact, substantiated both by practical experience and by genetic evidence, that appearance is not always a good criterion of an animal's breeding worth. It is of value and must be taken into account, but it is only a part of the story. The question is, not what an animal looks like, but what inheritance it will pass on; and it is impossible to determine this from appearance.*

to Europe, many attempts were made to establish them but without success until the nineteenth century.

In 1838 Angora goats were first introduced into South Africa. These goats were crossed with native goats and by a process of selection and inbreeding, herds of high merit were established. The goats were prized by the Boers, not so much for their mohair, but, according to Rose (*12*), because the infusion of the Angora blood into the native herds made the cross-bred goats less subject to cutaneous diseases and more able to resist scab. The cross-breds were also earlier maturing and heavier than the native goats, and their flesh was more palatable. No more importations were made into South Africa until 1856, but after that date several were made and the industry has grown until today South Africa, Turkey, and the United States are the countries producing the largest quantities of mohair.

The first importation of Angoras into the United States was made in 1849 by James C. Davis of Columbia, S. C. It consisted of nine choice animals—seven does and two bucks. These goats were exhibited at many fairs, where they won numerous prizes and received much publicity, with the result that great interest was stimulated in Angora goats.

In 1860 a second importation of 8 Angoras was made by William Henry Stiles of Cartersville, Ga., this being followed by an importation of 67 goats by Winthrop W. Chenery of Belmont, Mass., in 1861. In the next decade several importations were made, including one by Israel S. Diehl, who had been commissioned by the United States Commissioner of Agriculture in 1867 to visit the Province of Angora for the purpose of investigating the mohair industry.

During the 30 years from 1870 to 1900 several small importations were made by various breeders, mostly bucks to be used in the importers' herds. In 1904 one of the largest and most notable of all importations, consisting of 148 goats, was made by G. A. Hoerle of Midland Park, N. J. This shipment, which came from South Africa, was made possible by the temporary suspension during the Boer War of the very high export duty of 100 pounds sterling on each Angora goat by the South African Government. Soon thereafter the exportation of Angora goats was prohibited from South Africa and this embargo remained in effect for nearly 20 years.

Recent importations of Angora goats have been few and limited to a small number of individuals, mostly bucks. The latest importation from South Africa was made by E. Cawood into Texas in 1925.

THE ANGORA GOAT INDUSTRY IN THE UNITED STATES

FOLLOWING the Civil War the growing of Angora goats spread into many parts of the country and the number of goats increased rapidly. Introduction into new regions was at first largely for the purpose of brush extermination on new lands being opened for settlement in the West. In some regions where these goats proved to be well adapted, however, an interest in Angoras for the production of mohair developed, and the industry has finally become firmly established in certain sections.

Since 1900 the industry in the United States has undergone rapid expansion. The number of Angora goats increased from 329,300 in

1900 (*1*) to 2,101,591 in 1920 and to 3,785,127 in 1930 (*14*). Figures showing the status of the Angora goat industry in the United States in 1930 are given in table 1.

TABLE 1.—*The status of the Angora goat industry in the United States in 1930*

Region	Total Angora goats	Angora goats by regions	Total farms in the United States	Farms reporting Angora goats		Average per farm reporting
	Number	*Percent*	*Number*	*Number*	*Percent*	*Number*
Texas	2,956,584	78.1	495,489	9,287	1.9	318.4
New Mexico	193,639	5.1	31,404	1,177	3.7	164.5
Arizona	193,320	5.1	14,173	590	4.2	327.7
Oregon	119,341	3.2	55,153	2,895	5.2	41.2
Missouri	78,839	2.1	255,940	3,454	1.3	22.8
California	45,286	1.2	135,676	1,025	.8	44.2
All other States	198,118	5.2	5,300,813	15,951	.3	12.4
United States	3,785,127	100.0	6,288,648	34,379	.5	110.1

From these figures it is apparent that Angora goat production is largely confined to the southwestern part of the United States; and that Texas had over 78 percent of all Angora goats in 1930, with New Mexico and Arizona accounting for over 10 percent of the remaining goats. In Texas the majority of the goats are raised in the Edwards Plateau area in the southwestern part of the State, where they are kept in large numbers on ranches. In Arizona and New Mexico similar conditions exist, this method of production being responsible for the large number of goats reported per farm in those States.

Since 1930 there has been some decline in the total number of Angora goats in common with a reduction in number for most classes of livestock. The 1935 census of agriculture listed 4,093,441 goats of all kinds in the United States, whereas in 1930 a total of 4,821,294 were listed. If there was a proportionate reduction in the number of milk and Angora goats the approximate number of Angora goats in the United States in 1935 was 3,211,000.

The production of mohair and estimated average weight of mohair fleeces at 5-year intervals since 1920 for the six leading States are shown in table 2. While the total production of mohair increased in proportion with the increase in number of goats, it may be noted that the average production per goat did not increase greatly, although there was a slight, but not constant, increase in average fleece weight. For some States, notably Texas, New Mexico, and Oregon, the average weight of fleece was greater than for other States. The reason for this is not apparent, but it is probable that both better breeding and better management were responsible. For instance, Angora goats in Missouri are kept in small herds principally for the purpose of clearing brushland, whereas in Texas and some of the other States they are kept in large herds primarily for the production of mohair. It is to be expected that in Texas more careful attention will be given to the selection of breeding stock, as well as to providing conditions most favorable for mohair production.

In addition to its value as a producer of mohair, which is a very important textile fiber, the Angora goat is useful for clearing brush

from virgin land (fig. 1 illustrates the feeding habits of the animals) and it is a valuable source of meat. During the fiscal year ended June 30, 1936, a total of 51,461 goats were slaughtered in packing plants under Federal inspection (*13, p. 27*), a large proportion of which were

Figure 1.—Angora goats browsing. This is a common scene in the Edwards Plateau section of Texas. The goats obtain a large part of their feed from the browse that grows abundantly in this section.

Angora goats. This meat, sometimes known as chevon, is similar in flavor to lamb and mutton.

Goat meat, according to Williams (*19*), goes quite generally into the regular meat trade. In cities and towns in the range districts Angora wethers are marketed freely as such and the meat is consumed without discrimination by the buyer. According to some buyers properly finished goat meat has a sweetness lacking in mutton. Studies by Miller [3] indicate that the flavor of the meat from kids and lambs is very similar; in fact, the flavor was identical as far as the committee judging the two types of meat could decide. The goat meat was a little coarser in texture and for the older goats was graded as slightly tougher and somewhat drier. In eastern markets the status of goat meat has never been established and occasional efforts to sell it in these markets have been disappointing.

In general the goat carcass is not so well-fleshed, it is not susceptible of so high a finish, nor is the dressing percentage so high as that of the average sheep carcass. The selling price of the Angora wether is about 60 percent of that of the sheep wether where large numbers are sold. The lower price of chevon meat is attractive to consumers, and the quality of the meat is probably superior to that of mutton that could be obtained for the same price (*19*).

Improvement Brought About by Selective Breeding

The improvement of Angora goats in the United States has come about through selective breeding. Following the early importations, imported bucks were used extensively on a foundation of common short-haired does. Through selection and the use of imported bucks improvement progressed until the supply of high-class stock is now so plentiful that cross-breeding is seldom practiced. At present the chief method of breed improvement is based on a program of selection within purebred Angora stocks. Figure 2 shows a buck and a doe representative of the breed.

For the most part, the range herds of Angoras are composed of high-grade does that are mated with purebred bucks obtained from breeders who specialize in the production of registered animals. Most of these breeders are in the States of Texas, Oregon, New Mexico, and Arizona.

Agencies That are Sponsoring Breed Improvement

In 1900 the American Angora Goat Breeders' Association established a registry system for Angora goats. The foundation animals admitted to registry were chosen after official inspection of high-grade American Angoras, and only animals conforming to the standards required by the association were admitted. From 1900 to 1924 all goats registered by this association traced to these foundation animals or to Angoras imported during this period. In 1918 another association, the National Angora Record Association, was organized and incorporated under the laws of Texas, but this association merged with the American Angora Goat Breeders' Association in 1924. At present the latter association is the only organization registering Angora goats in the United States. Up to 1937 a total of about 170,000 Angora goats have been registered. Claudine Bourland of Rock Springs, Tex., is the secretary of this association. The directory of the association, pub-

[3] Miller, R. H. Quality and palatability of chevon. Master's thesis, Oreg. State Col. 1929.

lished in October 1934, lists a total of 353 members, 266 of whom are in Texas.

Other organizations that are active in sponsoring Angora goat breeding and improvement are the Arizona Mohair Growers' Association and the Texas Sheep and Goat Raisers' Association.

The Angora Journal, published at Portland, Oreg., by A. C. Gage, is the only journal in the United States that specializes exclusively

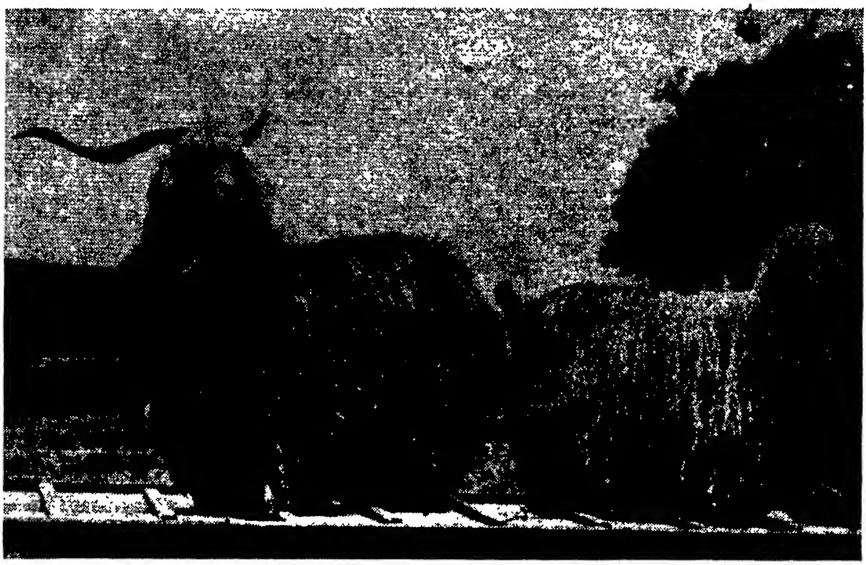

Figure 2.—An Angora buck and doe in full fleece. These individuals are good representatives of the breed.

on the promotion and improvement of Angora goats. The Southwestern Sheep and Goat Raisers' Magazine is the official publication of the Texas Sheep and Goat Raisers' Association.

RESEARCH, INCLUDING THAT AT FEDERAL AND STATE STATIONS

Research pertaining to Angora goats either by States or by the Federal Government is very limited. At present, only three projects are listed in the Office of Experiment Stations that deal with Angora goats, and these are all being conducted at the Texas Agricultural Experiment Station. They cover:

1. The inheritance of type in Angora goats.
2. Inheritance of the ridgling [4] characteristic in goats.
3. Cytological and hybridization studies with goats.

In 1915 the Texas Agricultural Experiment Station established a branch experiment station, generally known throughout the Southwest as the Ranch Experiment Station, in the Edwards Plateau section midway between Sonora and Rock Springs (fig. 3). Much

[4] Ridglings or "rigs" are animals characterized by cryptorchidism, the condition in which one or both testes fail to descend into the scrotum. Usually it involves but one testis, but occasionally both.

of the research at this station has been devoted to a study of Angora goats and mohair, and several bulletins have been published dealing with various aspects of mohair production, particularly studies on the influence of such factors as age, sex, individuality, and pregnancy upon the quantity and quality of mohair produced. The Bureau of Animal Industry of the United States Department of Agriculture has

Figure 3.—The laboratory building at the Texas branch experiment station near Sonora, Tex. This is the only research institute in the United States that is carrying on investigations with the Angora goat.

cooperated in some aspects of these investigations, chiefly on studies pertaining to quality of mohair.

Several years ago the Oregon Agricultural Experiment Station maintained an experimental herd of Angora goats, but with the curtailment of funds for research that followed the depression, this herd was disbanded.

Results of the Germ-Plasm Survey

As a part of the survey of germ plasm in animals and plants, the Department of Agriculture sent questionnaires to agricultural experiment stations in those States where Angora goats are of considerable economic importance and also to all prominent breeders whose names could be obtained. The breeder was asked for information concerning (1) the size of his herd, (2) the number of purebred and grade goats in the herd at present and during each of the last 5 years, (3) the total yield of mohair for each of the last 5 years, (4) the number of sires used in the herd, (5) the proportion of single and multiple births observed during the last 2 years, (6) the names of any outstanding strains bred by him, and (7) whether he was practicing inbreeding. If he was practicing inbreeding the breeder was requested to furnish pedigrees of several of his most highly inbred animals.

There were very few returns from the questionnaire, and as a result no very definite conclusions can be drawn. Some breeders

reported that they were practicing some inbreeding, but no pedigrees from which the degree of inbreeding could be determined were included in their replies. Nor is this information available anywhere in published form, since the record association does not publish herd-books. While a few breeders have attempted to develop and maintain certain breed lines, the number of attempts to do this is small and no families that could be compared with some strains of cattle—as, for instance, the Anxiety 4th Herefords—were reported. It is improbable that such strains exist among Angora goats. Some breeders follow the plan of using bucks produced in their own herds; others the plan of purchasing sires from other herds; while some use a combination of both plans. Since no importations have been made in recent years, little improvement has recently been accomplished in this manner. Apparently there has been a tendency among Angora breeders to breed for definite points such as certain fleece types, the elimination of beards, etc., rather than for the development of breed lines of especial merit.

From the data submitted it is apparent that mohair production in the flocks of the better breeders is much above the average reported in table 3. Two breeders reported an average annual production per goat during the last 5 years of over 7½ pounds; others, an average annual production of over 6 pounds. These figures are from 2 to 3 pounds, or some 40 to 70 percent, above the estimated average production for all Angora goats.

No great tendency was observed in any of the herds reported for the production of multiple births. A considerable reduction has been made in the size of some purebred flocks since 1930.

Genetic and Fleece Studies on the Angora Goat

Only a few investigators have studied the genetics of the Angora goat and most of the studies reported thus far are in their preliminary stages. Warwick (*16*) found that the presence of horns is dominant to hornlessness in the Angora and he suggests that one major factor governs the inheritance of this character, although the data are too few to allow for definite conclusions. Most purebred Angora goats have horns.

Cryptorchidism, an inherited defect that is quite common in Angora goats, has been investigated by Lush, Jones, and Dameron (*8*), and by Warwick (*15*). The exact mode of inheritance is not known, and its determination is difficult since the defect can be observed only in the male. The condition is recessive and at least two pairs of factors are involved.

The mode of inheritance of fleece length has not been determined, but Davies (*3*) states that the long-haired condition appears to be recessive. From the meager evidence available, however, it seems probable that hair length is determined by multiple factors.

The effect of individual differences and of such factors as age, sex, pregnancy, and lactation on the quality and quantity of fleeces produced by Angora goats has been investigated by Lush and Jones (*7*), and by Jones, Warwick, Dameron, and Davis (*6*). The studies by Lush and Jones show that about 17 percent of the differences in fleece weight produced by goats similar in age, sex, and general breed-

ing is permanent throughout the life of an individual and hence is subject to selection. The exceptional individual is of more importance in the less uniform flocks, and it is in such flocks that selection would be most effective. It was determined, furthermore, that permanent differences in fleece weight show up less accurately at first shearing than at later shearings and that they show more accurately at the fall yearling shearing, usually the second shearing, than at any other age. This is an important determination from the breeder's standpoint since culling at this age will result in the selection of those goats with the greatest inherent mohair production.

Jones, Warwick, Dameron, and Davis (*6*) found that the age of the animal had a marked influence on both the unscoured and the clean weight of the fleece, the weight increasing to a maximum at 3 years, after which it becomes steadily less. Diameter of mohair fiber and body weight were shown to increase until the animal reached 8 years of age. Length of staple, amount of kemp or coarse inferior hair in the fleece, and the extent of belly covering were somewhat less influenced by the age of the animal. Staple length reaches its maximum the first year and the mohair produced during the first year is of somewhat better quality than that produced later.

The body weight of bucks was found to be about 23 percent greater than that of does, while their fleece weights averaged about 18 percent greater unscoured and 29 percent greater when clean. The diameter of fiber was observed to be coarser in the fleece of the male but the staple length was somewhat less. Pregnancy was shown to reduce the fleece weight, as did the suckling of young. A somewhat similar effect of pregnancy was observed upon staple length although this effect is more pronounced in younger than in older animals.

Attempts to Cross the Sheep and Goat

Various investigators (*11*) have described apparent sheep-goat hybrids and a few writers have stated that such hybrids are rather common in some sections. Other workers have questioned these conclusions, and in the light of controlled attempts to make this cross it is probable that living hybrid offspring are rare, if they exist at all.

Heller, cited by Popenoe (*10*), reported that attempts to make such crosses between Barbados sheep and the goat in the laboratories of the Bureau of Animal Industry were unsuccessful. Recently Warwick, Berry, and Horlacher (*18*) described attempts to cross Angora does with rams, mostly of the Merino breed. In all 38 such matings were made. In 21 females it was determined that fertilization and implantation of the egg took place, but in no case were living young obtained. Two of these does were sacrificed, one 44 days after breeding and the other 62 days after mating. In both cases apparently normal embryos were found. The causes for the early death of the hybrid fetuses have not been determined.

Not all rams that were tried would mate with the does and, contrary to general opinion, Angora males would not mate with ewes. However, one Angora male that was raised on a sheep foster mother was mated with 17 ewes, but there is no evidence that fertilization occurred in any of these cases (*17*).

OPPORTUNITIES FOR FURTHER IMPROVEMENT

It is apparent from the facts presented here that credit for improvement of Angora goats must go to private breeders, past and present, who alone have been responsible for bringing this breed to its present development. But improvement is now very slow, and if further progress is to be stimulated and encouraged, new measures are called for. On this point few will disagree, but the breeder may well ask what steps can be taken to bring about further improvement. It must be confessed that there is no single easy formula. If further improvement is desired, what will be needed is a program that includes the active cooperation of breeders, breed associations, State and county extension workers, and finally, the research staffs of State and Federal experiment stations.

No attempt will be made here to outline a research program for Angora improvement, but some of the points that need be considered will be briefly discussed.

One of the most urgent needs for breed improvement in all branches of livestock husbandry at the present time is the development of more and better criteria for the selection of breeding animals. Too generally, selection is based solely on the animal's appearance, or phenotype, and it is a well-known fact, substantiated both by practical experience and by genetic evidence, that appearance is not always a good criterion of an animal's breeding worth. It is of value and must be taken into account, but it is only part of the story. The question is, not what an animal looks like, but what inheritance it will pass on; and it is impossible to determine this from appearance. How to determine it is a question that science is as yet far from having answered in the case of animals. Research workers are attacking the problem, however, and eventually methods should be devised for determining and evaluating the factors of greatest importance in the selection of breeding stock.

Meanwhile, in spite of present uncertainties, it is known that the progeny test is important in evaluating breeding animals. To use the progeny test properly, however, requires the development of better records than those that now exist for mohair production. This is one part of an improvement program in which the practical breeder can cooperate to advantage with the scientist. Before such tests are undertaken, however, careful thought must be given to the kind of records that will be of the greatest use.

To use the progeny test most effectively the breeder must have accurate data on the offspring of his herd sires. Among the records of most importance are quality of mohair, freedom from kemp, uniformity of body covering, and yield of mohair determined on a clean basis. While facilities are probably not now available for securing all such information, records could undoubtedly be obtained if there were a sufficient demand for them. In addition to their value to the breeder in the selection of sires, such records would be of use to the scientist in getting at the basic physiological problems concerned in mohair production; and a more complete knowledge of such factors is essential to continued progress.

Very little information exists concerning the inheritance of any characters in the goat and particularly of those characters that are

concerned in the production of good fleeces. Research in this field is badly needed, since progress in breeding for fleece improvement must ultimately depend on a better understanding of the genetic factors involved. As an example, take the appearance of kemp in the fleece (fig. 4). The elimination of kemp fibers, which greatly reduce the value of the fleece, is one of the most important problems in Angora goat improvement. Until it is known how the kemp-producing characteristic is inherited, it can hardly be eliminated from herds.

There are now outstanding animals in the herds of many breeders, but along with them there are many mediocre and some inferior

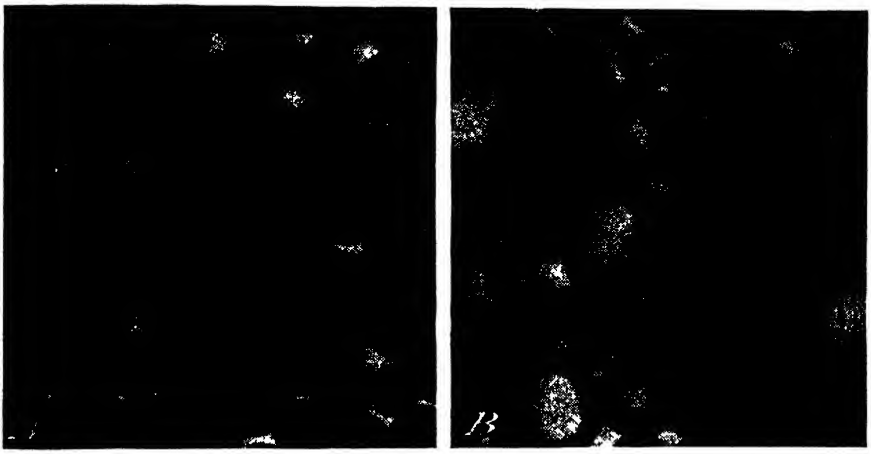

Figure 4.—Cross sections of mohair fibers showing (*A*) freedom from kemp and (*B*) the presence of many kempy fibers. The kempy fibers, which are short, coarse, and irregular, are characterized by a medullated or hollow central portion. They do not take dye readily, and because of this and their stiffness and poor spinning qualities, the presence of such fibers in a fleece lowers its value.

animals. If it were possible for the breeder to increase the uniformity of the animals in his flock it would be a decided step forward. Little is now known of the factors making for uniformity of fleece type, although this question is of vital concern to the breeder and the producer alike. Research that will lead to the development of methods for improving uniformity in flocks is badly needed.

These are two problems that should form part of a research program. Others might be discussed, but enough has been said to indicate the need for a scientific approach to the problem of improvement. Research commonly yields large returns for the funds and efforts expended, but the active encouragement of the industry is needed if an adequate research program for the improvement of Angora goats is to be carried on.

Some Immediate Practical Steps

In addition to sponsoring research Angora goat producers might foster improvement in other ways. One method that has particular merit would be the development of a system of recording based on

meritorious production of mohair similar to the register of merit for many breeds of dairy cattle. In such records scoured weight, fineness, and uniformity of fleece and freedom from kemp should be particularly stressed. Other steps that would be helpful would be the inclusion of more information in pedigrees than they now contain, with provision for certification of production records by some competent and impartial authority. Since Angora goat breeders are concentrated in a relatively few States, it should be possible to arrange for such certification of records with a minimum of cost to breeders. Such programs have been developed for register-of-merit records for other animals, and a similar scheme could be easily devised that would meet the requirements for breeders of Angora goats.

Again, if mohair were sold on a quality rather than on a weight basis it would exert an influence toward improvement in the breed by stimulating producers to raise better goats. This is worth serious effort on the part of the breeders and their record association. The adoption of different methods for the awarding of prizes at shows would also be a step to encourage better breeding practices. More emphasis should be placed on the get of sires and on outstanding families, and prizes should be awarded to breeders on this basis. This is in line with the progeny test, and it would focus the attention of breeders on the breeding ability of their choice animals.

Many difficulties beset those who undertake the improvement of modern breeds of livestock. But in spite of the excellence of modern breeds, their inherent variability is still great and the opportunities for improvement are many. The situation is a challenge to breeder and scientist alike, and if any great progress is to be made they must work closely together.

IMPROVEMENT OF MILK GOATS

V. L. SIMMONS, Assistant Animal Husbandman, and
W. V. LAMBERT, Senior Animal Husbandman,
Animal Husbandry Division, Bureau of Animal Industry

ACCORDING to a recent survey by the United States Department of Agriculture, only two research institutes in the United States are now conducting investigations on milk goat breeding. Both institutions, the New Mexico Agricultural Experiment Station and the Department of Agriculture, have brought about great improvement in their herds by grading up common does with purebred bucks of milk breeds, and the results indicate great potentialities for milk goat improvement by the application of breeding methods.

THE GOAT AS A MILK PRODUCER

MILK goats are widely distributed in the United States but, in contrast with Angora goats, they are generally found in small herds and in many cases as one or a few individuals kept on the farm or in the back yard of the urban dweller. While they have not attained the position of economic importance of other classes of livestock, their numbers are increasing. Because a good milk goat will supply sufficient milk for the average family for at least 9 to 10 months of the year and can be kept where it would be impossible to keep a cow, they occupy a place in American agriculture not filled by any other class of livestock, and one that is probably destined to be increasingly important.

The average milk production is low, but there are many high-producing individuals and some herds in which the average milk production is high. Great variability exists both in rate and persistency of lactation.

The income of milk goat producers is derived principally from two sources—the sale of breeding stock and the sale of milk and milk products. Goats' milk has only a specialized demand and the development of goat dairy enterprises has been limited largely by the market created by the producer's own initiative. The producer of good breeding stock, on the contrary, has been in a more favorable position, for generally a greater demand exists for good stock than can be supplied.

Goat meat and goatskins also contribute to a limited extent to the income of the goat producer. Thousands of goats are slaughtered annually and their meat enters the same general channels of trade as mutton and lamb. Their skins are used in the manufacture of shoes, gloves, book bindings, pocketbooks, and other small articles. The number of skins produced annually in the United States is not large

and millions of skins are imported each year. From July 1934 to July 1935 a total of about 60 million pounds of skins were imported.

Breeds of Milk Goats in the United States

The goat is one of the most ancient of domestic animals. Most authorities agree that the numerous varieties are descended from the Persian wild goat, *Capra hircus aegagrus*, a species common in Asia Minor. Just when it was first introduced into Europe is unknown, but remains of goats are found among the ruins of early European races.

Records of early settlements in Virginia and New England indicate that goats of the milk type were brought to the United States by Capt. John Smith and by Lord Delaware. Goat raising, while of some consequence to the early settlers, gradually declined after the middle of the seventeenth century.

Serious attention began to be paid to the breeding of milk goats in the United States about 30 years ago. Prior to 1904 there were scarcely any purebred Swiss goats in the United States, records revealing but one importation, that of four head in 1893. In 1904 a consignment of 10 Saanen and 16 Toggenburg goats was brought in, and this was followed by several other importations during the next two decades. Animals from these importations were widely dispersed by sale throughout the United States, and have provided the basis for the development and improvement of milk goats in this country.

The important breeds of milk goats in the United States are those that have proved most popular on other continents—the Saanen, Toggenburg, Nubian, Maltese, and Alpine. Representatives of these breeds of improved milk goats, although increasing, are not so numerous in this country as the unimproved types of short-haired goats. Among them are large numbers of the common, or American, goat. A quarantine against the importation of goats from many countries largely accounts for the small number of breeds found in the United States.

A GOAT *can be kept where it would be impossible to keep a cow, and a good producer will supply sufficient milk for the average family. The milk is a wholesome and nutritious food, and in addition the meat is palatable and nutritious. In localities where an adequate supply of milk is not available and the keeping of cows is impracticable, good milk goats would contribute materially to the welfare of many families, especially those of low income. Thus there can be no doubt of the value of efforts to improve the milk production of these animals in the United States. However, the improvement of the milk goat, in common with that of other species of livestock, is a large task that requires the best efforts of the breeder, the research worker, and all other interested agencies.*

The Saanen and Toggenburg breeds of milk goats are the most popular in point of numbers in this country. Both breeds originated in Switzerland. Purebred Saanens (fig. 1, *A*) are solid white in color and large in size, mature males weighing 175 pounds or more and mature females, 125 pounds or more. The dairy conformation is especially well developed. The marked ability of this breed to produce milk is evidenced by the fact that the highest official test on record in the United States was made by a Saanen doe that produced 4,161.7 pounds of milk in 9 months and 10 days, an average for the period of 6.9 quarts a day.

The body color of Toggenburg goats (fig. 1, *B*) is brown or chocolate with a white stripe or bar down each side of the face, and the legs below the knees and hocks are white. Two wattles attached to the underside of the neck are very characteristic

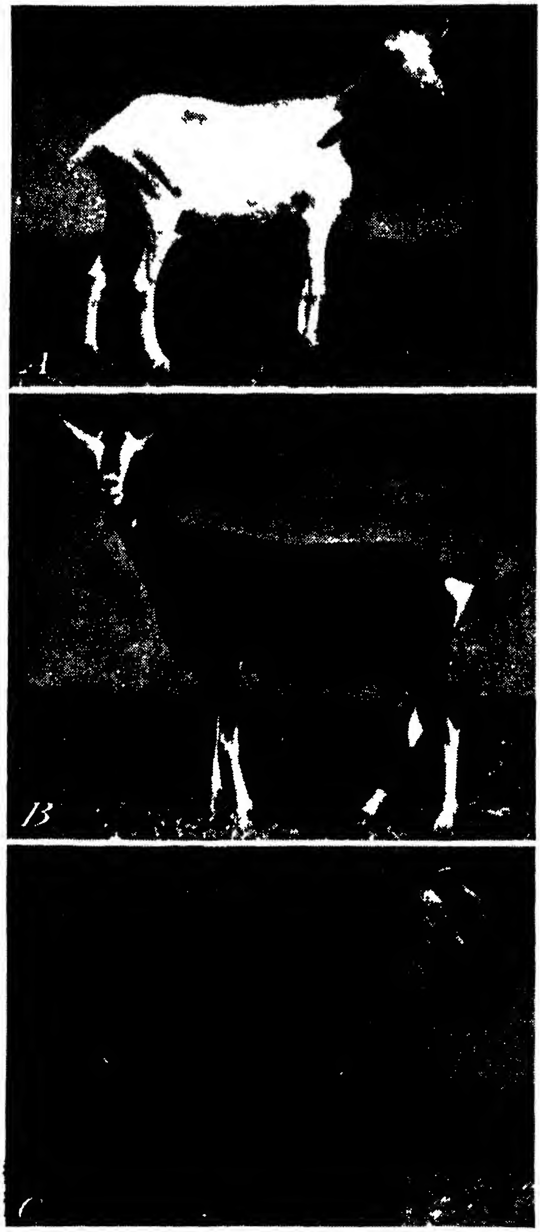

Figure 1.—High-producing does from three different breeds: *A*, Saanen; *B*, Toggenburg; *C*, Anglo-Nubian. The Saanen doe (No. 40728, Advanced Registry No. 191 A. M. G. R. A.) produced 3,144.4 pounds of milk and 95 pounds of fat in 10 months. Her highest daily yield was 17.6 pounds. The Toggenburg doe (No. 41642) produced 11 pounds of milk daily for a 30-day period as a 4-year old. Each one of these does came from high-producing ancestors and each has won high honors in the show ring. The Anglo-Nubian doe (No. 34278, Advanced Registry No. 201) produced under official test as an 8-year old an average of 12.1 pounds of milk, averaging 5.7 percent fat, daily for 3 months.

of this breed. Does of this breed, while not usually producing as large quantities of milk as those of the Saanen breed, are excellent milkers and a Toggenburg doe has made an official record of 2,759 pounds of milk in 10 months. Toggenburg does, when mature, weigh from 100 to 135 pounds and mature bucks, from 150 to 175 pounds. Owing to the fact that Toggenburg goats are more plentiful here than other breeds, a good many grade goats of the Toggenburg type are found in various parts of the country. In fact, many herds have been established by crossing Toggenburg bucks on does of the American type.

Nubian milk goats, although considered a valuable breed, are not numerous in this country. They are natives of Nubia, upper Egypt, and Abyssinia. The colors of Nubians are black, dark brown, or tan, with or without white markings. They have a striking appearance, with drooping ears, a convex face, and a prominent forehead. Nubian bucks when mature weigh 165 pounds or more and mature does, 125 pounds or more. The Nubian breed is considered one of the best for milk production and the milk is noted for its high butter fat content; however, no figures are available on production for this breed.

There are also some Anglo-Nubian goats in this country. These are a very popular type of goat in England and are descended from crosses between the Nubian and goats of English origin. The predominant colors are black, tan, and red, with or without white. Some good specimens have shown a color approaching a roan, which is the color of the doe shown in figure 1, *C*. Anglo-Nubians are considered good milkers. Richards (*21*)[1] states that Nubians and Anglo-Nubians are less well adapted to cold climates than are the other breeds.

A scattering of Alpine goats are found in the United States and trace to an importation of 3 bucks and 18 does brought into California from France in 1922. The Alpines range in color from pure white to pure black with frequent white spotting on the neck, legs, or underneath the body. They are of large size and quite hardy, and they have excellent capacity for milk production.

The Maltese breed, while considered valuable in some parts of the world, is of no special importance in this country at present, except that it has had some influence on the type of goats in the Southwest. It is native to the island of Malta. The color is white and reddish brown or black. It is considered one of the best breeds for milk production.

In the southwestern part of the United States there is found a type of goat known as the Spanish Maltese, which is descended from crosses between the Maltese and goats of Spanish origin. It is said that at a former time many Maltese goats were taken into Spain and from there to Mexico and finally to Texas and New Mexico. This type of goat is white or grayish in color, but many have brown, bluish-black, or reddish spots. The ears are pendulous. It is asserted that some are very good milk producers.

The common, or American, goats (fig. 2, *A*) found in many sections of the United States, especially in the South, are of mixed origin. In many sections these goats have been bred for a great many years without the introduction of outside blood, so that in general conformation they are nearly uniform, being of medium size, somewhat short legged, and rather meaty in appearance. They do not show

[1] Italic numbers in parentheses refer to Bibliography, p. 1312.

Figure 2.—*A*, Common American doe no 66 used as one of the foundation does of the United States Department of Agriculture herd at Beltsville, Md. This doe produced 367 pounds of milk in a lactation period of 275 days. *B*, United States Department of Agriculture doe no. 214. This doe represents the third top cross of high-producing Saanen bucks on a foundation of common American does. This doe produced 1,796.3 pounds of milk in a lactation of 266 days.

the conformation of the Swiss breeds, and they are of various colors—brown of various shades, brown and white, black and white, bluish gray, and white predominate. Although a few goats of this type are occasionally found that are good milkers, the quantity of milk produced is usually small and the lactation period lasts only a few months. Yet by crossing common does with bucks of the Saanen, Toggenburg, and Nubian breeds for several generations, some of the very best milkers in the United States have been produced. Because of the scarcity of good milk goats, common does have been used largely for grading up with the improved breeds.

Distribution of Milk Goats in the United States and the World

With the exception of the dog, the goat is the most widely distributed of all domesticated animals, and the genus *Capra* is found throughout the world outside of the Arctic regions. Table 1 shows the distribution of goats of all types for those countries that reported an average of 500,000 or more during the 5-year period 1926–30. Although the types of goats are specified in only a few instances in census data, it seems probable that the majority of the goats reported are used for milking purposes. The total number of goats in the world is estimated at 189,000,000, of which 8,000,000 are classed as Angora goats.[1]

[1] Figures from census of 1930.

[1] The proportion of Angora to milk goats in the United States is much different from that prevailing in most parts of the world. According to the 1930 census, milk goats constitute less than one-fourth of the total number of goats in the United States. In many countries, such as Spain and Germany, the proportion of milk goats to Angora goats is much larger.

The total number of milk goats [2] in the United States can only be estimated as no specific census figures are available. The total number of goats of all kinds in 1930 according to the census of that year was 4,821,000, of which 3,785,000 were specified as Angora goats. Only a small percentage of the 1,036,000 other goats, of short-haired type, could be classed as improved milk goats. In 1930 [3] the five leading States in number of short-haired [4] goats and kids were Texas with 185,737; New Mexico, 102,548; Arizona, 97,628; Georgia, 84,503; and Tennessee, 53,948.

Milk goats are found in practically all sections of the United States and in recent years have increased in numbers in the Eastern and Middle Western States. While California ranks eleventh in total number of short-haired goats, the milk goat industry in southern California has developed to a greater extent than in any other section of the United States. The dry, even climate, the abundance of feed, both wild and cultivated, and the favorable marketing conditions present opportunities not offered in most sections.

In a number of countries milk goats have been bred for many years, and in a few countries, Switzerland in particular, they have been brought to a state of considerable efficiency and perfection. In Spain goats are the chief source of the milk supply. In Europe and Asia the goat is used quite generally as a dairy animal, while in Africa meat and skins are the principal products.

PROPERTIES AND USES OF GOATS' MILK

Goats' milk differs in some respects from the milk of the cow. Chemical analyses of the two kinds of milk are shown in table 2.

TABLE 2.—*Composition of goats milk* [1] *and that of two common breeds of dairy cows*

Source of milk	Water	Total solids	Fat	Protein	Lactose	Ash
	Percent	*Percent*	*Percent*	*Percent*	*Percent*	*Percent*
Goat	88.02	11.98	3.50	3.13	4.55	0.80
Holstein-Friesian	87.50	12.50	3.55	3.42	4.86	.68
Jersey	85.31	14.69	5.18	3.86	4.94	.70

[1] Average of purebred and high-grade Saanen and Toggenburg does.

Considerable variability is observed in the composition of milk from different breeds of both goats and cows, between individuals in the same breed and even in samples taken from the same individual, especially when such samples are taken at widely different periods of lactation. The above results for the goat are based on analyses of milk from the herd kept by the United States Department of Agriculture at Beltsville, Md., while the results for the two breeds of dairy cattle are from data reported by the Associates of Rogers (*22*).[5]

[2] The term "milk goats" is one applied to goats that have been bred and developed especially for milk production. The term "Angora" is one given to that breed of long-haired goats which have been bred and developed especially for mohair production. The term "short-haired goats", as used herein, is one commonly applied to unimproved goats of mixed breeding that are sometimes used for milk production. In no case does the term refer to goats producing mohair.

[3] Fifteenth Census of the United States, Agriculture, v. 4. 1930.

[4] The term "short-haired goats" as used by the census probably includes some milk goats

[5] Italic numbers in parentheses refer to Bibliography, p. 1312.

Studies by Jordan and Smith (*11*) showed that there are no essential differences in the casein of goats' and cows' milk. Similarly, studies on milk from the Department of Agriculture herd show that there are no significant differences between these two kinds of milk in content of calcium, phosphorus, iron, and copper. Studies made in the nutrition laboratories of the Department on the vitamin content of goats' and cows' milk showed no marked superiority of one over the other. Jersey milk was found to contain somewhat more vitamin A, but goats' milk more of vitamins B and C. It was also determined that goats' milk has a much softer curd than the milk of either Holstein-Friesian or Jersey cattle.

Through the cooperation of the Department of Agriculture and Johns Hopkins University, normal infants were fed Holstein, Jersey, and goat milk. The milk used in these studies was boiled for 1 minute and was supplemented with orange juice and cod-liver oil. While the number of infants fed on any one kind of milk was too small to furnish conclusive results, no essential differences in health, general appearance, and well-being of the infants were observed, good results being obtained with each kind of milk.[6] The gains in weight were in proportion to the total nutritive contents of the milk. No attempts were made to compare the two kinds of milk on infants with a history of malnutrition. Goats' milk may be of value for infant feeding in cases of food idiosyncrasies, for many cases are on record in which children are able to utilize goats' milk, but not the milk of the cow.

The fat globules are much smaller in goats' milk and this characteristic, together with a softer curd, makes it easier to digest than cows' milk. Because of the small fat globules, which prevent the cream from rising to the surface, the ordinary method of obtaining cream by allowing it to rise is impracticable. By the use of the separator, however, practically all the butterfat can be obtained and it may be used satisfactorily for making butter. Several varieties of cheese are also made from goats' milk. To a limited extent, powdered, condensed, and evaporated goats'-milk products are being manufactured in the United States.

No figures are available concerning the total production or consumption of goats' milk and of the products made from it. In general, there has been only a specialized market for goats' milk and the development of goat dairy enterprises has been limited to a large extent by this market. The price of goats' milk has ranged from 10 to 50 cents a quart and sometimes even higher. There is one brand of evaporated, unsweetened goats' milk on the market which sells for 25 cents for a can of 6 ounces. This is equivalent to about 65 cents a quart for the original milk.

Studies on the Physiology of Milk Secretion

Cunningham and Addington (*8*) studied the effect of early breeding upon milk production. It was found that does freshening for the second time at 2 years of age produced significantly more milk than does that freshened for the first time as 2-year-olds. However, the does freshening for the first time at 2 years of age had somewhat

[6] Four infants were fed on goats' milk and 3 each on Holstein and Jersey milk. The results were in conformity with similar comparisons of the 3 kinds of milk on both kids and rats.

longer lactation periods. The greater production of the goats freshened first as yearlings is contradictory to the belief of many goat breeders.

The question of breeding does early or late in the lactation period has been studied by Brooks (*5*). He found that while delayed breeding tends to prolong the lactation period indefinitely, the later production is at a much lower level. Furthermore, breeding early in the lactation period did not seem to decrease the rate of production during the first part of lactation.

The goat is a seasonal breeder. Turner (*26*) investigatéd this question for goats of various breeds in the United States and found that estrous cycles in normal does occur quite regularly at intervals of about 21 days during the period from September to February. During the months from April through July, and perhaps mostly through August, estrous cycles are generally suppressed. Similar findings were reported by Kupfer (*13*) for goats in South Africa and in Switzerland.

By the injection of an extract prepared from the anterior lobe of the pituitary gland, Asdell (*2*) was able to bring about some improvement in milk secretion of goats in the late stages of lactation. No improvement was observed from injections made early in lactation, especially in the better milkers. Evans (*9*) was able to induce lactation in several virgin milk goats following the injection of a pituitary extract, and in one mature goat during her dry period. In cattle he reports that the Bureau of Dairy Industry of the U. S. Department of Agriculture has been able to get increases in milk yield following the injection of pituitary extract in some low-producing cows that apparently had a deficiency of this hormone. The yield returned to former levels as soon as the injections ceased. Good-producing cows did not respond. These results indicate that there is a relationship between the secretion of the pituitary body and the ability to lactate, but sufficient information is not yet available to make it possible to use this information in a practical way.

Turner and Reineke (*27*) observed that involution of the mammary gland (shrinking of the secretory tissue) was almost complete in a goat in the late stages of lactation, and that the stimulation of milking was ineffective in maintaining the secretory tissue in such goats. Their results suggest that attempts to increase the milk flow by the use of hormones will fail unless growth of the secretory tissue is first induced.

RESEARCH AND PRACTICE LOOKING TOWARD MILK GOAT IMPROVEMENT

In 1936 the Department of Agriculture undertook, as a part of the germ-plasm survey, to determine the status of milk goat breeding in the United States. Questionnaires were sent to experiment stations in those States where milk goats are raised in large numbers, and also to important private breeders whose names had been obtained from State experiment stations and from breed association secretaries. The following information was requested: (1) The name and registration number of important sires; (2) the number of each daughter and her dam; (3) the age when the doe was tested; (4) the number of days in milk; (5) the pounds of milk produced; and (6) the pounds of butterfat produced, and the percentage of butterfat, for each daughter and her dam.

The returns from private breeders were limited. While there are some herds of fairly large size, it appears that few breeders are keeping records on milk and butterfat production, although many breeders expressed a desire for such records and a willingness to cooperate in the keeping of records. Certainly no progress in locating superior germ plasm can be made until better records exist than those now available.

From this survey it was also determined that New Mexico is the only State now conducting research on milk goat breeding. This station has had an extensive breeding program under way since 1919 and the results are discussed in a later section.

Research in Milk Goat Breeding in the Department of Agriculture

Research was initiated with milk goats by the Bureau of Animal Industry in 1909 with the breeding of common or American does to bucks of the same type, with the purpose of developing a superior strain for milk production. Progress was slow and difficult and after 2 years of experimentation of this sort purebred bucks of both the Saanen and Toggenburg breeds were obtained for grading up the common does. The lines started from the top crosses of the original does by males of these two breeds were kept distinct. In each generation the best producing does were retained for top-crossing in the succeeding generation.

Progress has been slow since only a relatively small number of breeding does could be maintained and breeding activities were curtailed at various times. However, there has been some progress. The average length of the lactation period for the top-cross does, on the basis of the 1934 and 1935 results, has increased 145 percent and the average annual milk yield, 335 percent over that of the native does.[7] It should be pointed out that only six native does were available for comparison and the average length of lactation for these does was only 113 days.

The influence on both milk yield and length of lactation as a result of continuous top-crossing with purebred bucks is shown in table 3. With few exceptions, the does were approximately 24 months old at the beginning of lactation.

TABLE 3.—*Influence of top-crossing with purebred bucks on the milk yield and length of lactation of does during their first lactation*

Does (number)	Grade of does[1]	Milk yield: First 120 days (average)	Milk yield: Range during first 120 days	Lactation period: Total average length	Lactation period: Range in length	Increase in average milk yield over natives
		Pounds	*Pounds*	*Days*	*Days*	*Percent*
6	Native	[2] 325.2	253.2–445.2	113	107–122	----------
5	½	[2] 417.6	376.8–450.0	256	230–276	28.4
8	¾	466.7	295.5–554.6	273	205–333	43.5
13	⅞	470.4	313.3–698.2	235	137–309	44.6
18	15/16	496.0	306.2–707.0	256	144–366	52.5
13	31/32	491.4	156.7–807.8	244	122–302	51.1
7	Purebred	523.9	298.6–765.0	278	227–340	61.1

[1] Proportion of pure breedng. [2] Estimated milk yield for first 120 days.

[7] Total annual milk yield is dependent on increased production and persistency in lactation. Much of the increase in annual milk production of the top-crossed does was due to their greater persistency in lactation.

Since the length of lactation varied greatly, the quantity of milk produced by each doe during the first 120 days of her first lactation is used as a basis for the comparison of the productive abilities of does of the different top-cross generations.

As the trend in improvement of milk yield was similar for the top-cross does from the Saanen and Toggenburg bucks, the results for the two breeds were combined. A doe of the third top cross is shown in figure 2, *B*. The milk production of the does from the fourth and fifth top-cross generations was almost equal to that of the purebred does in the herd. No production data are available for grade does of more than thirty-one thirty-seconds pure breeding. A fourth top-cross doe produced 2,221 pounds of milk in 355 days, while the best purebred doe produced 2,297 pounds in 312 days. A number of the grade does had production records exceeding 1,600 pounds for one lactation.

The length of the lactation period also was increased as a result of the top-crossing, although a large part of the improvement was observed in the first top-cross generation. Since only six native does were tested, the average of 113 days observed for them may have been lower than the average for the population of does from which they were chosen.

A comparison of the milk production of does of different ages in the Department herd is shown in table 4. These results show that the period of maximum milk production for does is between 4 and 6 years of age. The length of lactation period also is greatest between the ages of 4 and 6 years but the change observed in length of lactation was not so great as that for milk production.

TABLE 4.—*Average milk yield of does of various ages in the Department of Agriculture herd at Beltsville, Md., 1930–35*

Age of does	Does	Average milk yield	Average length of lactation period	Age of does	Does	Average milk yield	Average length of lactation period
Years	*Number*	*Pounds*	*Days*	*Years*	*Number*	*Pounds*	*Days*
2	28	964.8	255	6	12	1,427.1	286
3	19	1,173.5	281	7	7	1,335.8	268
4	17	1,449.1	290	8	4	1,196.2	266
5	12	1,424.4	276				

A comparison of the purebred sires used in this herd, as measured by the sire index (calculated by the commercial form of the Mount Hope index, as described by Prentice (*20*)), showed that marked differences exist in the ability of sires to transmit their characteristics to their offspring. None of the sires possessed the necessary inheritance for raising both the milk yield and the length of the lactation period of all his daughters.[8] However, more sires increased the milk yield of their daughters than increased the length of the period of lactation.

[8] This study would indicate that all the sires compared are heterozygous for some of the genes affecting milk yield and length of the lactation period.

Research at the New Mexico Agricultural Experiment Station

Since 1919 the New Mexico Agricultural Experiment Station has conducted experiments to determine the improvement that might be expected from grading up native does of the Southwest with purebred Toggenburg bucks. The native does were descendants of the goats brought into the United States by the Spaniards. Since its initiation, the experiment has been expanded to include such studies as the inheritance of horns and wattles, length of gestation, prolificacy, the sex ratio, and a determination of the effects of inbreeding and outcrossing on milk production, and the birth weight of kids.

The foundation animals for the breeding experiment consisted of 10 native yearling does that came from a herd in which there was no apparent evidence of improvement by the use of improved bucks of either Angora or milk type. Milk records were secured on 8 of the 10 foundation native does and their progeny.

The improvement in production resulting from top crosses of purebred Toggenburg bucks on native does and their resulting offspring is shown in table 5 in comparison with the production of purebred does. Each of the does was approximately 2 years old at the beginning of her lactation period. In all cases the quantity of milk produced by a doe was corrected to a butterfat basis of 4 percent by use of the formula of Gaines and Davidson (*19*).[9]

Table 5.—*The effect on milk production of using purebred Toggenburg bucks on native does and their offspring*

Breeding	Animals	Milk	Butterfat		Fat-corrected milk	Length of lactation period	Gain over native does [1]	Dam-daughter pairs	Daughters higher than dams in f. c. m.[2]	
	Number	*Pounds*	*Percent*	*Pounds*	*Pounds*	*Days*	*Percent*	*Number*	*Number*	*Percent*
Native does	8	522.2	5.0	26.14	611.0	230	0	-------	-----	-----
½ Toggenburg	22	1,059.7	3.99	42.23	1,057.6	279	73	22	21	95
¾ Toggenburg	30	1,133.0	3.62	41.14	1,070.3	282	75	28	9	32
⅞ Toggenburg	27	1,319.4	3.61	47.60	1,241.7	288	103	26	21	81
15/16 Toggenburg	19	1,505.2	3.73	56.16	1,444.7	303	136	18	9	50
Above 15/16 Toggenburg	10	1,311.4	3.82	50.03	1,274.7	300	109	9	2	20
Purebred Toggenburg	22	1,488.7	3.76	55.96	1,436.7	293	135	16	10	63

[1] Gain is based on increase in production of fat-corrected milk. [2] Fat-corrected milk.

Marked increases in milk production were obtained from the top-cross does, the greatest increase occurring in the first generation. From the fourth top cross, does equaling the production of the purebred females were obtained.

A number of does in the station herd have made creditable records under the rules for advanced registry of the American Milk Goat Record Association, several being leaders in their respective classes. One of these, Val Verde's Zula 25467, has a record of 2,759.0 pounds of milk and 100.2 pounds of fat. Another, NMAC Mary Ann, a daughter of Val Verde's Zula, has a record of 2,570.4 pounds of milk

[9] This formula is as follows: f. c. m. (fat-corrected milk) = 0.4 m + 15 f. M represents weight of milk and f weight of fat. This formula expresses the energy produced by an animal in the form of milk and butterfat as an equivalent amount of 4-percent milk.

and 77.08 pounds of fat, while several others have records exceeding 2,500 pounds of milk and 90 pounds of fat. Two of these high-producing does, Laura Lorenzo 35768 and NMAC Amelita 35769, are twins.

During the course of the experiment at the New Mexico Station, line-breeding has been practiced to three outstanding bucks in an attempt to fix the desirable characteristics of the family from which these bucks came. The production of the inbred and outbred daughters from these males is shown in table 6.

Table 6.—*A comparison of inbred and outbred daughters from three outstanding sires in the New Mexico herd*

[1] Calculated by method of Wright (*33*). [2] American Milk Goat Record Association.

The effect of the inbreeding in general has been to lower slightly the milk production of the inbred does in comparison with the production of their dams, whereas the outcrossed daughters have exceeded their dams in milk production. In the production of butterfat, however, as measured by the percentage of butterfat in the milk, the inbred does did somewhat better than the outbred does. While it would appear from these results that close inbreeding is not a good practice for the average breeder of goats, it is to be hoped that experiment stations conducting breeding experiments with milk goats, and likewise some of the larger breeders, can practice some inbreeding in their herds.

Much experimental work on animals and plants has shown that inbreeding is a certain method for increasing the purity or homozygosity of inherited characteristics. If accompanied by rigid selection, good inbred strains may eventually be isolated. Individuals of these strains, because of their greater purity for certain desirable charac-

teristics, should have a greater chance to transmit these characteristics when outcrossed to unrelated goats, and they may be valuable parental material in other ways. It should be emphasized, however, that the use of close inbreeding for animal improvement is still in the experimental stages, and that it is not recommended for the average private breeder.

In addition to the studies on production, the New Mexico station has presented data on the length of the gestation period, on fertility and fecundity, and on the sex ratio.

A total of 144 gestation periods were recorded, 115 being for does over 18 months old and 29 for does under 18 months. The mean

Figure 3.—United States Department of Agriculture Saanen doe no. 412 with her quadruplet kids. Quadruplets are uncommon in milk goats, only 3 sets being recorded in a total of 617 parturitions in the Department herd. In the herd of the New Mexico Agricultural Experiment Station 4 sets of quadruplets have been recorded in a total of 144 parturitions. Instances of a larger number of kids at one parturition are very rare.

length of the gestation period for all does was 149.9 days, with a range from 136 to 157 days. For the younger does the range was from 136 to 154 days and for the older does from 139 to 157 days. The mean for both groups was 149.9 days.

Fertility in this herd was high. From 152 matings a total of 144 conceptions was secured; 127 of these were from single services, 13 from the second, 3 from the third, and 1 from the fourth service. From the 144 parturitions 286 kids were produced, the distribution of single and multiple births being as follows: Single, 40; twins, 70; triplets, 30; and quadruplets, 4. A somewhat higher proportion of multiple births was observed for the older does. A Saanen doe with quadruplet kids is shown in figure 3.

A preponderance of males was observed, the ratio of males to females being 115 to 100, for a total of 363 kids examined. This is a somewhat lower proportion of males than has been reported by other investigators.

Private Organizations Sponsoring Improvement

Promotion of the interests of milk-goat breeders in the United States has depended largely on various breed associations and on State and local organizations of breeders. Through the medium of exhibits at State and county fairs, and by advertising in various periodicals mostly devoted to the promotion of goats, much interest in milk goats has been created in many sections of the country.

At the present time three associations are registering goats—the American Milk Goat Record Association of Vincennes, Ind., the International Dairy Goat Record Association, at Lincoln, Nebr., and the American Goat Society, Inc., of Wayland, N. Y. Of these, the first mentioned is the oldest and largest. It was organized in 1903, and by the end of October 1936 had recorded 51,118 purebred and grade goats. The second association was organized in 1927 and had recorded a total of 2,323 purebred goats, while the third organization was established in 1935 and had registered 1,527 purebred animals by the end of October 1936.

The American Milk Goat Record Association has established an advanced registry and is sponsoring the testing of does for milk and butterfat production. Its requirements for advanced registration are comparable in some respects with those adopted by the various organizations promoting advanced registry of dairy cattle.[10] A total of 201 females have met the requirements for advanced registry—123 Toggenburg, 60 Saanen, 11 Nubian, and 7 native does. In 1936 the American Goat Society, Inc., established a herd-improvement registry for the purpose of obtaining individual production on each doe in the herds registered under this plan.

In addition to the registry associations there are many State and local societies that are promoting the milk-goat industry in various ways. Three papers—the Goat World, the Dairy Goat Journal, and the American Goat Herd—are devoted primarily to sponsoring the interests of milk-goat breeders.

Needs of the Future

Much progress has been made by some breeders of milk goats in improving their herds. While figures are not available on the aver-

[10] The advanced registry of the American Milk Goat Record Association has been divided into two divisions, one designated as class A and the other as class B. The division known as class A is divided into classes A, B, C, D, E, F, and G, depending on the age of the animal at the beginning of the test. In order to enter a doe in the 10-month, or class A division, it is necessary for the owner to weigh the milk from each individual milking and keep a proper record of the weights throughout the testing period. A copy of this record must be forwarded to the association at the end of each month. The doe must also be tested for a 24-hour period each month by a representative from the State agricultural college or experiment station, in order to determine the amount of fat in the milk. The testing period cannot exceed 10 months but may be for any period under this that the owner may desire, the tests commencing on the seventh day after parturition. However, a 2-year-old doe must produce at least 52 5 pounds of fat or 1,500 pounds of milk during the consecutive test period in order to be admitted to advanced registry. For each day that the doe exceeds 2 years at the beginning of the test, and up to 5 years, the required production is increased by 0.007 pound of fat or 0.2 pound of milk per day. No further increase is required for does older than 5 years. The class B, or short-time division, of the advanced registry requires that a doe produce an average of 10 pounds of milk during three 24-hour test periods, taken at least 30 days apart. This record to be supervised by three disinterested persons who make sworn statements in regard to the production. Bucks are entered in the advanced register when they have sired three advanced-registry daughters out of three different dams.

age production of milk goats in this country, certainly it is far below that of the better herds and probably below the average production of herds in such countries as Switzerland, where the goat plays a greater part in domestic economy than in the United States.

There can be no doubt of the need for improvement in the milk production of goats in the United States. While it is not to be expected that the goat will supplant the dairy cow to any great extent, there are sections of the country where good milk goats would contribute materially to the welfare of many families. The facts that a goat can be kept where it would be impossible to keep a cow and at the same time will supply sufficient milk for the average family, are features that seem to make goats suitable for families of low incomes living on small acreages in suburban districts, in mining districts, and in other areas where a good supply of milk is not available and the keeping of cows is impracticable.

In addition to milk production, attention should be given to improvement in the fat content of the milk, to increasing the average duration of lactation, to the improvement of fertility and the development of strains that will breed at any season.[11] Practically no attention has been given to these characteristics, all of which are important.

But improvement of the goat alone will not solve the problems of the industry as a commercial business. If an industry is to grow, it must have new or better markets for its products. Research is greatly needed to develop uses for goat products, and one of the chief activities of breed organizations should be to encourage research in this field. Among the problems that might well be studied are (1) the value of goats' milk for the feeding of infants, invalids, and persons allergic to cows' milk and its products, (2) its value for the making of cheese of various types, (3) methods for the preparation of condensed milk in order to make it more widely available, (4) the creation of a greater demand for goat meat, by advertising and the development of new and better recipes for its preparation, and (5) studies on the economics of production under various systems of farming.

The Part of the Breeder in Future Milk Goat Improvement

Future improvement in milk goats must come largely through the efforts of breeders. Fundamental research is needed to guide breeding efforts, but research of this kind will be undertaken only at the demand, and with the support and encouragement, of breeders. In addition, breeders can do much themselves to improve the goat. Practices that should be of general benefit would include:

1. The keeping of more complete records on milk and butterfat production, fertility, and fecundity of the goats in the breeding herd. Such records are vital to breed improvement, and the germ plasm survey conducted by the Department of Agriculture indicates that many prominent breeders have been lax in keeping such records.

2. The development of a more extensive record-of-performance program that will enroll the better breeders. Fortunately the foun-

[11] Most goats breed only during certain months of the year, generally from September to March. This fact provides a problem for the producer who has need for a continuous milk supply. A few investigators have given attention to the problem. It has been suggested that perhaps the most economical solution is the breeding of does that come in heat regularly throughout the year. To what extent such does occur is not known but it seems probable that such strains might be developed by the application of a proper breeding program.

dation for such a program has been laid and it should be encouraged to the fullest extent. Dairy breeders have made much progress in the use of record-of-performance tests and goat breeders can utilize many of these findings in the development of their own program.

3. The more extensive use of proved sires. It is well known that sires differ greatly in their ability to transmit inherited characteristics to their offspring. While the record of his ancestors furnishes some information about the value of a sire, the surest way of determining this is to study the records of his daughters. Once a sire has proved his ability to transmit desirable characteristics, provision should be made to use him to the fullest extent. Because of the wide distribution of goat breeders and the relatively small size of the herds, this will prove difficult in many cases. However, the need for the use of such sires is so great, if proper progress is to be made, that breeders and breed associations should make every effort to develop means whereby exchanges of such sires could be made between breeders.

4. The development of a better spirit of cooperation among breeders. Too frequently in the past there has been a tendency for the development of factions. This has resulted in tendencies for various groups in the industry to be working at cross-purposes. For instance, several breed associations have been established, each recording all breeds of milk goats. The result has been to lower the effectiveness of the breed associations in sponsoring breed promotion and improvement. It also makes it more difficult for the breeder to record his animals, especially if transfers from one association to the other are desired. With the relatively small number of purebred milk goats in the United States, one vigorous organization receiving the support of the whole industry certainly would seem to be sufficient.

5. Finally, more consideration needs to be given to the development of better procedures to guide breeders in the selection of breeding animals. Much information on the basic problems of animal breeding that should be of great use to goat breeders is contained in the 1936 Yearbook of Agriculture.[12]

The improvement of the milk goat, in common with the improvement of other species of livestock, is a large task that will require the best efforts of the breeder, the research worker, and all other interested agencies.

GENETIC STUDIES OF THE GOAT[13]

SINCE the improvement of goats has rested largely in the hands of private breeders and very few research agencies have had projects pertaining to goat husbandry in any form, genetic studies of this species have lagged. Nevertheless, some facts concerning the genetics of various characters have been reported, although most of the conclusions must be considered as tentative.

The inheritance of horns in goats has been studied by Lush (*14*) Warwick (*29*), Addington and Cunningham (*1*), Asdell and Crew (*3*), and Asdell and Smith (*4*). The evidence in each case strongly suggests that the polled and horned conditions constitute a pair of Mendelian characters, the horned condition being recessive and due

---

[12] See particularly pp. 119–206, 831–862, 907–923, and 997–1069.

[13] This section is written primarily for students and others professionally interested in genetics or breeding.

to a single recessive gene. In a few cases, however, individuals with scurs (imperfectly developed horns, usually without an attachment to the bone) were observed, but the data were too few to warrant an attempt to interpret the significance of the scurs. Muller (*18*) investigated the inheritance of the multihorned condition in goats but found that, while the character is inherited, the mode of inheritance was complex.

The mode of inheritance of wattles—sometimes called tassels—has been investigated by Asdell and Smith (*4*), Lush (*14*), and Addington and Cunningham (*1*). The evidence indicates that the wattled condition is dominant over the nonwattled condition and that one pair of genes is concerned. The exact manner of inheritance of the bearded condition has not been determined, but Asdell and Smith suggest that it is a sex-limited character dominant in the male and recessive in the female.

An inherited nervous instability of the goat has been reported by White and Plaskett (*32*), Hooper (*10*), and Lush (*15*). If suddenly frightened or surprised, goats with this affliction become rigid and the worst frightened usually fall. The spell usually lasts from 10 to 20 seconds. The animals recover the use of the muscles in the fore part of the body first, and on recovery often start moving away with the rear quarters dragging or very stiff. After being frightened once, the goats cannot be affected again, regardless of the extent of fright, until 20 to 30 minutes have elapsed. These goats apparently were quite unable to jump over obstacles of ordinary height. The mode of inheritance has not been determined.

The presence of short ears in the goat has been reported by Wassin (*31*) and Käb (*12*). Wassin suggests that one pair of genes is involved and that long ears are incompletely dominant. This would account for the three types of ears observed, the homozygous (*AA*) being long, the heterozygous (*Aa*) intermediate, and the recessive (*aa*) type being short. The short ears described by Käb, on the other hand, were dominant. In neither case, however, was the mode of inheritance definitely determined.

Much variability in color and marking occurs in the goat. The chief colors observed are white, brown, tan, red, roan, gray, black, fawn, and cream, but several other colors occur less frequently. Relatively little is known concerning the mode of inheritance of the various colors and the interactions of the genes concerned.[14]

Cryptorchidism (the condition in which one or both testes fail to descend into the scrotum) occurs quite commonly in the goat, and Warwick (*30*) and Lush, Jones, and Dameron (*16*) have shown that the condition is inherited, though the exact mode of inheritance has not been determined. At least two pairs of genes appear to be involved. Abnormalities of the reproductive system, which take the form of an intimate mixture of male and female parts belonging to the accessory

[14] Lush (*14*) considers that solid white, as found in the Saanen, is epistatic to all colors, this being in agreement with the opinion of Asdell and Smith (*4*). The latter, however, suggests that there is another type of white, a light cream, which may be due to an extreme type of spotting. Lush suggests that there is a tendency for black to be epistatic over nonblack and for extensive white spotting to be epistatic over nonspotting. Asdell and Smith, on the contrary, suggest that black may be the lowest term in an allelomorphic series of black, chocolate, fawn, and cream, the last color being dominant to all others. They suggest that brown is epistatic to all colors of the black series and, also, of the red and tan series, with the red and tan being hypostatic to the black series. Gray and roan appeared to be epistatic to the red and tan, and to the black series but hypostatic to brown.

sexual organs, are rather common in the goat, according to Crew (*7*). Since the abnormalities occur more frequently in some districts than in others, and because certain individuals in successive matings produce one of more of these intersexual offspring, it would seem that the condition is inherited. Nothing has been reported on the mode of inheritance.

Calder (*6*) has studied the incidence of multiple births in the goat and believes that prolificacy is a character controlled to some extent by genetic factors. The male appears to be equally influential with the female in transmitting the potentialities for multiple births. Calder suggests that most effective results will be obtained in selecting for prolificacy if due consideration is given to the prolificacy of both strains, and to the actual size of the litters from which the females and males are chosen.

HEREDITY IN THE DOG

W. M. DAWSON, Associate Animal Husbandman, Animal Husbandry Division, Bureau of Animal Industry

NO OTHER animal serves so many widely different purposes or has been so plastic in man's hands as the dog. Those characteristics by which dogs differ most from other domestic animals and which make them especially useful to man are largely of a psychological nature such as intelligence and willingness to cooperate. This can be especially appreciated by one who has watched a trained sheep dog working a quarter or half mile away from his master, yet obeying every signal that his master gives.

Partly because of their original inheritance and adaptability and partly because of the great variability that has resulted from centuries of selection, dogs today serve man as hunters, retrievers, guards, companions, aides in war, herders of livestock, police aides, guides, draft animals, entertainers in sports and shows, subjects in medical and scientific investigations, scavengers, fur bearers, and in case of necessity as food. Many of these uses can be subdivided and doubtless others might be given.

The range in size is so great that some animals in the largest breeds weigh 100 times as much as other normal individuals of the smallest breeds. An Irish Wolfhound standing on his hind legs can often look over the head of a tall man, while some full-grown Chihuahuas may stand comfortably on one's outstretched palm. Not only in size but in form, physique, temperament, aptitude, and intelligence there is great variation. Long, short, wide, narrow, tall, squat, slender, chunky, graceful, awkward, excitable, placid, robust, delicate, intelligent, stupid, friendly, savage, affectionate, self-contained, dignified, ridiculous, ugly, and beautiful are terms that might be aptly applied to different breeds and individuals. Figure 1 illustrates some of the wide variations in type.

In many of the breeds there is a so-called "standard" size, but there also may be a small or "toy" size, and sometimes a giant size. There are varieties with smooth, wire-haired, curly, long, stand-off, or corded coats.[1] Some breed standards permit all colors, others certain vari-

[1] A stand-off coat is a long profuse coat with the hair standing straight out from the body as in the Pomeranian and Chow. A corded coat is a coat of long curly hair matted together in the form of long ropelike cords as in the corded poodle.

Figure 1.—Variation in body form, type of coat, and color patterns as shown by some popular breeds of dogs in the United States. *A*, Pointer; *B*, German Shepherd; *C*, Toy Poodle; *D*, Bulldog; *E*, Dachshund; *F*, Pekingese; *G*, Cocker Spaniel; *H*, Chow; *I*, Scottish Terrier; *J*, Fox Terrier; *K*, Greyhound; *L*, St. Bernard. ations in color, and others only a single color or color pattern. Later in this article the causes for much of this variation will be discussed.

ORIGIN AND DOMESTICATION OF THE DOG

It is certain that doglike animals existed on the earth thousands of years ago. The origin of the dog (*Canis familiaris*), however, is not known. There is considerable speculation as to whether dogs originated from such present-day wild species as wolves, jackals, and dingoes, with which they will interbreed (fig. 2), or from other forms now extinct

Quite probably they trace to more than one of these sources. It has often been supposed that the fox, which has many doglike characteristics, was one of the ancestors of the dog. However, few, if any, authentic cases of successful crosses between these two species are known,[2] although numerous unsuccessful attempts to cross them have been reported. Accordingly, it appears improbable that the fox has played a very large part in the ancestry of our present dogs.

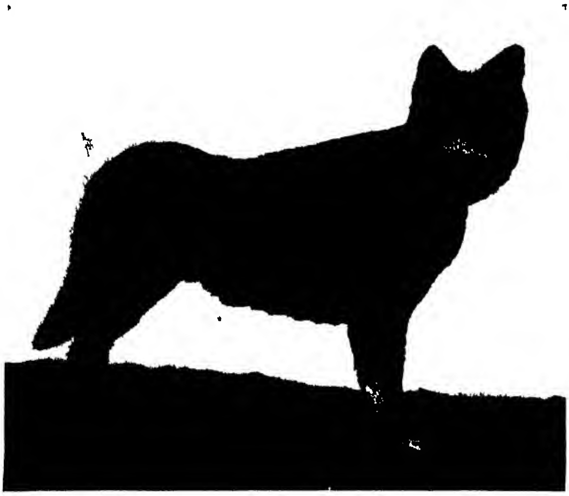

Figure 2.—Hybrid from a German Shepherd dog and a female wolf. (Photograph by courtesy of John Gans and Fachschaft für Deutsche Schaferhunde after von Stephanitz (54))

Students of the antiquity of the dog, Studer (*57*, *58*),[3] Breuil (*7*), Elliot (*15*), Osborn (*46*), Allen (*2*), von Stephanitz (*54*), and Clark (*10*) are agreed that dogs were domesticated before any of the other animals, but how long ago they do not know. In Europe bones of dogs have been found associated with the remains of men who invaded Europe at the close of the Paleolithic or Old Stone Age, and at the beginning of the Neolithic or New Stone Age. Since earlier remains of dogs have not been found in Europe, apparently they were brought to that continent by the pre-Neolithic peoples and were probably already partially domesticated, serving possibly as scavengers and guards and for food. This makes it seem probable that the dog was first domesticated in Asia at an even earlier date. Somewhat more recent evidence of domestication has been left us in the form of crude pictures carved by prehistoric man (fig. 3) showing dogs used in the chase (*8*, *35*).

Dogs as Farm Animals

Dogs have held an important place in agriculture and rural life for centuries. Probably they have been most important to the American farmer in guarding property, herding livestock, contributing to the sport and the larder of the master when he goes hunting, helping exterminate vermin, and as companions and pets. While it is impossible to estimate the value of these services, one can hardly imagine a cheaper or more efficient guard service for the farm than that furnished by a good watchdog, and if the same animal serves in other ways, as it often does, one can be sure that its value considerably exceeds the cost of keeping it. The value of dogs as companions, especially where people lead rather isolated lives, as they sometimes do in certain agricultural districts, is often underestimated. And what other animal gives the growing boy, either on the farm or in the city—or the growing girl, for that matter—as good an opportunity

Figure 3.—Prehistoric rock tracing representing reindeer, a horse in a boat, men, and dogs. Cut in the quartz at Massleberg, Skee Parish, Bohuslän. Height, 5 feet; width 12½ feet. (Courtesy of Cassell & Co., London, after Leighton (35).)

JUST *as some outstanding advances in other scientific fields—advances of very great value to humanity—have been made with the help of dogs, so their use in certain fields of genetic research seems to offer the most practical means of attacking some very important but difficult problems, notably those connected with the inheritance of psychological characteristics. Because they show so wide a range of intelligence, aptitudes, and temperament, and can be handled easily dogs appear to be better adapted to studies of this kind, especially with our present limited methods of measurement, than any other animal. Aside from the possibility of improving one of our most useful animals through such studies, there is the still more significant possibility of adding materially to knowledge of mammalian genetics, especially the inheritance of psychological traits—a field in which relatively little progress has been made.*

to learn self-control and consideration through the care and control of his pet?

According to an old saying, there is no good flock without a good shepherd and no good shepherd without a good dog. There are without doubt some exceptions to this, but there is no doubt that a trained herding dog is a great help and under some conditions indispensable in handling livestock. Many farmers enjoy hunting so that good hunting dogs are found on many farms. If one were to estimate the percentage of the 6,812,350 farms [4] in the United States that have at least one dog from the sample of which he has personal knowledge, it would certainly be very high

PRESENT STATUS OF GENETIC RESEARCH ON THE DOG

Although dogs have been domesticated for many centuries and have been successfully molded into many forms adapted to man's uses by the processes of heredity and selection, most of the breeds we know today have originated in comparatively recent time, and up to within a few years ago there had been very little, if any, breeding work with dogs that could be considered of a scientific nature.

However, there is a considerable store of scientific information concerning various aspects of the dog. Anatomists, physiologists, and psychologists have found the dog an excellent subject, especially in connection with medical research, for studying mammalian characteristics. In fact the diet, physiology, and temperament of dogs make them indispensable for certain types of experiment. Some of the outstanding advances in physiology, psychology, and medicine have been made with the help of dogs, as for example the work on conditioned reflexes by Pavlov (*48*) and much of the fundamental information on artificial respiration, and the control of diabetes and pernicious anemia (*9*)

In addition to the gain for humanity that has resulted from these experiments, dogs have been used, of course, in the study of their own disorders. The control of hookworm following the work of Hall (*19*) and of distemper resulting from the investigations of Dunkin and Laidlaw (*13*, *14*, *30*, *31*, *32*, *33*), who were provided with funds by the Field Distemper Council in Great Britain, has been made possible by the use of a relatively small number of dogs in the laboratory.

Although the results obtained in some of these researches indicate that the dog would serve as an excellent subject in the study of certain aspects of mammalian genetics, few systematic attempts have been made to obtain information on inheritance in this animal. However, many reports dealing with various aspects of the genetics of the dog have been published. The characters reported in these papers will be considered in this article in the following order: (1) Cytological (concerned with the chromosomes in the cell), (2) psychological, (3) morphological (concerned with form and structure), and (4) color.

Investigators are in disagreement as to the number of chromosomes in the dog. Thus Malone (*40*) has reported the number in the body cells as being 21 and 22 in the male and female, respectively; Minouchi, according to Oguma and Kakino (*44*), has reported 78 chromosomes in the body cells of both the male and the female; Painter (*47*)

[4] 1935 census figures.

has reported the number to be about 50, probably 52; while other investigators have found intermediate numbers (*29*).

Mental Characteristics and Temperament

In the study of mental characters psychologists have been able to measure various abilities of dogs such as the speed with which they form conditioned reflexes or immediate reactions to a given situation constantly repeated; their powers of discrimination with regard to visual objects and sounds of different kinds; their ability to make delayed responses to stimuli; and their ability to solve problems such as the opening of a box to get food or finding their way out of a maze or labyrinth. Since most such measurements are difficult to make accurately and require considerable time and expense, practically no information exists on the variation in these abilities among dogs of the various breeds and strains or on the mode of their inheritance.

Some information has been collected regarding the inheritance of certain aptitudes in dogs, as is shown in the appendix. For example, both Marchlewski (*41*) and Whitney (*64*) have reported that the aptitude for hunting with the head carried high appears to be dominant to the aptitude for hunting with the head carried low when certain strains or breeds of dogs are crossed. Although the list given seems impressive, it presents information on relatively few of the great variety of aptitudes possessed by dogs and most of the conclusions are based on a few observations only and have not been completely confirmed.

One of the best studies of temperament in dogs and the practical application of genetic principles to breeding dogs with superior abilities is that of Humphrey and his associates in producing and training dogs for leading the blind, and for police and army service, at Fortunate Fields, Switzerland (reported by Humphrey and Warner (*22*)). The tests used were largely subjective judgments by the trainers and while it was apparently impossible for them to determine the exact mode of inheritance of most of the characters, they were able by assuming that certain of these characters were largely controlled by a few major genes to make marked progress in producing superior animals.

Body Characteristics

In addition to mental traits, such body characters of the dog as conformation, functioning of internal organs, fertility, and resistance to disease play an important part in his usefulness. The body characteristics that have been studied genetically are listed in the appendix. Of particular interest in this connection is the work being carried on in this country by Stockard (*55*) and his associates at the Cornell University Medical College on the genetics of modified endocrine secretion and of associated form patterns—such as head shape—among dog breeds. (See the reported findings of Stockard and Vicari in the appendix.)

Although the color of the animal is a body character, it is so easily differentiated from other characters that it seems best to consider it separately. The third part of the list (p. 1337) gives the color characters in dogs for which information concerning the mode of inheritance has been reported.

On the whole, where more than one investigator has reported on the inheritance of a color factor, the results have been similar or the differences can be reasonably well accounted for. There appear to be marked similarities between color inheritance in dogs and that in rodents and in other carnivora (*18*), which makes some of the conclusions appear reasonable even where the evidence from dogs themselves is rather scant. No cases of proved linkage have been reported. There is, however, fairly good evidence that there are a number of allelomorphic (alternative) series of genes that affect color in the dog. These have been summarized briefly in table 2 in accordance with what seems to be the best evidence available. Some genes exhibit multiple effects, such as those caused by the gene for dominant irregular spotting, which in addition to affecting the coat color produces defective sight and hearing, frequently a reduction in general vigor, and sterility in the female (pp. 1333, 1936, and 1339).

Probably the greatest contribution of the science of genetics to practical breeding has been the formulation of a definite system of inheritance. This system furnishes the basis for a rational approach to breeding problems. However, at present it is difficult, for several reasons, to make specific recommendations on many practical problems confronting the dog breeder—the breeder's aims are extremely diversified; the dogs themselves exhibit such tremendous variations; there are not nearly enough known facts on inheritance in dogs to solve most of the problems of practical importance; and many practical men have not yet familiarized themselves with general genetic principles. (The discussion of these principles in introductory articles in this Yearbook will probably be found helpful in this connection.) This emphasizes the need for encouraging research on inheritance in dogs and for organizing breeders so that they can obtain information with regard to specific problems and can at the same time contribute to the knowledge of inheritance in dogs from their own records.

One method of encouraging improvement in the animals themselves would be to offer prizes at dog shows on the basis of the breeding record of an animal instead of almost wholly on the basis of its individual appearance or performance. Genetics has very definitely shown that in many instances the appearance of an animal is not a reliable basis for judging its value as a breeder. Its real breeding value depends on its ability to pass on desirable characters and combinations of desirable characters to its descendants. Because of the effect of dominant genes, the appearance of an animal may give no hint of the presence of recessive genes for quite opposite characters, more or less covered up by the dominants. Thus a short-legged dog may carry the gene for normal legs, which would show up in some of his descendants if they received the same recessive gene from the other parent. Similarly, a black dog may carry the gene for liver color. (See pp. 1334 and 1337.)

Not only individual genes but the particular combination of genes that an animal inherits also determines its appearance or performance. Since most animals are very mixed in their inheritance, they are capable of transmitting a large number of different combinations of genes to their offspring. For example, a dog of intense agouti or wild gray color without white spots may carry the genes for dilute coat color, for nonagouti, and for piebald white spotting. When this dog

was mated with an animal of similar mixed genetic composition, one would expect, if agouti, intense coat color, and absence of piebald white spotting are considered to be completely dominant,[5] to get puppies of eight different types so far as appearance is concerned, provided enough puppies are produced: (1) Intense agouti without white spots, (2) intense agouti with white spots, (3) intense nonagouti without white spots, (4) dilute agouti without white spots, (5) dilute agouti with white spots, (6) intense nonagouti with white spots, (7) dilute nonagouti without white spots, and (8) dilute nonagouti with white spots. These 8 types could represent as many as 27 different combinations of genes, considering only the characters mentioned. Examples of the effects of certain combinations of genes for color are given in the appendix (p. 1343). In many cases there are no data on the results to be expected from given combinations.

This illustrates the fact, well known to geneticists, that often the only way to judge what an animal does carry in its inheritance is by a sufficiently extensive progeny test.

Genetic studies indicate that color, type of hair, length of legs, form of head and body, and many other characters can be transferred from one breed to another by cross-breeding. It is undoubtedly by cross-breeding followed by selection that much of the variation in dogs has come about. New mutations—sudden changes in the germ plasm, later passed on in inheritance—were undoubtedly transmitted to different breeds by cross-breeding and greatly increased the number of types. The large number of types in turn allowed great leeway for selection and the development of still different forms. Many mutations are decidedly disadvantageous to the animals possessing them—so much so that under wild or primitive conditions they may not survive. Under the conditions of domestication, however, many of the mutant types not only survive, but may be superior for certain of man's uses. For example, certain inherited characters possessed by the Russian Wolfhound give him greater speed than the wolf so that he is useful for hunting wolves. On the other hand it is doubtful whether the Russian Wolfhound could compete successfully with the wolf in the wild state because he possesses certain other inherited characters that would put him at a disadvantage, such as a less well-developed sense of smell and a type of intelligence that is not quite so well adapted to self-preservation as that of the wild animal. Reports (*5, v. 1, p. 38*) of dogs that have returned to the wild state—feral dogs—indicate that their descendants are often wolflike in form.

MEASURING THE ABILITY OF DOGS IN COMPETITION

If one were to undertake a comprehensive genetic program on the inheritance of many of the characters that make dogs useful, a system of measurements of these characters would have to be worked out so that accurate comparisons could be made. At the present time dogs are used in competitive trials of various kinds, out of which certain measurements have been developed. Generally, however, these tests are of a sporting nature and chiefly measure the ability of the animal to win over its opponents under the particular conditions of the trial.

[5] Dominance probably would not be complete in all cases so that it might be possible to subdivide some of the phenotypic classes.

138904°—37——84

Often they measure several distinct characteristics. Thus a winning combination must generally include a strong desire on the part of the dog to succeed, excellent morphological and psychological adaptability, a high degree of coordination of physical and mental powers and often a high degree of intelligence, and perfect cooperation between the dog and his trainer or handler. While such things are often only crudely differentiated or measured in competitive trials, nevertheless, such trials have been a very important factor in the development of breeds especially suited to certain types of competition. The following brief descriptions are given to illustrate what has been done in this connection as well as because of their general interest to dog breeders.

Track and Sled Racing

Dog racing has been on the increase in the United States since the devising of a mechanical rabbit for the dogs to chase. The first track using this invention was opened in 1919 in California. In 1935 meets were held in Arizona, Arkansas, California, Florida, Massachusetts, Minnesota, New York, Ohio, Oregon, Pennsylvania, Texas, and Washington. American racing records taken from the All Sports Record Book (*42*) are given in table 1

Table 1.—*American racing records of Greyhounds*

Distance (mile)	Dog	Time	Place and date
		Seconds	
3/16	Kiowa	18½	Tulsa, Okla , 1920
¼	Damon Runyan	25	Miami, Fla , 1927
¼ [1]	Swift and Sure	26⅘	Milwaukee, Wis , 1927
Futurity [2]	Karl Kelly	28	New Orleans, La , 1927
Do [1]	Domestator	29⅗	West Jefferson, Ohio, 1931
5/16	Oh Boy	31⅖	Miami, Fla , 1924
⅜	Altcar Drain	38⅗	New Kensington, Pa , 1930
7/16	Midnight Joe	45⅗	Miami, Fla , 1925
½	Red Skipper	52⅕	Belmont, Calif , 1932

[1] Handicap [2] Futurity is 55 yards longer than ¼ of a mile

These records are not quite so fast as the best time reported for running horses on oval tracks—three-eighths of a mile in 33½ seconds, seven-sixteenths of a mile in 39 seconds, and one-half mile in 46⅕ seconds. Mick the Miller, a British dog, considered the world's fastest Greyhound, has a record of 600 yards (a little less than three-eighths of a mile) in 34 seconds, which compares very well with the best running-horse record for approximately the same distance. Perhaps a clearer idea of how fast this dog was traveling may be gained from stating the rate as an average of 36 miles per hour for a distance of 600 yards.

According to Menke (*42*), Mick the Miller is said to be the most intelligent of greyhounds and showed uncanny ability in getting clear of "jams" in the running of races, thus giving him undisputed passageway. From 1929 to the end of 1931 he won $50,000 in purses and numerous cups and trophies. He was 9 years old in 1935, retired and quartered at Walton-on-Thames for breeding purposes even though his exact ancestry was unknown. The increase of track racing in this country has resulted in the importation of thousands of Greyhounds

from England and Ireland and the crossing of these dogs with American Greyhounds.

Another form of racing requiring a very different type of dog is dog-sled racing. The most famous of these races are run in Canada and Alaska—for example, the Eastern International Dog Sled Derby run annually over a 120-mile course at Quebec; the Hudson Dog Sled Derby (generally called The Pas Derby) run over a 200-mile course from The Pas, Manitoba, to Flin Flon and return; and the All-Alaska Dog Race at Nome. Similar races have been run in New Hampshire, in upper New York State, and from Winnipeg, Manitoba, to St. Paul, Minn. As the races are run on scheduled dates regardless of the weather, there is considerable variation in the time required by the winning teams. Thus, over the 200-mile course at The Pas Derby the time has varied from 24 hours 51 minutes in 1922 to 37 hours in 1929. Alaska's Borden marathons run over a course of 26 miles 385 yards, has been won in time varying from 1 hour 50 minutes 27 seconds to 3 hours 35 minutes. Albert Campbell, a Cree Indian, drove his team of six dogs 522 miles in 118 hours 16 seconds to win the Red River International Derby from Winnipeg, Manitoba, to St. Paul, Minn. Rules governing the contests vary with regard to the number of dogs allowed per team, whether the race must be run in laps, and other points.

Because of their remarkable strength and endurance, Huskies have been very successful in these dog-sled races. These dogs are the result of crossing Eskimo dogs, which probably have considerable wolf inheritance, with such breeds as Great Dane, Newfoundland, or German Shepherd. It may well be that at least a part of their superiority in strength and endurance is an expression of hybrid vigor. Deerhounds have been used in recent years in crosses with the Eskimo dogs, but though the offspring are big, rugged animals, it is said that temperamentally they are more of a hunting-dog than of a sled-dog type and so are not such useful draft animals as some of the other cross-breds. Greyhounds are also said to have been tried in crosses with the Eskimo dogs. The offspring have superior speed but lack the ability to withstand the severe climatic conditions under which the sled races are often run. Today it is hard to find pure Eskimo dogs in the North as the Eskimos themselves prefer the stronger cross-breds.

Hunting and Herding Field Trials

Field trials for dogs are now widely held in the United States and in some other countries, notably England, to test the ability of bird dogs such as Setters and Pointers. These trials are actual hunting contests in which the dogs are scored by judges for their ability to locate the birds by scent, to point in the direction of the game, to hold the point until the hunter fires at or flushes the birds, to retrieve the game when crippled or killed, to cover a large area both rapidly and efficiently, and to demonstrate endurance, tractability, style, and perseverance. Generally the competition is divided into three classes, puppy, derby, and all-age, the division depending on the age of the dog. Contestants are run either singly or in pairs.

Similar trials are also being run for Retrievers and Spaniels. In these, the animals must work both on land and in the water and more

attention is paid to retrieving the game and less to pointing. Field trials with Foxhounds, Bloodhounds, and other types of sporting dogs, as well as ratters, are sometimes held, and there seems to be a growing interest in them.

One of the effects of these trials has been a decided tendency to develop two strains within some of the breeds involved, one being bred to meet the requirements of field trials and the other to meet bench-show requirements of the fancier or the standard set up by the breed association. In the first strain, mental aptitudes and physique are stressed, and in the second, body conformation and color. A good example of this is to be found in English Setters, in which the Llewellin strain has been very successful in the field, while the Laverack strain has been most noted on the bench.

The herding of sheep by dogs goes back to prehistoric times, though, of course, organized sheep dog trials such as are held today in a number of countries to determine the ability of the dogs in competition are of comparatively recent origin. In Germany organized trials were held about the beginning of the present century. In 1873 the first sheep dog trial was held in Wales. Since the World War, these trials have become very popular in Great Britain and are also held on a large scale in Australia. In the United States for the last 9 years a sheep dog contest has been held annually in New England and exhibitions are given at a number of fairs and livestock shows.

So far the trials in the United States have been of the type held in Great Britain. One dog is run at a time and is directed entirely with whistles and gestures by the master. Scores are given for the manner and style with which the dogs handle the sheep. Trials are held in a meadow, with the sheep being liberated at one end while the dog and shepherd enter at the other. The dog is then sent out to gather in the sheep, which he must bring to the shepherd. Then he must drive them through a number of hurdles and finally into a small pen in the open field. In some contests the dog is also required to cut out or "shed" a certain number of marked sheep from the flock. All of this must be done within a certain time limit, without hurrying the sheep, and always with complete obedience to the shepherd's commands.

Practically all the dogs entered in the contests in Great Britain or the United States are Border or Working Collies. These dogs generally have long black and white coats and are somewhat smaller than the Collies seen at dog shows. Their heads also are somewhat broader and shorter than those of the show Collies, which have been selected for long, flat, narrow-type skulls. Scotch and English shepherds train their dogs not to bite the sheep but only to bluff them, while in Germany, where the dog must often protect the crops from the sheep, the shepherds train the dogs to grip the sheep if necessary. Border Collies seldom bark, which is an advantage under the conditions prevailing where they ordinarily are used. In brush country, however, a barking dog can be heard by the sheep when he cannot be seen and is thus often more successful in his work than a quiet one. In some countries, the sheep must be protected from wolves and other wild animals so that large and powerful dogs are needed. Because of these differences in requirements and training, it is not to be expected that

the more than 40 varieties of herding dogs, including such varied breeds as the German Shepherd, Aftscharaka, Kelpi, Puli, Old English Sheepdog, Komondor, Bundas, Riesenschnauzer, etc., can compete satisfactorily in trials designed for the Border Collie alone.

In former years some breeds of dogs were bred to fight each other in the pit or arena or, as in bullbaiting, to fight a bull. This kind of competition has largely been outlawed, and the fighting breeds—Bull Terriers, Bulldogs, and Boxers—are now kept largely as companions and guards.

Some of the recent dog shows have been featuring a new type of contest called an obedience trial in which prizes are awarded on the obedience of each animal to a number of commands. Poodles have been outstandingly successful in these competitions.

Dog Shows

Of the organized competitive activities connected with dogs, the dog shows attract the most interest. In 1935 there were, according to Menke (*42*), 2,760 bench shows in the United States, with 200,000 entries and 1,000,000 paid admissions. No one knows how many dogs there are in the United States, though a rough estimate would be between 10,000,000 and 12,000,000. There were registered with the American Kennel Club in the single year of 1935, 72,000 dogs that were eligible for shows.

The largest dog show in the United States, the Westminster Dog Show held in Madison Square Garden, New York, N. Y., had a record in 1935 of 2,837 entries with 85 breeds represented. This was the fifty-ninth Westminster Dog Show held under the auspices of the American Kennel Club and it drew entries from all over the world.

As is the case with other domestic animals, the dogs that can win highest honors in competition either in field trials or bench shows, usually attract the breeders, and dogs that can transmit their ability to win soon become the foundation animals of a strain or breed. Thus the sires Gladstone and Count Noble, which produced 25 and 30 field-trial winners, respectively, are to be found in the ancestry of most field-type English Setters in the United States. Dog shows also have been one of the most potent influences on breeding in the last half century. By fostering the adoption of breed standards and the use of these in judging they have kept before dog breeders fairly definite aims to be attained. They have also been a most efficient medium for advertising those animals that, in the opinion of the judges, were the best in their respective breeds and have helped to spread information and interest in dog breeding. The standards, of course, have often been largely influenced by changing fashions and frequently have little or no relation to utility.

On the whole this use of bench-show or field-trial winners as breeders has made for progress, although the overwhelming emphasis on individual performance has also sometimes perpetuated and spread through the breeds defects carried by the foundation stock. The ideal condition for the progress of the breeds would be to place the emphasis on breeding records, which should include all the offspring of a given animal instead of the winners only or at best the offspring

without serious defects. Thus breeders would have a progeny test that would indicate the real genetic constitution of a given animal.

The American Kennel Club (*3*), under whose auspices most of the dog shows are held, included descriptions and standards of 102 breeds of dogs in their book Pure-Bred Dogs published in 1935. These breeds, together with their color, size, and principal uses, for the most part as given in Pure-Bred Dogs, have been listed in table 3. This table clearly indicates the variety of dogs in the United States. It is impossible, however, to give an adequate amount of detail, and for more complete information the readers should consult the American Kennel Club's publication.

POSSIBILITIES OF FURTHER GENETIC RESEARCH WITH DOGS

The improvement of dogs along certain practical lines by the use of a knowledge of inheritance appears to offer definite promise for the future. Thus the relative number of German Shepherd dogs that are suitable as guides for the blind or for police or army work can be greatly increased by means of selective breeding and the application of genetics as has been demonstrated at Fortunate Fields (*22*). Also, working ability can be successfully combined to a considerable extent with show form according to the results obtained by the same organization.

Superior hunting dogs may be bred for certain conditions as was done by Adametz (see Iljin (*25*)), who crossed English Pointers to German Pointers to produce a rapid-working dog that could stand the heat on the steppes of Moravia.

Improved physical and disciplinary traits can probably be secured from certain crosses. Iljin (*25*) states that in several regions of the Union of Soviet Socialist Republics German Shepherd dogs and Doberman Pinschers are crossed for that purpose.

The histories of a large number of the present breeds as given by the American Kennel Club (*3*) indicate that they originated from matings between animals of two or more breeds made purposely to combine certain desirable characteristics in one strain.

Doubtless many abnormalities or defects, such as cryptorchidism, cleft palate, reduced larynx, certain types of periodic eczema, etc., can be eradicated or controlled through breeding as indicated by the work of Koch (*28*). Studies on the inheritance of resistance to infectious diseases with other species of animals, as the mouse, rabbit, guinea pig, and chicken (see Hill (*20*) for a review of the subject) would indicate that it may be possible to develop strains of dogs with high resistance to certain of the infectious diseases, such as distemper.

In addition to the improvements that might be made in the dogs themselves, undoubtedly studies of the inheritance of various characters in dogs would aid in a better general understanding of mammalian genetics.

That dogs have been used extensively in anatomical, physiological, and psychological research, as already indicated, but to a very limited extent in genetic research is probably due to a number of reasons. (1) Research workers in the fields mentioned have been able to utilize dogs from city pounds and cheap animals of nondescript breeding,

whereas in making a genetic analysis a large number of animals would have to be produced from specific matings. (2) In studying the inheritance of certain characters, notably psychological traits, for the study of which dogs are especially good subjects, methods of measuring many of the characters must first be perfected before genetic studies will be very fruitful. In the last analysis, however, probably the principal reason why less attention has been paid to genetic research with the dog has been the feeling that results promising greater immediate economic gain were to be had in other fields.

Yet within a single species dogs show so wide a range of intelligence and temperament that they are better adapted for studies of the inheritance of these characters with the crude methods now available than other species in which the differences are less marked, such as guinea pigs, rats, mice, rabbits, and poultry. Dogs also reproduce with reasonable rapidity and would not be so expensive to maintain in sufficient numbers under laboratory conditions as horses, cattle, sheep, goats, and swine. Thus the use of dogs as subjects in certain fields of genetic research appears to offer the most practical means of attacking certain very important problems.

Figure 4.—Puli bitch. One of four animals of this breed recently imported by the United States Department of Agriculture from Hungary for use in studying the inheritance of intelligence and related characters in animals. The Puli has the reputation of being an exceptionally good herding dog in its native country. The most favored colors are white, cream, gray, and black. Dogs weigh about 30 pounds, bitches about 25 pounds.

The Bureau of Animal Industry has just initiated a project to study the inheritance of intelligence and associated characters in farm animals with especial reference to the influence of such characters upon performance and production. Dogs are being used in the early phases of these studies because they probably exhibit a greater range in temperament and in intelligence than most animals; different breeds have been developed for widely different purposes and some of them have important agricultural uses.

In this project dogs of several breeds of different temperament will be subjected to certain tests to determine the range and type of intelligence and their suitability for various purposes, especially for the herding of sheep. Crosses also will be made between breeds and similar tests will be made on the offspring of the first generation and later generations following the cross. One of the breeds being studied is the Puli. Four individuals of this breed (fig. 4) were recently imported

by the Department from Hungary. These dogs are noted in their native country for their sheep-herding ability. Studies on this breed and its hybrids from crosses with several other breeds are now under way.

From these experiments facts will be secured on (1) the degree to which intelligence is inherited, (2) the manner of its inheritance, and (3) the influence of intelligence, temperament, and certain other psychological traits upon certain special aptitudes of the dog. The experiments will also furnish fundamental information on the type of temperament and psychological traits that are needed in dogs for special purposes. Furthermore, information will be secured on the relation of various types of temperament to such things as feed utilization, appetite, management, and growth. The results obtained from these experiments are expected not only to furnish information on these functions in dogs but also to be of value in pointing the way for further investigations of this nature with other farm animals.

APPENDIX

CHARACTERS IN DOGS, THE INHERITANCE OF WHICH HAS BEEN STUDIED BY VARIOUS RESEARCH WORKERS [6]

Mental Aptitudes

Characters and breeds	Investigator
High head carriage of the English Pointer appears to be dominant to low head carriage of some strains of the German Pointers (a).[7]	Marchlewski (*41*).
High head carriage of bird dogs is dominant to low head carriage of Bloodhounds and Foxhounds (a).	Whitney (*64*).
Quiet style of hunting of the English Pointer appears to be dominant to the yelping style of some strains of the German Pointer (a).	Marchlewski (*41*).
Trail barking of hounds is dominant to still trailing of various breeds of mute trailers (a).	Whitney (*63*, *64*).

[6] It must be emphasized that many of the conclusions are tentative and that the phenotypic or outward expression of a character may in some cases differ decidedly as a result of differences in the environment or of various combinations and interactions of the gene or genes involved.
[7] Letters in parentheses indicate: (a) Author's statement, no data given, (b) conclusions drawn from small sample, (c) studbook records.

Mental Aptitudes—Continued

Characters and breeds	Investigator
Water-going propensity of the Newfoundland and bird dogs is dominant to lack of it in hounds (a).	Whitney (*64*).
Bird-hunting aptitude of bird dogs is imperfectly dominant to lack of it in hounds and other breeds (a).	Do.
Higher grades of pointing instinct appear to be incompletely dominant to lower grades in crosses of English Pointers and German Pointers (a).	Marchlewski (*41*).
The "backing" instinct is dependent on specific genes in crosses between English and German Pointers and strains of the same (a).	Do.
The active, almost nervous, temperament of the English Pointer is incompletely dominant to the more lethargic temperament of the German Pointer.	Adametz. (*See* Iljin (*25*).)
A factor inhibiting liveliness appears to be present in dogs. Thus the offspring of German Shepherd × Siberian are rarely lively. However, the situation is complicated as shown by the fact that the offspring of Doberman Pinscher × German Shepherd or of Doberman Pinscher × Airedale Terrier are often excitable (a).	Iljin (*25*).
Disposition showed a tendency toward segregation in the offspring from a cross of a very gentle and timid Old English Sheepdog to a playful aggressive Scotch Collie (b).	Gates (*16*).
Auditory undersensitiveness appears to be incompletely dominant to oversensitiveness in German Shepherd dogs. Probably more than one factor is involved.	Humphrey and Warner (*22*).
Tactual (body) undersensitiveness appears to be incompletely dominant to tactual oversensitiveness in German Shepherd dogs. Probably more than one factor is involved.	Do.
Both auditory and tactual sensitiveness appear to be associated with sex. Relatively more males are undersensitive and more females oversensitive than would be expected by chance.	Do.
Energy, distrust, willingness, and trailing willingness appear to be inherited, but evidence is not conclusive (a).	Do.

Body Characters Other than Color

Narrow pointed head of the sheep dog is dominant to the broad dished type of the Pointer (a).	Marchlewski (*41*).
Elongated type of head in the Greyhound is dominant to the Bulldog and Pug types of skull formation.	Stonhege and Wriedt. (*See* Marchlewski (*41*)).
Wide form of skull and lower jaw is dominant to narrow (as studied in the German Shepherd and crosses between the dog and the wolf) (a).	Iljin (*25*).
Head shape of the Boston Terrier and French Bulldog gives intermediate head shape when crossed with Dachshunds. Multiple factors are involved, some dominant and some recessive (a).	Stockard (*55*).
Head shape of English Bulldog is incompletely dominant to head shape of the Basset Hound (a).	Do.
"Brick"-shaped head of the Airedale Terrier is incompletely dominant to the type of the Doberman Pinscher (a).	Iljin (*25*).
Bulldog type of head is dominant to the head type of the Doberman Pinscher (a).	Do.
Short crown is dominant to long crown (a)	Do.
Head length shows intermediate type of inheritance (a)	Do.

Body Characters Other than Color—Continued

Characters and breeds	Investigator
The orbital angle [8] appears to be controlled by at least two factors in crosses between the German Shepherd dog and wolf. In the F_1 animals the angle is intermediate but closer to the dog type.	Iljin (*26*).
The form of the zygomatic process and maxillary angle (cheekbone and angle at its anterior end) appears to be controlled by at least two factors. Crosses were between the German Shepherd and the wolf. The F_1 animals were intermediate but closer to the wolf type.	Do.
Rotundity of the bullae ossea or ear bladders appears to be controlled by at least two factors in crosses between the German Shepherd dog and the wolf. The F_1's were intermediate.	Do.
Nonribbedness of the ear bladders appears to be controlled by at least two factors. Crosses between German Shepherd dog and wolf. F_1 intermediate but closer to wolf type.	Do.
Cheekbone breadth appears to be controlled by at least two factors. Blending type of inheritance.	Do.
Length of muzzle and head shape intermediate in offspring of normal-nozed Schnauzer-Dachshund × short-nosed Pekingese. Results from backcrosses indicate that the broad skull and greatly shortened muzzle of the Pekingese results from a single factor (b).	Wriedt (*67*).
Defective sight is associated with merle dilution (p. 1461) in the homozygous condition in Collies and with albinism in Pekingese	Mitchell (*43*); Pearson, Nettleship, and Usher (*49, pt. 2, pp. 460–520*).
Double nose is inherited apparently as an incomplete dominant in Siberians, Boxers, and Boxer × Bulldog (a).	Iljin (*25*).
Normal palate is a simple dominant to various types of cleft palate frequent in dogs with short skulls. The defect is due to a disturbance of the pituitary growth hormone (a).	Koch (*28*).
Normal larynx is dominant to reduction and narrowing of the larynx in Skye Terriers (a).	Do.
Pitch and timbre of the voice appear to be inherited, but there has been no analysis (a).	Iljin (*25*).
Yapping bark appears to be dominant to hound drawl (a).	Whitney (*63*).
Normal number of teeth is dominant to missing teeth in German Shepherds. Probably more than one factor is involved (a).	Humphrey and Warner (*22*).
Deafness is associated with homozygous merle dilution in Collies and with extreme white spotting in Great Danes and Bull Terriers.	Pearson, Nettleship, Usher (*49*); Mitchell (*43*).
Small ear size of Alsatian appears to be dominant to large ear size of the Pointer (a).	Marchlewski (*41*).
Triangular type of ear in English Pointer is dominant to the larger lobed type ear of the German Pointer (a).	Do.
Hanging or pendant ear carriage appears to be incompletely dominant to erect ears in Pointer × Alsatian and Ceylon Hairless × Dachshund.	Plate (*51*), Marchlewski (*41*).

[8] The angle formed by the intersection of a plane across the eye socket with a horizontal plane across the top of the skull.

Body Characters Other than Color—Continued

Characters and breeds	Investigator
Ear carriage appears to be generally due to three allelomorphs with the following relationships suggested: H^a semierect, H– lop, h– erect. H^a completely dominant to H or h. H incompletely dominant to h. H^aH^a – H^aH – H^ah – semierect Collie type. HH – lop. Hh – semierect. hh – erect.	Iljin (*25*).
There is also an independent semierect type of ear carriage as in the Russian Wolfhound, and an independent lop-eared type recessive to erect ear. No information is given on this last type (a).	Do.
Erect ear carriage seems to be partly dominant to faulty ear carriage in German Shepherds and probably depends on multiple factors (a).	Humphrey and Warner (*22*).
Narrow chest is dominant to broad chest (a)	Iljin (*25*).
Development of chest is intermediate in inheritance in crosses of English and German Pointers (a).	Marchlewski (*41*).
Dewlap in the German Pointer is dominant to lack of it in the English Pointer (a).	Do.
Body form in cross-breds from Doberman Pinscher × Rottweiler is intermediate.	Wriedt (*67*).
Body and trunk form of St. Bernard is dominant to that of Dachshund (b).	Lang (*34*).
Body and leg form showed segregation in a cross of Old English Sheepdog with Scotch Collie (b).	Gates (*16*).
Short tail or absence of tail is due to several factors apparently not related to sex (b).	Klodnitsky and Spett (*27*).
Short tail is dominant or incompletely dominant to long tail in Schipperkes, and Belgian or Brussels Griffons.	Iljin (*25*), Little (*38*).
Form and posture of the tail appear to be inherited in addition to length (a).	Iljin (*25*).
Homozygous short tail is lethal	Vilmorin. (*See* Wriedt (*66*)); Iljin (*25*).
Normal tail of Dachshund is dominant to screw tail of Boston Terrier or French Bulldog. Two factors appear to be involved (a).	Stockard (*55*).
Screw tail does not appear to be linked with bull-shaped head in crosses of the Boston Terrier or French Bulldog with Dachshund and in crosses of the English Bulldog with the Basset Hound (a).	Do.
Normal tail of the Basset Hound is a simple dominant over screw tail of English Bulldog (a).	Do.
Normal tail is a simple dominant to screw tail in the French Bulldog. Screw tail is apparently based on defective functioning of the growth hormone of the anterior lobe of the pituitary (a).	Koch (*28*).
Short legs of Dachshund, Basset Hound, Scottish Terrier, etc., are incompletely dominant to normal long legs of Saluki, Bull Terrier, French Bulldog, English Bulldog, Schnauzer, Fox Terrier, and other normal-legged breeds.	Lang (*34*); Stockard (*55*); Wriedt (*67*).
Catlike compact foot of the English Pointer appears to be incompletely dominant to open harelike foot of German Pointer (a).	Marchlewski (*41*).
Closed foot appears to be dominant to open foot in German Shepherd (a).	Humphrey and Warner (*22*).
Short foot appears to be dominant to long foot in German Shepherd (a).	Do.

Body Characters Other than Color—Continued

Characters and breeds	Investigator
Supernumerary (fifth) toe on the hind feet appears to be inherited in various breeds. Mode of inheritance has not been determined (a).	Iljin (*25*).
Short hair (S) is due to a single gene almost completely dominant to long hair (s) in the Newfoundland × Pointer, Belgian or Brussels Griffon, and Dachshund.	Lang (*34*); Anker (*4*); Iljin (*25*); Little (*38*).

Figure 5.—Haired and hairless Mexican dogs from the same litter. (Photograph by courtesy of the Journal of Heredity, after Stockdale (*1*).)

Rough or wire hair (R) appears to be due to a single gene incompletely dominant to smooth short hair (r) in Belgian or Brussels Griffons, Dachshunds, and Ceylon Hairless dog × Dachshund. The R series ($R-r$) interacts with the S series ($S-s$) to give the following phenotypes: RS and Rs=wire rS=short rs=long.	Plate (*51*); Anker (*4*); Iljin (*25*); Little (*38*).
In a cross of Old English Sheepdog with Scotch Collie, type of coat showed segregation with the additional appearance of short smooth coat. This indicates a more complex genetic basis for the inheritance of length of coat than shown above (b).	Gates (*16*).

Body Characters Other than Color—Continued

Characters and breeds	Investigator
Hairlessness (fig. 5) is due to a single gene incompletely dominant to normal hair in Mexican, Ceylon, African, and Egyptian hairless dogs and Ceylon Hairless × Dachshund. The gene appears to be lethal in the homozygous state and to be associated with defective teeth and often with a slender, greyhoundlike body conformation in the heterozygous individuals.	[Stockdale] (*1*); Plate (*51, 52*); Letard (*36*).
Cryptorchidism is inherited in many breeds. Normal descent of the testes is a simple dominant to cryptorchidism in breeds having pronounced head shortening and screw tail; apparently cryptorchidism is caused by defective functioning of the anterior lobe of the pituitary (a).	Koch (*28*).
Thyroid size is relatively larger in the offspring of Dachshund crossed to Boston Terrier than in either parent (a).	Vicari (*60*).
Relative size of thyroid in the German Shepherd is incompletely dominant to relative thyroid size of the Basset Hound (a).	Do.
Differences in structure of the thyroid found in various breeds appear to be inherited in Mendelian fashion (a).	Do.
The greater power of destruction of uric acid with the formation of allantoin found in most dogs appears to be dominant to the decreased ability reported in specimens of the Dalmatian breed (b).	Onslow (*45*).
Death of certain motor and sympathetic neurones in the lumbar region of the spinal cord causing weakness and paralysis of the hind legs and in the males chronic dilation of blood vessels to the erectile tissue appears to be caused by multiple genes. The hypothesis that three dominant genes must be present in order that the character be expressed is suggested by Stockard. This condition was observed by Stockard in crosses between St. Bernard and Great Dane, and between Bloodhound and Great Dane. It has been reported at times in purebred St. Bernards and Great Danes.	Stockard (*56*).
Estrual weakness [9] occurs as a dominant to its absence in many breeds of dogs. The defect is due to deficient functioning of the follicular hormone (a).	Koch (*28*).
One rut during the year is dominant to two ruts during the year in cross-breds from the wolf and dog (a).	Iljin (*26*).
A pleiotropic gene in the Dunker breed (dominant irregular spotting) affects color, eyes, general vigor, and the reproductive cycle in the female.	Wriedt (*66*).
Hypertrophy of the vaginal mucosa during heat, often leading to prolapse of the vagina, is probably dominant to the normal condition. It is especially frequent in families showing cryptorchidism and cleavage malformations and is apparently due to the imperfect functioning of the follicular hormone, the production of which is controlled by the sex hormone of the anterior lobe of the pituitary (a).	Koch (*28*).
Inherited periodic exzema is probably a simple dominant to its absence. Indications are that it is due to a thyroid disturbance (a).	Do.
Tendencies toward certain diseases, as cataract, whistling asthma, several forms of epilepsy, and recurrent inflammation of the eyes, appear to be inherited (a).	Iljin (*25*).

[9] The lack of readiness for copulation in the presence of normal morphological estrual phenomena.

Color Inheritance

Characters and breeds	Investigator
Color (C) appears to be a simple dominant to imperfect albinism (c^b) in the offspring of colored and albino Pekingese and in the progeny from albino Pekingese × black Pomeranians (Wright, using the data of Pearson, Nettleship, and Usher). Inconsistencies in the data are probably due to the interaction of other genes.	Pearson, Nettleship, and Usher (*49*); Wright (*68*); Pearson and Usher (*50*).
White coat with dark nose and eyes of white Pomeranian (c^d) appears to be a dominant allelomorph of partial albinism (c^b) (Cornaz albino, very pale grayish coat with pale-blue eyes appearing red in some lights) in the Pekingese (b).	Dawson (data from Pearson and Usher (*50*)).
The basic gene for color (C) is dominant to (c^r) which dilutes red to yellow (found in the Siberian) and to partial albinism (c^d) found in the Samoyede (a).	Iljin (*25*).
Intense color is incompletely dominant to a factor causing partial albinism (nearly white coat with grayish black nose and dark eyes) found in the Samoyede dog. In the heterozygous state recessive red is reduced to pale chamois while black is not affected (b).	Tjebbes and Wriedt (*59*), and data from Pearson and Usher (*50*).
Black (B) is a simple dominant to brown or liver (b) in Pointers, Cocker Spaniels, Dachshunds, Doberman Pinschers, Newfoundland × Pointer, and in crosses of wolf and German Shepherd dog.	Lang (*34*); Little (*37*); Barrows and Phillips (*6*); Wright (*68*); Anker (*4*); Iljin (*24*, *26*).
Yellow (A^Y), wild gray color (A) and black and tan spotting (a^t) appear to form an allelomorphic series. A^y restricts the distribution of black and is incompletely dominant over a^t. A^y and a^t are found in the Belgian or Brussels Griffon (b).	Little (*38*).
Sable is dominant to nonsable in Collies. It is due to a single gene (A^y) allelomorphic to the recessive bicolor or black and tan (a^t) and is in the agouti series. It is dominant to agouti or wild gray color (A) of the German Shepherd. Mitchell reports the following relationships: A^yA^y = clear yellow sable. A^ya^t = varies from almost a clear yellow to dark sable apparently governed by modifiers. A = agouti. A^ya = sable.	Mitchell (*43*).
Dominant black and tan (A^t), wild color (A), self-color (a), and recessive black and tan or liver and tan spotting (a^t) appear to form an allelomorphic series with dominance in the order given from crosses of Doberman Pinscher with a wolf, and Doberman Pinscher crossed to wild colored German Shepherds.	Iljin (*24*).
Wild gray, self-color, and black and tan appear to be present in an allelomorphic series in crosses of wolf and German Shepherd dog with dominance in the order given.	Iljin (*26*).
Dominant yellow and its allelomorph brindle are epistatic to all other color pigmentation except dominant black, common in Great Danes, sheep dogs, and certain breeds of terriers; also probably in the Bulldog and Mastiff, practically absent from breeds of Russian and French origin. (In the light of other evidence, it may be questioned whether dominant yellow and brindle are allelomorphs.)	Marchlewski (*41*).

138904°—37——85

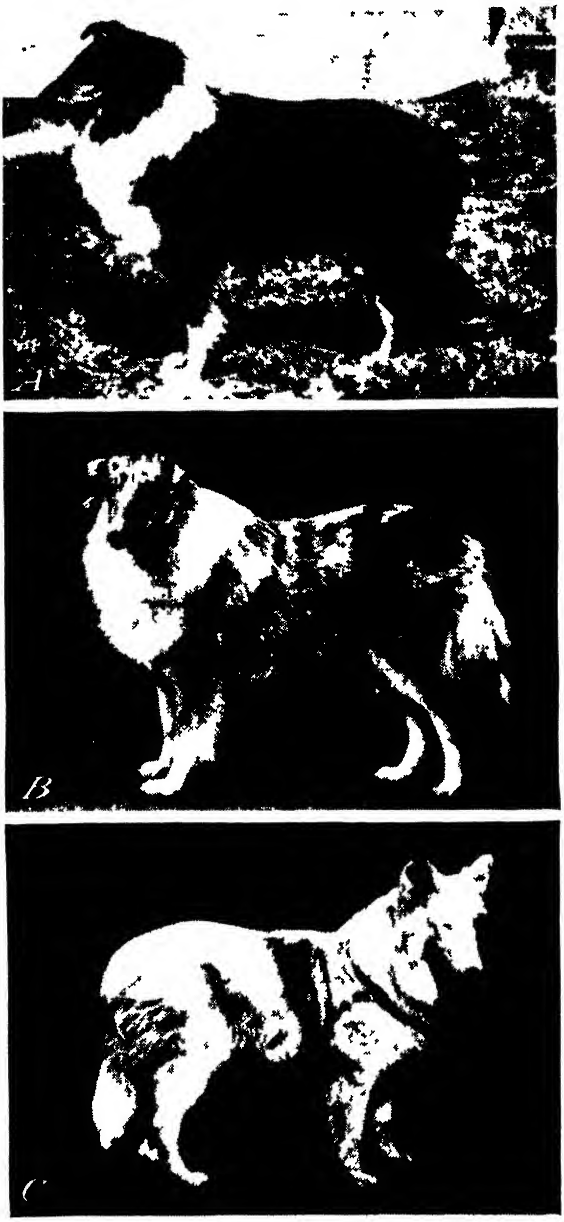
Color Inheritance—Continued

Characters and breeds	Investigator
Recessive black is hypostatic to dominant yellow but epistatic to brown (chocolate) and recessive yellow. It is also recessive to wild or wolf-gray color. Occurs in Irish Setters, Dachshunds, Liptaks, shepherd, and pastoral dogs (b).	Marchlewski (*41*).
Self-color (T)[10] is dominant to bicolor (black and tan) (t) in the Basset Hound and Dachshund. In combination with B=black and E=extension the (T–t) series gives: BET=self-black, BEt=black and tan. BeT =self-tan, red with black nose. Bet =red and lemon with black nose. Ibsen states bicolor is not in the agouti series but does not give evidence. (In the light of other evidence this may be questioned.)	Ibsen (*23*); Anker (*4*).
Solid color in incompletely dominant to bicolor (black and tan, brown and tan, red and lemon) in Cocker Spaniels, Doberman Pinschers, Collies, Gordon Setter × Irish Setter.	Barrows and Phillips (*6*); Iljin (*24*); Mitchell (*43*).
Dominant red is dominant to black and tan in Dachshunds.	Hagedoorn (*17*); Ibsen (*23*); Anker (*4*).
Yellow or red is epistatic to black and brown in Dachshunds.	Hagedoorn (*17*); Anker (*4*).
Red of Irish Terrier (probably (A^y)) is a simple dominant to black and tan of Fox Terrier or Welsh Terrier.	Hirschfeld (*21*).
Black and tan may be related to black in the following three ways: 1. The recessive factor by which it differs may be identical with factor by which red differs from black. A subsidiary factor is necessary to modify a red into black and tan. 2. Black and tan may be due to an allelomorph of the extension series. 3. Black and tan may be due to a factor independent of the extension series.	Wright (*68*).
Reddish brown (B) is epistatic to black (A) (except $AABb$=black) in Dachshunds and Ceylon Hairless crossed to Dachshund. Plate suggests the following: $AABB$=dark red. $AaBB$ and $aaBB$=light red. $AaBb$ and $aaBb$=yellow. $AABb$, $AAbb$ and $Aabb$=black. $aabb$=brown (c).	Plate (*51*); Anker (*4*).
Red appears to cover up the presence of agouti or "hare coloring" in the wire-haired Dachshund (c).	Anker (4).
Agouti is dominant to black and tan or brown and tan in the wire-haired Dachshund (c).	Do.
The more extensive tan markings in the Gordon Setter are partially dominant to the lesser tan markings (a).	Iljin (*25*).
Dominant black is epistatic to all other types of pigment formation and probably is an allel in the extension series. It is found in Pointers, Setters, Great Danes, Spaniels, and in some of the terriers, as the Fox Terrier (b).	Marchlewski (*41*).
Extension of black pigment (E) is dominant to restriction of black pigment; i. e., yellow (e) in Pointers (c).	Little (*37*).

[10] The symbol T used by Ibsen and Anker is not the same as that used in table 2 where bicolor is placed in the agouti series and T is used as the symbol for the ticking series.

Color Inheritance—Continued

Characters and breeds	Investigator
Black (E) is dominant to brindle (E^1) and to red or fawn (e). Brindle (E^1) is dominant to red or fawn (e) in Great Danes and Greyhounds. Little and Jones, and Warren suggest that they form a triple allelomorphic series (c).	Little and Jones (*39*); Dighton (*12*); Warren (*61*).
Brindling appears to be dominant to the lack of it in Irish Wolfhounds and Great Danes (c).	Darling and Gardner (*11*); Little and Jones (*39*).
Black or liver is a simple dominant to red (*ee*) (a)	Wright (*68*).
Black appears to be dominant to tan or red in the Doberman Pinscher.	Iljin (*24*).
Black and liver are dominant to recessive yellow present in Pointers, and frequently in English Setters (a).	Marchlewski (*41*).
Dirty-white belt, yellow-brown belt of medium intensity, and bright-yellow belt in wild gray hair appear to be determined by triple allelomorphic genes in crosses of the wolf and German Shepherd dog. Dominance tends to be in the order given but is very weak between the first two.	Iljin (*26*).
Grayish-white dappling, light-yellow dappling, red dappling, appear to be present in an allelomorphic series in crosses of wolf and German Shepherd dog. Dominance is in the order given.	Iljin (*26*).
Intense coat color is a simple dominant to a factor diluting black coat color to blue and red to fawn or lemon in Cocker Spaniels, Great Danes, Doberman Pinschers, and Greyhounds. In Greyhounds, Warren found some evidence indicating the factor diluting red was not the same as the one diluting black.	Barrows and Phillips (*6*); Little and Jones (*39*); Dighton (*12*); Warren (*61*); Iljin (*24*).
The rough hair gene appears to dilute the coat colors, especially yellow, in Belgian or Brussels Griffons.	Little (*38*).
Intense pigmentation of hair, ball of foot, claws, and skin in hairless dogs (D) is incompletely dominant to dilute pigmentation of same (d) in crosses of the Ceylon Hairless dog × the Dachshund.	Plate (*51*).
Dominant irregular white spotting harlequin pattern, often associated with wall eye and in extreme white individuals with deafness, is reported to be a simple dominant to the absence of such spotting in Cocker Spaniels, Great Danes, Old English Sheepdogs, Dalmatians, and possibly Bull Terriers. Though reported as a dominant, most individuals affected appear to be heterozygous. Iljin reports that this spotting pattern does not show when present in yellow or lemon hounds.	Pearson, Nettleship and Usher (*49*); Barrows and Phillips (*6*); Wright (*68*); Little and Jones (*39*); Wriedt (*65*); Marchlewski (*41*); Iljin (*25*); Humphrey and Warner (*22*); Mitchell (*43*).
Dominant irregular spotting (merle dilution—fig. 6) often associated with wall eye is reported to be due to a single gene dominant to the absence of such spotting in the merle Collie, dappled Dachshund, and Norwegian Dunker Hound. In the heterozygous condition it produces irregular dark spots on a lighter pigmented ground color. With yellow or sable animals, however, its presence is often difficult to detect unless it has affected the eyes. In the homozygous condition it produces pale-gray or yellow spots on a white coat and generally defective sight and hearing. Mitchell suggests the above pattern is produced by the same gene as the harlequin pattern except that in the latter case there is an independent modifying gene which dilutes the ground color to white.	Wriedt (*65*); Anker (*4*); Mitchell (*43*).



Collies showing the effects of the genes *V–v* for dominant spotting (merle dilution): *A*, Normal black and tan Collie (*vv*); *B*, blue merle Collie (*Vv*), which happens to have both eyes normal, but often one or both eyes will be wholly or partly of a pale bluish-white color—"wall-eyed"; *C*, merle Collie with defective sight and hearing (*VV*). Since blue merles or sable merles are mixed (*Vv*), they will not breed true when mated together. (Photographs by courtesy of the Journal of Heredity, after Mitchell (43).)

Figure 6.

Color Inheritance—Continued

Characters and breeds	Investigator
Self-color (S) is dominant to piebald white spotting (s) in hounds, sheep dogs, Doberman Pinschers, Great Danes, Cocker Spaniels, Newfoundland×Pointer, Ceylon Hairless×Dachshund, Airedale×Fox Terrier, and wolf×German Shepherd dog. It appears to be subject to modifying genes causing it to range from a very little white on the coat to practically entirely white animals. The lesser degrees of piebald white spotting appear to be dominant to the greater degrees. Haldane attributes this variation to three allelomorphic factors, s_1, s_2, and s_4. Wriedt suggests Ss animals are generally solid color except for small white markings on chest and toes.	Lang (*34*); Wright (*68*); Little and Jones (*39*); Wriedt (*65*); Plate (*51*); Warren (*61*); Haldane (*18*); Marchlewski (*41*); Iljin (*24, 25, 26*); Hirschfeld (*21*); Mitchell (*43*).
Self-color with white on chest and toes completely dominant over markings in Newfoundland×Pointer.	Lang (*34*).
Dominant white (W) is dominant to color (w). It occurs in the Russian Shepherd and sometimes in the Siberian (a).	Iljin (*25*).
Colored coat (W^1) appears to be a simple dominant to white coat (w^1) in Collies. Heterozygous animals (W^1w^1) often have more prominent white markings than those free of the factor. These white Collies have dark eyes and nose. As a rule there is some color on the head (a).	Mitchell (*43*).
Tricolor is caused by a combination of black and tan (bicolor, a^t) and piebald white spotting (s) in hounds and Collies.	Ibsen (*23*); Wright (*68*); Mitchell (*43*).
Pigmented point in the midst of a white area on top of the head usually dividing the pigmented auricular regions behaves as a dominant to the lack of it in Pointers (a).	Marchlewski (*41*).
Self-color of ear appears to be dominant to white spots on the ear. In the heterozygous condition there are a few white hairs on the ear (a).	Do.
Ticking or roan (fig. 7) is a simple dominant to the lack of it in Cocker Spaniels, Setters, Pointers, and Foxhounds. It does not show except on white, and heavier grades appear to be dominant to the lighter grades.	Barrows and Phillips (*6*); Wright (*68*); Whitney (*62*); Marchlewski (*41*).
Nonsilvering appears to be a simple dominant to silvering in Doberman Pinscher (a).	Iljin (*24*).
Eye color showed segregation in a cross of a dark brown-eyed Old English Sheepdog with a light brown-eyed Scotch Collie with the additional appearance of "wall eye."	Gates (*16*).
Dark eyes appear to be dominant to lighter colored ones in Cocker Spaniels and German Shepherds (a).	Barrows and Phillips (*6*); Humphrey and Warner (*22*).
Brown or yellow eyes (Y) appear to be dominant to blue eyes (y) (a).	Iljin (*25*).
Normal eyes (P) appear to be dominant to ruby eyes (p^r) (a).	Do.
Wall eye is associated with merle dilution in Collies, Old English Sheepdogs, Shetland Sheepdogs, Dappled Dachshunds, and Norwegian Dunker Hounds, and with irregular black and white spotting in harlequin Great Danes, Dalmatians, and Bull Terriers.	Gates (*16*); Pearson, Nettleship, and Usher (*49*), Anker (*4*); Wriedt (*65*); Mitchell (*43*).
The nose is always the same color as the footpads in Cocker Spaniels.	Barrows and Phillips (*6*).
The colors (black, blue, red, fawn, white, brindle, or white spotting) do not appear to be linked with sex in Greyhounds.	Warren (*61*).
None of the colors appear to be linked with sex in the Dachshund.	Anker (*4*).

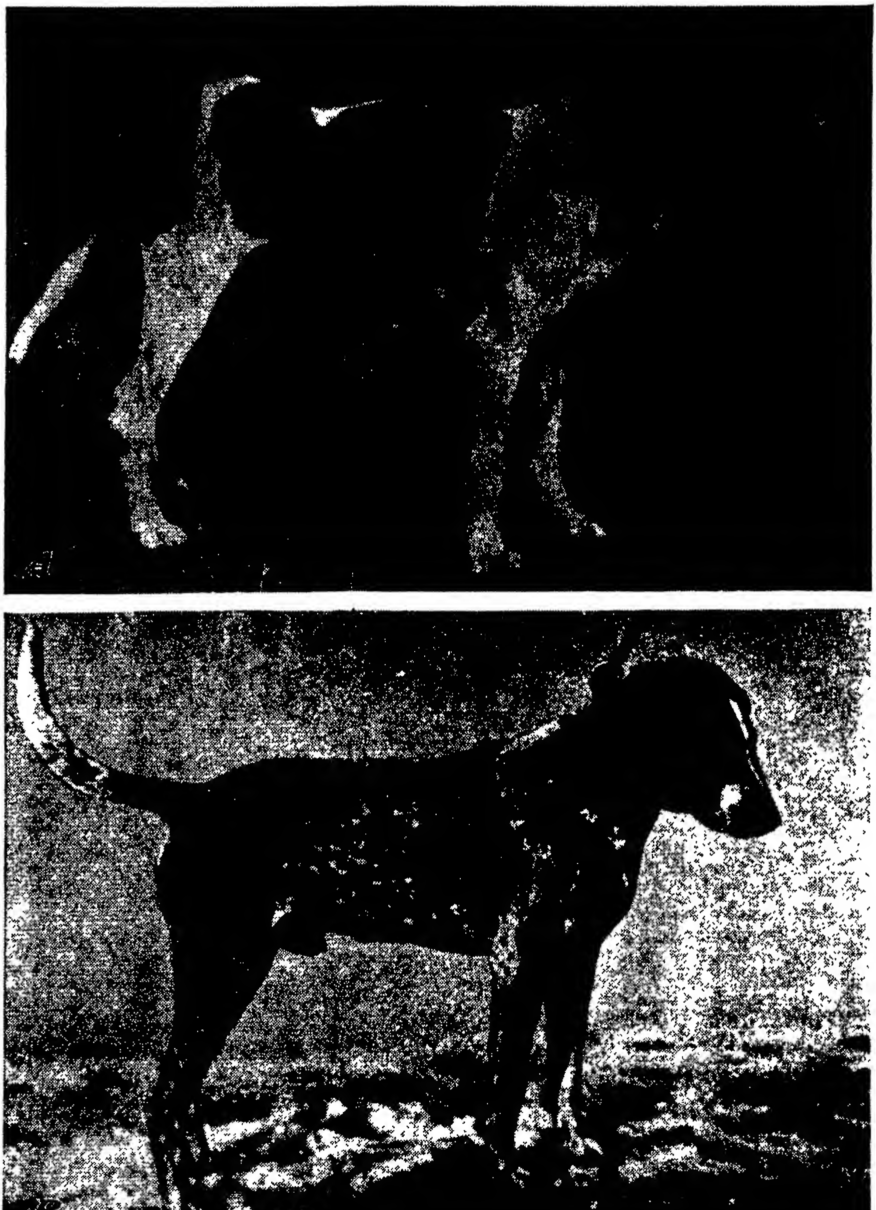


Figure 7.—Foxhounds showing the absence and presence of ticking, colored hairs intermingled with white hairs on those portions of the body that would otherwise be white: *A*, Foxhound bitch without ticking (*tt*); *B*, Foxhound dog with ticking (*Tt*). Eight of the fifteen offspring from the above animals were ticked. (Photographs by courtesy of the Journal of Heredity, after Whitney (*62*).)

TABLE 2.—*Allelomorphic color series in the dog* [1]

Series	Gene symbol	Phenotypic effect
C	C	Basic factor for color.
	c^r	Dilutes red to yellow (found in Siberians) may be Cc^d.
	c^a	Partial albinism, white coat, dark eyes and nose as in Samoyede and white Pomeranian.
	c^b	Partial albinism, slightly colored coat, blue eyes appearing red in reflected light, albino Pekingese.
B	B	Factor for black.
	b	Dilutes black of coat to chocolate or coffee brown and also dilutes nose and eye color.
A	A^y	Dominant yellow or sable.
	A	Wild gray, agouti.
	a	Self-color, black or nonagouti.
	a^t	Bicolor, black and tan, liver and tan, red and yellow.
E	E^D	Dominant black.
	E	Normal extension of black pigment.
	e^p	Partial extension of black pigment (brindle).
	e	Nonextension of black pigment, red or recessive yellow.
I	I	Dirty-white belts in wild gray hair.
	i^m	Yellow-brown (medium intensity) belts in wild-gray hair.
	i	Clear-yellow (intense) broad belts in wild gray hair.
I_1	I_1	Gray-white dapples.[2]
	i_1^m	Light-yellow dapples.[2]
	i_1	Red dapples.[2]
D	D	Intense color.
	d	Dilutes black to blue and possibly red to fawn or yellow.
V	V	Dominant spotting dilutes the coat and often the eye, nose, and footpads except for irregular pigmented areas, as in the merle Collie and harlequin Great Dane (apparently effected by modifiers).
	v	Self-color (in the absence of other genes for spotting).
S	S	Self or solid color.
	s	Piebald white markings (there may be other allels in this series).
W'	W'	Dominant white in Russian Shepherd dog and sometimes in the Siberian.
	w'	Colored.
W	W	Colored.
	w	White coat as found in Collies (possibly is an allelomorph of S or s with a modifier).
T	T	Ticking or roaning on white (there may be other allels in this series).
	t	Lack of ticking or roaning.
S_i	S_i	Nonsilvering.
	s_i	Silvering.
Y	Y	Brown or yellow eye color.
	y	Blue eye color.
P	P	Normal eye (greenish reflection).
	p^r	Ruby eye (red reflection).

[1] In general dominance within the series is in the order given. There is a divergence of opinion and lack of certainty with regard to the existence of some of the above genes and also with regard to the allelomorphic relationships (see list (pp. 1331-1341) and discussion in the text). The symbols have been changed in some cases from those used by the original investigator.

[2] Possibly the same as the I series; the different phenotypic effect may be due to different gene combinations.

FORMULAS FOR SOME OF THE MOST COMMON COLORS AND COLOR PATTERNS IN WORKING DOGS (HOMOZYGOUS INDIVIDUALS) [11]

Genetic formula	Phenotypic appearance
$CCAABBDDEESS$	Wild gray.
$CCaaBBDDEESS$	Black.
$CCaabbDDEESS$	Liver.
$CCaaBBddEESS$	Blue.
$CCaaBBDDe^pe^pSS$	Brindle.
$CCaaBBDDeeSS$ $CCAABBDDeeSS$	Yellow, black nose.
$CCaabbDDeeSS$	Yellow, brown, or light colored nose.
$CCa^ta^tBBDDEESS$	Black with tan markings.
$CCa^ta^tbbDDEESS$	Liver with tan markings.
$CCa^ta^tBBddEESS$	Blue with tan markings.
$CCaaBBDDEEss$	Black with white spots.
$CCaabbDDEEss$	Liver with white spots.
And generally c^dc^d W'	White—Thus c^dc^d and W' are epistatic to, or cover up the action of the other genes given.

[11] From Iljin (25) with slight modifications. He included in working dogs the following breeds: Doberman Pinscher, German Shepherd, Airedale Terrier, Rottweiler, Giant Schnauzer, Boxer, Siberian, shepherd dog of southern part of the Union of Soviet Socialist Republics. Because of the phenomenon of dominance, heterozygous individuals will often appear similar to homozygous ones; however, segregation may show up among the offspring of the former. Since there are many genes affecting color, animals heterozygous for at least some of them are quite common even among purebred dogs.

TABLE 3.—*Color, weight, and most important uses of breeds of dogs recognized by the American Kennel Club* [1]

GROUP 1, SPORTING DOGS

Breed	Principal colors	Weight		Principal uses
		Males	Females	
		Pounds	*Pounds*	
Wire-haired Pointing Griffon.	Steel gray with chestnut splashes. Gray white with chestnut splashes. Dirty white mixed with chestnut. Never black.	About 56	About 56	Pointing game birds; retrieving.
Pointer	White with liver, black, or lemon markings, solid black or liver.	50–55	45–50	Pointing and retrieving game birds; companions.
Short-haired German Pointer.	Solid liver, liver and white spotted, liver and white spotted and ticked, liver and white ticked.	55–70	45–60	Pointing and retrieving game birds, including ducks; trailing; companions.
Chesapeake Bay Retriever.	Dead-grass color, dark brown to faded tan.	65–75	55–65	Retrieving, especially ducks.
Curly-coated Retriever.	Black or liver	60–70	60–70	Retrieving game, land or water.
Flat-coated Retriever.	do	60–70	60–70	Do.
Golden Retriever.	Rich golden	65–68	55–60	Do.
Labrador Retriever.	Generally black	55–65	55–65	Retrieving and gun dogs.
English Setter	Black, white and tan, black and white, blue belton,[2] lemon and white, lemon belton, orange belton, liver and white, liver belton, solid white.	55–70	50–65	Pointing and retrieving game birds; companions.
Gordon Setter	Black with tan markings	About 70	About 70	Do.
Irish Setter	Golden chestnut or mahogany red.	50–65	40–55	Do.
Brittany Spaniel	Liver and white or orange and white. Often with roan ticking.	([3])	([3])	Pointing and retrieving.
Clumber Spaniel	Lemon and white, orange and white.	55–65	35–50	Finding game, especially birds; retrieving.
Cocker Spaniel	Solid black, red, or liver. Above colors with white on chest.	18–24	18–24	Finding game, especially birds in heavy cover; retrieving; companions.
English Springer Spaniel.	Any color except red and white, and lemon and white.	Average 45	Average 42	Finding and springing game, especially birds; retrieving.
Field Spaniel	Solid black, liver, golden liver, mahogany red, roan, or the above with tan over the eyes and on cheeks, feet, and pasterns.	35–50	35–50	Finding game, especially birds; retrieving.
Irish Water Spaniel.	Deep pure liver without white.	About 60	About 60	Retrieving ducks.
Sussex Spaniel	Rich golden liver	35–45	35–45	Finding game, especially birds in heavy cover.
Welsh Springer Spaniel.	Dark rich red and white	33–40	33–40	Finding game, especially birds in rough country with heavy cover; retrievers; companions.

[1] For more complete descriptions and histories of the various breeds see the American Kennel Club (3) from which most of this information was taken. An approximate weight to give the reader some idea of the size of the breed has been added, where possible, for those breeds having no official weight range in the breed standard. Dogs of all breeds are used as companions to at least some extent, even though that use is not listed for each breed in the table. The group classification is that used by the American Kennell Club. It is realized that in some respects this classification is not consistent with respect to the uses and characters of certain breeds. However, it would be difficult to make a classification that would not be subject to similar criticism, also the above classification appears to meet the needs of breeders fairly well.

[2] The belton color is produced by an intermingling of colored and white hairs in the coat.

[3] No published weights.

Table 3.—*Color, weight, and most important uses of breeds of dogs recognized by the American Kennel Club*—Continued

GROUP 2. SPORTING DOGS (HOUNDS)

Breed	Principal colors	Weight		Principal uses
		Males	Females	
		Pounds	*Pounds*	
Afghan Hound	Black and tan, black, golden	About 60	About 60	Coursing jack rabbits; in its native country, hunting gazelle and leopard.
Basset Hound	Generally black, tan or white, or a combination of these.	25–40	25–40	Hunting foxes, rabbits, and pheasants; trailing in dense cover.
Beagle	Black, tan, black and tan, black and white, tan and white, black and tan and white.	(3)	(3)	Hunting individually, or in packs for hare, rabbit, and drag hunting.
Bloodhound	Black and tan, red and tan, tawny, sometimes with small amounts of white.	90	80	Trailing criminals and hunting for lost persons and articles.
Dachshund, 3 varieties—smooth or short-haired; wire-haired; long-haired.	Solid red (tan) of various shades, black with tan points, chocolate with tan points.	5–35	5–35	Companions; hunting rabbits; in their native country hunting badger.
Scottish Deerhound.	Dark blue gray, darker and lighter grays, brindles, yellow and sandy red, red and fawn.	85–110	75–95	Hunting wolves, coyotes, rabbits; formerly for hunting deer in Scotland; companions.
American Foxhound.	Black, tan, black and tan, black and white, tan and white, black and tan and white, often ticked.	50–60	50–60	Fox hunting; drag hunting; used singly or in packs.
English Foxhound.	Black, tan, black and tan, black and white, tan and white, black and tan and white.	60–80	60–80	Fox hunting; drag hunting; generally in packs.
Greyhound	Black, blue, brindle, red, fawn, white and above colors with white.	65–70	60–65	Coursing hare and jack rabbits; racing.
Harrier	Black, tan, black and tan, black and white, tan and white, black and tan and white, sometimes of a blue mottled color.	About 56	About 56	Hunting hare and drag hunting.
Norwegian Elkhound.	Gray with black tips to the long covering hairs, somewhat lighter on under part of body.	About 60	About 60	Hunting big game; companions.
Otterhound	Blue and white, grizzle or sandy, black and tan.	Up to 65	Up to 65	Companions; formerly for hunting otter in England.
Saluki	Cream, fawn, red, grizzle and tan, black and tan, white and chestnut, tricolor (black, white and tan), solid black.	About 70	About 70	Coursing; hurdle racing; companions.
Whippet	Black, blue, red, white, fawn, gray, brindle, and combination of these with white.	10–28, average 20.	10–28, average 20.	Racing; coursing rabbits; companions.
Irish Wolfhound	Gray, brindle, red, black, pure white, fawn.	Minimum 120	Minimum 120	Running and killing coyotes and wolves; guards; companions.
Russian Wolfhound.	White usually predominating marked with lemon, tan, brindle, gray, or black.	75–105	55–90	Hunting wolves; coursing hare; companions.

[3] No published weights.

TABLE 3.—*Color, weight, and most important uses of breeds of dogs recognized by the American Kennel Club*—Continued

GROUP 3. WORKING DOGS

Breed	Principal colors	Weight		Principal uses
		Males	Females	
		Pounds	*Pounds*	
Alaskan Malamute.	Wolfish gray or black and white. Caplike or masklike marking on face.	65–85	50–70	Sledge dogs; dog-sled racing.
Belgian Sheepdog.	Long-haired variety, black. Short-haired variety, brindled fawn with black, mask.	About 53	About 53	Herding sheep; police and army service.
Bouviers de Flandre.	From fawn to black through pepper and salt, gray and brindle.	(3)	(3)	Farm dog; watchdog; police and army service.
Boxer	Fawn and brindle with mask, white with black, fawn or brindle markings.	About 50	About 50	Guards and watchdogs; police work; companions; formerly dog fighting and bull baiting.
Briard	Black, black with some white hairs, dark and light gray, tawny, and combinations of gray and tawny.	(3)	(3)	Sheep and guard dogs; police and army service.
Bull-Mastiff	Any shade of fawn or brindle.	115	100	Guards and watchdogs.
Collie (rough)	Black and tan with white frill and collar, sable with white markings, white, blue merle.	60	50	Herding or driving livestock; companions.
Collie (smooth)	Black and tan with white markings, sable with white markings.	60	50	Do.
Doberman Pinscher.	Black, brown, or blue with rust-red sharply defined markings.	65	75	Guards; watchdogs; police and army service.
Eskimo	Black, white, black and white, wolf gray, blue gray, all shades of tan or buff and all combinations of these colors.	65–85	50–70	Draft and pack service, especially on ice and snow; hunting in the Arctic.
German Shepherd.	Various shades of gray, black, black and tan, brindle, brown, white marking permitted.	About 55	About 55	Herding livestock; police and army service; watchdogs; guides for the blind.
Great Dane	Brindled, fawn, blue, black, harlequin.	120–160	100–130	Guards; companions; originally for hunting large game.
Great Pyrenees	White or principally white with markings of badger, gray, or tan.	100–125	90–115	Guards and companions; used for guarding flocks and for pack and draft service in the Pyrenees Mountains.
Kuvasz	Pure white	(3)	(3)	Guards and companions.
Mastiff	Silver fawn or dark fawn brindle, with muzzle, ears, and nose black.	About 170	About 170	Guards and companions; formerly for fighting (dog fighting, bull baiting, bear baiting, etc.).
Newfoundland	Dull jet black, white and black or bronze.	140–150	110–120	Water dogs; formerly for carrying life lines from stranded vessels; guards; companions.
Old English Sheepdog.	Gray, grizzle, blue or blue merled, with or without white markings in varying amounts.	About 65	About 65	Herding cattle or sheep; watchdogs; companions.
Rottweiler	Black with tan or brown markings.	(3)	(3)	Driving livestock; pulling carts; guards; police service.

3 No published weights.

GROUP 3. WORKING DOGS—Continued

Breed	Principal colors	Weight		Principal uses
		Males	Females	
		Pounds	*Pounds*	
Samoyede	Pure white, white and biscuit, cream.	About 45	About 45	Watchdogs; companions; sledge dogs and herding reindeer in Siberia.
Giant Schnauzer	Pepper and salt colored or similar equal mixtures, pure black or black and tan.	(3)	(3)	Police service; guards; formerly cattle driving.
Shetland Sheepdog.	Sable, black, blue, merle, marked with varying amounts of white and tan.	7-10	7-10	Watchdogs; sheep herding; companions.
Siberian Husky	White, black, gray, with white and black markings.	54-64	44-54	Sled dogs.
St. Bernard	Red, light or dark brindle, with white markings.	170-210	160-190	Guards; companions; rescue work at the Hospice of St. Bernard.
Welsh Corgis (Cardigan).	Red (sable, fawn, or golden), brindle, black and tan, black and white, blue merles.	18-25	15-22	Watchdogs; companions; driving cattle.
Welsh Corgis (Pembroke).	Any color other than pure white.	20-24	18-22	Companions.

GROUP 4. TERRIERS

Breed	Principal colors	Males	Females	Principal uses
Airedale Terrier	Head and ears tan, except for dark markings on each side of the skull, legs up to thighs and elbows tan; body, black or dark grizzle.	40-45	About 40	Guards; hunting; herding livestock; police and army service; companions.
Bedlington Terrier.	Dark blue, blue and tan, liver, liver and tan, sandy, sandy and tan.	24	22	Pets; formerly used on badgers, foxes, otter, etc.
Border Terrier	Red wheaten, grizzle and tan, or blue and tan.	13-15½	11½-14	Sporting terrier; bolting foxes.
Bull Terrier	White	12-60; average, 50.	12-60; average, 45.	Guards and companions; formerly for dog fighting.
Cairn Terrier	Any color except white, dark muzzle, ears and tail tip desirable.	14	13	Pets; killing vermin; formerly for bolting otter, foxes, and vermin.
Dandy Dinmont Terrier.	Pepper or mustard (dark bluish black to light silvery gray or reddish brown to pale fawn).	14-24	14-24	Watchdogs; companions; hunting and killing vermin.
Smooth and Wire-haired Fox Terrier.	Predominately white, black, tan or black and tan markings.	14-18	14-16	Watchdogs; companions; hunting and killing vermin; originally for bolting foxes.
Irish Terrier	Bright red, red wheaten, golden red.	27	25	Companions; hunting small game and vermin; house dogs; army service.
Kerry Blue Terrier.	Light to dark blue	33-38	32-36	Watchdogs; companions; hunting; shepherd dogs.
Lakeland Terrier	Blue, blue and tan, black and tan, red, mustard, wheaten, grizzle and black.	Not over 17	Not over 16	Watchdogs; companions; hunting small game.
Lhassa Terrier	Golden, sandy, honey dark grizzle, slate, smoke particolor, black, white or brown, dark tips to ears and beard an asset.	About 14	About 14	Watchdogs; companions; and pets.

[3] No published weights.

GROUP 4. TERRIERS—Continued

Breed	Principal colors	Weight		Principal uses
		Males	Females	
		Pounds	*Pounds*	
Manchester Terrier.	Black and tan	14-22	14-22	Pets; companions; hunting and killing vermin.
Miniature Schnauzers.	Pepper and salt or similar equal mixtures, light or dark, including red pepper, pure black, black and tan.	15	12	Do.
Standard Schnauzers.	All pepper-and-salt colored or similar mixtures; pure black or black and tan.	About 28	About 28	Watchdogs; companions; hunting and killing vermin.
Scottish Terrier	Steel or iron gray, brindled or grizzled, black, sandy, or wheaten.	18-20	18-20	Pets; companions; originally for bolting foxes and other vermin.
Sealyham Terrier	All white or with lemon, tan or badger markings on head and ears.	21	20	Pets; companions; originally for hunting fox, otter, and badger underground.
Skye Terrier	Dark or light blue, or gray or fawn with black points.	16-20	14-18	Pets; formerly for bolting foxes.
Welsh Terrier	Black and tan or black grizzle and tan.	20	20	Companions; hunting fox; otter; badger and small game.
West Highland White Terrier.	Pure white	15-19	13-17	Companions; hunting vermin.

GROUP 5. TOY DOGS

Breed	Principal colors	Males	Females	Principal uses
Chihuahua, short and long coated.	Any color, solid or marked or spashed.	1-6	1-6	Pets; ratters.
English Toy Spaniel:				
King Charles or Black and Tan.	Black with tan markings	9-12	9-12	Pets and companions.
Ruby	Chestnut red	9-12	9-12	Do.
Blenheim	White with bright rich chestnut or ruby red markings, evenly distributed in large patches, spot on forehead.	9-12	9-12	Do.
Prince Charles or Tricolor.	White with black and tan markings.	9-12	9-12	Do.
Griffon:				
Brussels (wirehaired).	Reddish brown, a little black at whiskers and chin.	Small-sized, not over 7; large-sized, not over 12.	Small-sized, not over 7; large-sized, not over 12.	Do.
Belgian (wirehaired).	Black and reddish brown mixed black mask and whiskers.	do	do	Do.
Brabancons (smooth-coated).	Reddish brown, black with reddish brown markings.	do	do	Do.
Italian Greyhound.	All shades of fawn, red, mouse, blue, cream and white.	Lightweight, 8 and under; heavyweight, over 8.	Lightweight, 8 and under, heavyweight, 8 and over.	Do.
Japanese Spaniel	Black and white, all shades of red and white.	Lightweight, 7 and under; heavyweight, over 7.	Lightweight, 7 and under; heavyweight, over 7.	Do.
Maltese	Pure white	Not over 7; under 3, ideal.	Not over 7; under 3, ideal.	Do.

GROUP 5. TOY DOGS—Continued

Breed	Principal colors	Weight		Principal uses
		Males	Females	
		Pounds	*Pounds*	
Mexican Hairless	Skin generally slatey gray, sometimes mottled with flesh-colored spots.	About 14	About 14	Pets and companions.
Pappillon	Unicolor—any pure color. Two-colored—any color, with white. Tricolored—any two colors with white.	Less than 9	Less than 9	Do.
Pekingese	Red, fawn, black, black and tan, sable, bridle, white and particolor well defined, black masks and spectacles desired.	Maximum 14	Maximum 14	Do.
Pinscher (miniature).	Lustrous black with tan, rust red or lemon markings, solid yellow, solid red or stag red, solid brown or brown with red or yellow markings, solid blue or blue toned with red or yellow markings.	5–10	5–10	Do.
Pomeranian	Black, brown, chocolate, red, orange, cream, orange sable, wolf sable, beaver, blue, white, and particolors.	Lightweight, not exceeding 7; heavyweight, over 7.	Lightweight, not exceeding 7; heavyweight, over 7.	Pets; companions; watchdogs.
Pug	Silver or apricot fawn, with dark mask, black.	14–18	14–18	Companions.
Toy Manchester Terrier or Toy Black and Tan Terrier.	Jet black with rich mahogany tan markings.	About 7	About 7	Pets; companions; ratters.
Toy Poodle	Any solid color	Under 12	Under 12	Pets; companions; trick dogs.
Yorkshire Terrier	Dark steel blue with tan markings.	$2\frac{3}{4}$–13	$2\frac{3}{4}$–13	Pets and companions.

GROUP 6, NONSPORTING DOGS

Breed	Principal colors	Males	Females	Principal uses
Boston Terrier	Brindle with white markings, black with white markings.	Lightweight, under 15; mediumweight, 15–20; heavyweight, 20–25.	Lightweight, under 15; mediumweight, 15–20; heavyweight, 20–25.	Companions.
Bulldog	Red brindle, other brindles, solid white, solid red, fawn, or fallow, piebald.	50	40	Companions; guards; formerly for dog fighting and bull baiting.
Chow Chow	Any clear color, usually red, black, or blue.	55–60	55–60	Companions, pets and guard dogs. In China as sporting dogs.
Dalmatian	Ground color, pure white with small black or liver-colored spots scattered over the entire animal.	35–50	35–50	Companions, sport, formerly as coach dogs.
French Bulldog	All brindle, fawn, white, brindle and white.	Lightweight, under 22; heavyweight, 22–28.	Lightweight, under 22; heavyweight, 22–28.	Companions and watchdogs.
Keeshonden	Wolf gray	About 40	About 40	Do.
Poodle	Any solid or even color	Large, over 20; miniature, 12–20.	Large, over 20; miniature, 12–20.	Companions, pets, trick dogs, retrieving, watchdogs.
Schipperke	Solid black	Up to 18	Up to 18	Watchdogs, ratters, pets, and companions.

THE BREEDING OF TURKEYS

STANLEY J. MARSDEN, Associate Poultry Husbandman,
CHARLES W. KNOX, Senior Poultry Geneticist,
Bureau of Animal Industry

THE chief problems of the turkey industry in its rapid development in the past have centered around feeding, management, and disease control. While advances have been made in these fields there is much yet to be learned, for new problems continue to arise. Breeding problems have received less study up to the present, partly because they have been crowded out by these other considerations, and partly because the turkey stocks of the United States have in a great measure fulfilled their purpose, which was to produce a superior meat product.

PRESENT NEEDS IN TURKEY BREEDING

BUT this situation will not necessarily hold forever and today both breeders and scientists are beginning to think about turkey-breeding problems. From the standpoint of the geneticist and the practical breeder, the desirable breeding objectives today might be summed up as follows:

1. The production of smaller size strains of turkeys to meet the growing demand for a family-size bird.
2. The improvement of body type to provide a higher proportion of edible meat, especially on legs and breast.
3. Early maturity in reaching market condition.
4. Higher egg production.
5. Higher fertility and hatchability.
6. Greater viability—that is, a lower mortality rate from various causes, including disease.

Constructive breeding methods can and should play an important part in reducing costs by considering these six objectives.

The breeding achievements of the past have consisted mainly of the production of color variations, a substantial increase in body weight and egg production, and a reduction in the length of legs and neck.

At present, for reasons that will be discussed later, there is a definite trend toward breeding a smaller, more efficient, more rapidly growing turkey. The main objective is a live bird weighing approximately 7½ to 10 pounds as a young hen or 11 to 15 pounds as a young tom, to meet the increasing popular demand for a well-matured small turkey. It might be thought that this demand could be supplied by selling turkeys at an early age when they average 8 to 15 pounds in weight. However, turkeys at this weight are continuing their rapid growth and they have too much "framework" and too little flesh. The real

object in breeding is to develop a small turkey that will be as plump and well grown as present-day turkeys are at Thanksgiving or Christmas time. A young tom of the small type is shown in figure 1.

The mortality of growing turkeys is a pressing problem and it is one that the breeder can materially assist in solving Turkey breeders, especially those that trap-nest their stock, can decrease these losses to a considerable extent by breeding from large families and from families whose progeny have had comparatively little mortality.

Figure 1 —A young small-type turkey tom, the second-generation product of a Bronze-White Holland cross. At 24 weeks of age this bird weighed 13 5 pounds, had a broad well-meated breast, and graded U. S. Prime. His keel measured 6 2 inches long and his shank 7.1 inches.

Egg production is an important factor in determining profit or loss in turkey-breeding work Turkey eggs are sold for hatching purposes by the producer for 10 to 50 cents each, depending on locality and breeding. Hence any increase in egg production will help profits considerably because it results in lowering the overhead and feed costs of producing hatching eggs In addition, turkeys are seasonal producers of eggs. They lay at a fair rate in the Northern and Central States from about the latter part of March to

NOTABLE *progress, based on scientific research, has been made in controlling that major menace to turkey growing, the blackhead disease. Less attention has been paid to breeding problems. Today the turkey industry would gain by a breeding program based on production records, pedigrees, and progeny testing, like that which has meant so much to progressive breeders of chickens. There is a great need for turkey breeders willing to initiate trap-nesting and pedigreeing, and possessed of the knowledge necessary to isolate superior families and breed from them. State and Federal stations might well lead the way by developing strains notable for certain characteristics of major importance.*

about the first of July. The use of electric lights has helped in getting birds to start laying in January, so that the laying season is extended to approximately 6 months. However, egg production in commercial quantities is still confined to about 6 months of the year, and this means that fresh-killed roasting turkeys must also be a seasonal product unless turkeys can be bred to lay throughout the year. This situation is partially remedied by cold storage, which makes a limited supply of frozen turkeys available at times when there is no fresh stock and

Figure 2.—Trap-nesting—the first step in the pedigree breeding of turkeys.

permits a large turkey crop to be marketed in the fall in an orderly manner without a serious price depression.

The greatest drawback to breeding for high egg production and the other desirable characteristics is the lack of a program based on production records, pedigrees, and progeny testing. Such a program has meant much to progressive breeders of chickens. Here the State and Federal experiment stations can lead the way by developing strains of high-producing turkeys with good viability, quick maturity, and good market quality. The greatest need of the industry today is for a number of breeders who are informed concerning the practices involved in selection and breeding and who are willing to initiate trap-nesting and pedigreeing and, on the basis of the information so obtained, to isolate superior families and breed from them. This is an essential step in the production of a superior strain. Two of the steps involved in the pedigree breeding of turkeys are shown in figures 2 and 3.

THE STATUS OF TURKEY GROWING AS AN INDUSTRY

Turkey raising has been increasing since about 1920 in the United States and now ranks as a 50,000,000-dollar industry. The interest in turkey raising has increased rapidly since that time. It was stimulated by a better knowledge of feeding and more effective control of the disease known as blackhead. The annual loss due to blackhead still amounts to approximately $5,000,000 a year, or 10 percent of the total gross income. In the past, often entire flocks of young turkeys were lost from this disease.

Figure 3.—The final step in the pedigreeing of turkey poults—banding the birds as they are taken from the pedigree baskets.

On January 1, 1920, the census showed 3,627,028 turkeys on 670,834 farms held as breeders after the marketing season. On January 1, 1935, the number had increased to 5,381,912 on 676,114 farms, which is 9.9 percent of all the farms in the United States. The leading States according to the number of turkeys kept were Texas, California, Minnesota, North Dakota, and Oklahoma.

The 1930 census was the first to record the number of turkeys raised rather than the number on farms on January 1. According to this census, there were 16,794,485 turkeys raised in the United States, most of them as a side line to other farm enterprises. The distribution and number of turkeys raised on farms in 1929 is indicated in figure 4. The number of turkeys raised in 1936 has been estimated by the Bureau of Agricultural Economics to exceed 20,000,000—an increase of at least 20 percent over the 1930 figures. There was little increase, however, in the number of farms keeping turkeys. In some localities, turkey raising has reached such proportions as to be a major full-time enterprise, and a great many commercial flocks are large enough to demand the time of one or more persons throughout the year. The largest turkey farm was reported to have produced approximately 50,000 turkeys in 1 year.

New Opportunities Through the Control of Blackhead

From a production standpoint, the opportunities in commercial turkey raising are more promising now than formerly, largely because of improved methods of management that aid in the control of blackhead and other filth-borne diseases.

138904°—37——86

Beginning late in the nineteenth century, blackhead invaded one district after another, traveling from east to west with the extension of the turkey industry, until nearly all of the turkey-growing areas became infested with it. It was this disease that ruined turkey growing in the East and Midwest and by 1920 threatened to ruin it everywhere. In the early eighties production per year amounted to

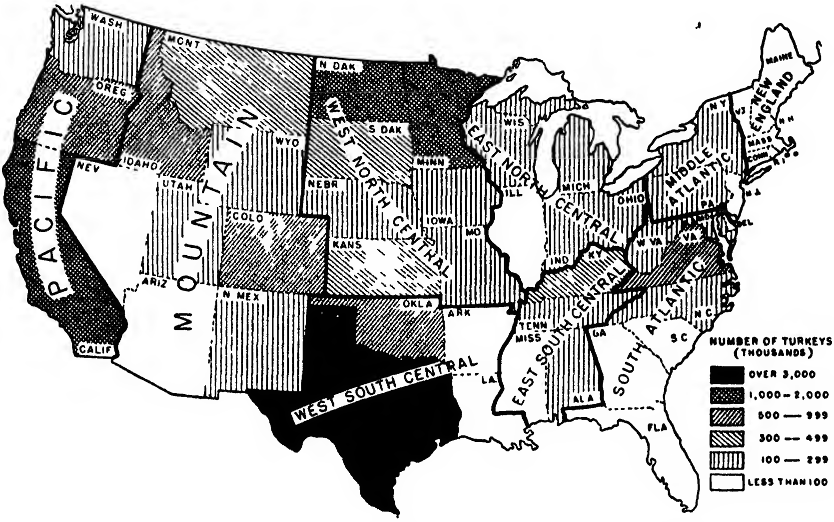

Figure 4.—Number of turkeys raised, by States, in 1929.

one bird for the average American family of about 5 persons, but by 1920 this had been reduced to approximately one bird for 15 persons. Since that time more adequate methods of controlling blackhead have been largely responsible for the increase to approximately one turkey for 6.5 persons. The new knowledge of sanitation and management as it affects the control of blackhead has meant a gradual return of turkey production to the East and Midwest and its firm establishment on a more profitable basis in all sections of the country except the Southeastern States.

MODERN TURKEYS AND THEIR WILD ANCESTORS

Turkeys are now classified by zoologists as a separate family, Meleagrididae, of the order Galliformes, or fowllike birds. In this family there are two genera now living—*Agriocharis*, the ocellated turkey of Yucatan (fig. 5), and *Meleagris*, the North American or common turkey. These genera contain only one species each.

The ocellated or Yucatan turkey (*Agriocharis ocellata*) is confined to the Yucatan Peninsula of Mexico and the adjoining territory, where it dwells in the tropical forests. Its flesh is considered a delicacy. It is smaller than the common turkey, lacks the breast tuft, is brighter colored, has two fleshy appendages on the head instead of one, and has eyed or ocellated tail feathers, from which it takes its name. So far as

is known, it has never been domesticated although natural crossing with the common turkey has been reported. In striking beauty the plumage of the ocellated turkey rivals that of the peacock. The plumage pattern is similar to that of the Bronze turkey although the colors are different. The general effect is green and black with a coppery red iridescence. The large wing feathers of the male are distinctly barred, almost exactly as in the Bronze, while those of the female are indistinctly barred. The head and neck of the ocellated turkey are described as blue, studded with orange warts. The eggs are brown and spotted like those of *Meleagris* but smaller.

Figure 5.—The ocellated turkey (*Agriocharis ocellata*) (male).

Five subspecies (races or varieties) of North American wild turkeys have been described. They interbreed freely with each other and with domesticated turkeys. Table 1 contains a brief description of these subspecies.

TABLE 1.—*Brief description of North American wild turkeys*

Subspecies	Original range	Color description
Meleagris gallopavo gallopavo Linnaeus, the Mexican turkey	Central Mexico	Similar to the Bronze variety but lacks the distinct tail penciling and the heavy-copper colored bronzing. The terminal edgings are almost white
M. gallopavo silvestris Vieillot, the eastern turkey	Eastern United States, excepting southern Florida, to the western and northern limits of the species as described above	Similar to the Bronze but lacks the heavy copper-colored bronzing and the pure white terminal edgings. The latter are dark chestnut or iodine color in *silvestris*
M. gallopavo osceola Scott, the Florida turkey	Florida, at least as far north as Gainesville	Closely resembles *silvestris* but is distinguishable from it by the white bars of the large wing feathers, which, in *osceola*, are much narrower than the black bars and do not cross the shaft of the feather. In all other wild varieties and in the Bronze and Narragansett, the white bars are as wide as or wider than the black ones and extend completely across the feathers
M. gallopavo intermedia Sennett, the Rio Grande turkey	Middle-north Texas to northeastern Coahuila, Nueva Leon, and Tamaulipas	Resembles *silvestris*, but its terminal edgings are light chestnut or cinnamon and its back feathers present a decidedly blackish appearance
M. gallopavo merriami Nelson, Merriam's turkey.	The mountains of southern Colorado, Arizona, New Mexico, western Texas, northern Sonora, and Chihuahua	Resembles *silvestris* but the terminal edgings are creamy to buffy white

The North American wild turkey (*Meleagris gallopavo*, fig. 6) formerly ranged over all of Mexico except the extreme southern and western parts; over southern Ontario, Canada; and over the United States south and east of a line extending from south to north through western Arizona, northeast diagonally across Colorado and Nebraska to include a small portion of southeastern South Dakota, east across

Figure 6.—A flock of wild turkeys at the National Agricultural Research Center. Crosses are being made of the wild on the domestic varieties.

northern Iowa, southern Wisconsin, southern Michigan, northern New York, northern Vermont, northern New Hampshire, and southern Maine.

Wild turkeys, principally the eastern turkey, are now bred to some extent on game farms, both public and private.

Varieties of Domesticated American Turkeys

The turkey, the Muscovy duck, and the Canada (gray) goose constitute the contribution of the Western Hemisphere to the list of species of poultry. At the time North America was discovered, the wild turkey was found in large numbers and, in some instances, had been domesticated by the natives. From the meager historical data available it appears that turkeys were first taken to Spain in 1498. The sources of these and later importations to Europe were turkeys domesticated by the natives of Mexico and Central America. All these turkeys apparently belonged to the Mexican subspecies of the North American turkey. From Spain turkeys were taken to other European countries, being introduced into England between 1524 and 1541. Several European varieties were developed, notably the Cambridgeshire Bronze and the Norfolk Black. From Europe and North America, turkeys were exported to all parts of the civilized

world. They are now raised in Europe, North America, South America, South Africa, Australia, the Philippines, and Hawaii.

After the United States was settled, it appears that the first domesticated turkeys to be raised came not from the native wild stock, but from the domesticated turkeys of Europe. These birds were probably all of the Bronze color pattern, although some Blacks may have been included. For a considerable time no serious attempts were made to domesticate the native wild turkeys, but finally early in the nineteenth century turkey breeders began to cross the domesticated stock with the wild.

About 1830–40, in the Narragansett Bay district of Rhode Island there was developed a local variety which was the forerunner of the modern Narragansett (fig. 7) and Bronze (fig. 8) varieties. About 1860 the first superior strain of Bronze turkeys came into prominence and this variety was described in the first (1871) American Standard of Perfection.

Figure 7.—A Narragansett hen showing typical markings. Wild, Bronze, and ocellated turkeys have the same general pattern although the colors are different.

The development of the Narragansett and White Holland varieties appears to have paralleled approximately that of the Bronze. A color standard for the Narragansett was published in 1874, along with standard descriptions for the Slate, Black, and Buff varieties. The last-named variety never became popular and was dropped from the standard in 1915.

The White Holland was admitted to the standard in 1878 and the Bourbon Red about 1909. Authentic information concerning the origin of the Slate and Buff varieties appears to be lacking. The White Holland variety originated as far as is known in North America, not in the Netherlands, and was developed from white mutations appearing in Bronze flocks. The Black turkey is an old variety that appears to have been developed in Europe, although some strains may have been developed independently in North America. The Bourbon Red had its origin in Bourbon County, Ky., and is the newest of the standard varieties.

According to the American Standard of Perfection all standard-bred turkeys are now classified as one breed, which is subdivided into varieties. The standard varieties all have the same shape and, except for the Bronze, which is a little heavier than the others, they are all

the same size. They are differentiated only by plumage color, and one variety is as good as another for commercial turkey production. However, there is considerable variation within each variety, so that the selection of a good strain is more important, from the standpoint of economical production, than the selection of a variety. Six stand-

Figure 8.—A farm breeding unit of Bronze turkeys.

ard varieties of domesticated turkeys are now bred in the United States. The data in tables 2 and 3 show some of the characteristics of these varieties.

TABLE 2.—*Standard weights of the six standard varieties of American turkeys*[1]

Variety	Adult tom	Yearling tom	Young tom	Yearling and adult hen	Young hen
	Pounds	*Pounds*	*Pounds*	*Pounds*	*Pounds*
Bronze	36	33	25	20	16
White Holland, Narragansett, Bourbon Red, Black, and Slate	33	30	23	18	14

[1] The weights shown are for young turkeys 8 to 12 months of age, for yearlings 12 to 24 months of age, and for adults 24 months of age or older. Actually, very few flocks of turkeys attain standard weights.

TABLE 3.—*Color of the six standard varieties of American turkeys*

Variety	Plumage color	Shank color
Bronze	Ground color is dull black but the exposed surfaces of the feathers are glossed with rich iridescent red green on the fore part of the body and with a brilliant copper-colored bronzing edged with black on the rear half. On the tail, tail coverts, and sides there is, in addition, a terminal edging of white, which also appears on the breast feathers of the female. Main tail feathers and tail coverts are distinctly penciled, medium brown and black.	Blackish in young birds, pinkish in adults.
Narragansett	The plumage pattern resembles that of the Bronze, but there is no red-green sheen and no bronzing. The Narragansett colors are metallic black with light steel-gray edging bordered in certain sections by a narrow black band on the ends of the feathers; main tail feathers and tail coverts distinctly penciled, light brown and black.	Blackish salmon in young birds; deep salmon in adults.
White Holland	White in all sections	Pinkish white.
Bourbon Red	Dark brownish red with white wings. The breast feathers have narrow black tips which,in the females, are bordered with white. The tail is white with an indistinct reddish bar near the end.	Reddish brown in young birds; reddish pink in adults.
Black	Black in all sections	Slate black in young birds; pink in adults.
Slate	Slate color in all sections	Pink

Past Work in Breeding

Even when raised in captivity and given every opportunity to make maximum growth, wild turkeys are smaller than their domesticated relatives. According to reliable observations, young North American wild turkey toms, when in good condition, in December and January average approximately 12 pounds in live weight and the young hens about 8 pounds. The adult wild males usually weigh from 19 to 22 pounds and in rare instances attain a weight of 33 pounds when fat. When grown in captivity under favorable conditions, the live weights of wild turkeys are somewhat greater than those mentioned. However, there is a decided contrast between the weights commonly attained by strains of Bronze turkeys and the much smaller weights attained by wild turkeys even when they are raised under similar conditions. Egg production in the better strains of modern turkeys has been increased substantially over that of the wild turkey. Progress in breeding for plumage color is evident by the variety of colors and patterns in the domestic birds. Some improvement in type has also been effected. The wild turkey has a rather shallow body, a long neck, a slender head, and long legs. The breeders of domesticated turkeys have developed a larger bird with a deeper body, shorter legs and neck, and heavier fleshing except over the breast, where the wild turkey is probably the equal of the domesticated bird.

Improvements made have been few and slow and thus the good qualities of the original stock have not been sacrificed. For example, the eggs laid by domesticated turkeys are as fertile and hatch fully as well as those laid by wild turkeys, and modern strains of turkeys are as resistant to disease as the wild type. Rate of maturity to market condition has been little influenced by domestication.

Comparatively little inbreeding or cross-breeding has been practiced in turkey breeding, except by a very few breeders who have developed distinctive strains or new varieties.

Private breeders have been responsible for the development of the modern turkey in all its beauty and usefulness. However, there is no accurate, detailed history of breed development and there has never been a pedigree-recording system for turkeys similar to the herdbook used with other animals. Such evidence as there is has been summed up in the preceding paragraphs.

Today the Bronze variety predominates to an overwhelming extent. Narragansetts, White Hollands, and Bourbon Reds are fairly common and appear to be gaining in popularity. The Black variety is less common although it too is probably gaining in favor. The Slate turkey may be classified as rare and the wild turkey as rare except on game farms.

MARKET TRENDS AND THEIR RELATION TO BREEDING

So far turkeys have been produced almost exclusively for roasting purposes and marketed between 6 and 8 months of age. Turkey broilers or fryers have not been produced in significant numbers and there is little reason to believe that they will ever be a factor in the turkey industry since smaller types of poultry fulfill this need. Turkey capons have been successfully produced but have not met with

special favor on the markets. Until they do, the extra cost of production will not be justified. Turkey eggs, although palatable and suitable for cooking, do not possess the delicacy of flavor and fineness of texture characteristic of chicken eggs. The profitable production

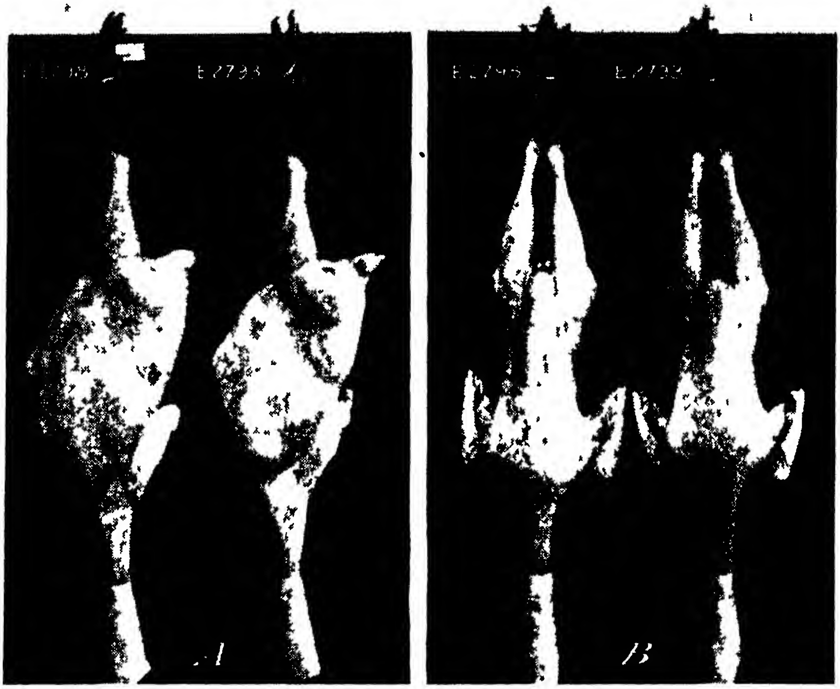

Figure 9.—Illustrating body type in dressed turkeys. *A*, Two young Black toms No. 2798, on the left, when killed at the age of 32 weeks, weighed 22.6 pounds (dressed), had a narrow poorly meated breast, a keel measuring 8.2 inches long and a shank 8.1 inches long and produced 3.9 pounds of breast meat. No. 2793, on its right weighed 22.3 pounds, had a broad well-meated breast, a keel bone measuring 7.5 inches in length, and a shank 8.3 inches long, and produced 4.1 pounds of breast meat. It is desirable to have a broad well-fleshed breast. The keel should be as long as the shank or longer. (Length of shank is distance between rear of hock joint and the ball of the foot.) *B*, Side view, no. 2798 on left, no. 2793 on right.

of market eggs from turkeys seems highly improbable even as a sideline enterprise for the turkey grower.

According to various observers, most but not all larger eating establishments and individuals buying for large dinner groups prefer turkeys weighing more than 15 pounds (dressed) while most of the smaller places and American housewives in general prefer dressed birds weighing less than 15 pounds. This preference for small turkeys by what is now the majority of consumers has increased the demand for hens and small toms.

Accurate estimates of the average weights at which turkeys are marketed throughout the country are not available, but the average

for young hens probably ranges, in different producing areas, between 9 to 12½ pounds live weight and 8 to 11½ pounds dressed weight (blood and feathers removed). The average for young toms probably ranges between 15 to 21½ pounds live weight and 13½ to 19½ pounds dressed weight. In some producing areas where large stock and good feeding methods are used, the average body weight will be larger than in other sections. A few years ago the average body weight of turkeys was smaller than at the present time, but the advent of commercial turkey raising with better feeding methods and stock bred for large size has increased the average weights. Standardbred young Bronze tom turkeys raised on full feed will average 18 to 19½ pounds dressed, and young hens 10½ to 11½ pounds, when marketed at the age of 26 to 28 weeks. Birds from strains of extra large turkeys may exceed these weights by 25 percent or more. Figure 9 *A* and *B* illustrates body types in dressed turkeys.

The present demand for smaller turkeys appears to be based on sound economics—the fitting of the dressed turkey unit to the needs of two great groups of consumers, the small-scale vendor of cooked turkey meat and the average family. For large family groups and for hotels and restaurants, the large turkey is in demand, as large toms dress out better than small toms and are fully as palatable. At the present time, the market receipts of large turkeys are slightly in excess of the demand, resulting in a price differential of ½ to 4 cents per pound in favor of hen turkeys and small toms. Unless the demand changes, which appears unlikely, future breeding operations in turkey production should be in the direction of smaller turkeys.

RESEARCH IN TURKEY BREEDING

There has been little breeding research with turkeys. One drawback has been the lack of sufficient funds for this purpose; a lack of adequately trained personnel with the proper interest in this aspect of poultry production; and third, the susceptibility of turkeys to blackhead—but this last drawback is being rapidly overcome.

A brief description of the results of scientific investigations to date follows and a list of references is included at the end of this article.

Work of State Experiment Stations

Except for matings to replenish flocks, turkey-breeding work has not been carried on extensively by the State experiment stations, though a few have initiated projects in the past or have some work under way at the present time.

Studies on the inheritance of plumage color have been limited and only a few individuals were used in the experiments from which conclusions were drawn. Some of the more important findings may be summed up as follows: (1) Black plumage color is imperfectly dominant to the bronze plumage pattern and imperfectly epistatic [1] to the Narragansett plumage patterns and red plumage color. (2) Red plumage color and Narragansett plumage pattern are epistatic to the bronze plumage pattern. (3) The factor for slate plumage color is a dominant dilution factor affecting the bronze and black

[1] Characterized by the dominant action of a gene over another gene situated on a different chromosome or at a different place on the same chromosome.

plumage patterns to produce slate-colored turkeys, or red plumage to produce slate-red turkeys. (4) The factor providing for the presence of plumage color is dominant to the absence of pigmentation of plumage. When allowed to express itself, the recessive factor produces a white bird that has brown eyes because this particular factor affects plumage color only and does not affect eye color. All white birds, therefore, carry the plumage pattern or color for bronze, Narragansett, black, or red but do not show any of these patterns or colors unless they are crossed with colored turkeys. However, when mated together, these white turkeys always produce white offspring. (5) Buff-colored turkeys may be produced by first crossing black turkeys with red ones. The resulting rusty black offspring are then crossed back to the red turkeys, which results in progeny having four types of plumage color—rusty black, Bourbon Red, bronze red, and buff. (6) The factor for Narragansett plumage color pattern is recessive and sex-linked. Males showing the Narragansett plumage pattern are produced only from matings of Narragansetts, but females showing Narragansett color and males showing bronze color may be produced from a mating of Narragansett males and bronze females. The reciprocal of the mating produces all bronze-colored progeny.

Work of the Federal Government

In the field of plant and animal genetics, there has been a good deal of experimental work in making wide crosses such as crosses between species. Certain of these results have been worth while. This is more true of plants than of animals, although the mule is an outstanding example of a useful wide cross in the animal kingdom. In most cases, however, the hybrid proves to be without economic value, although this means of obtaining a cross of unusual value cannot be overlooked.

An attempt was made by Quinn, Burrows, and Byerly at the National Agricultural Research Center, Beltsville, Md., to effect an intergeneric cross between the turkey and the chicken by the use of an artificial insemination technique developed at the center. Semen of turkey males was used to fertilize Rhode Island Red females and semen from purebred and cross-bred chicken males was used to fertilize turkey females. About 20 percent of the eggs laid by the turkey females were fertile, but all except one died in the early stages of embryonic development. In the reciprocal cross only a few of the eggs were fertile and all of these died within a 3-day period of incubation.

Although 25 percent of the fertile eggs died as embryos during the first day of incubation, one hybrid embryo, from the chicken male × turkey female cross, lived until it was fully developed and apparently ready to hatch. This hybrid embryo was found dead in the shell on the twenty-eighth day of incubation, death having occurred some time between the twenty-third and twenty-eighth days. No daily observations were made after the twenty-third day, so that the exact time of death, and the age of the embryo when death occurred, were unknown. The hybrid was obtained from an agg laid by a Bronze turkey hen on July 3, 20 days after the last fertile turkey egg had been obtained and 66 days after the removal of the turkey male.

The turkey-chicken hybrid was intermediate in conformation between the chicken and the turkey. The hybrid was also lighter in down color than the turkey, having a reddish cast in both head and body. It had yellow shanks whereas the shanks of the turkey parent were quite dusky. The hybrid had a distinct comb and no evidence of the characteristic fleshy protuberance of the turkey. It also showed a polydactylism in which the fourth toe of the left foot was triplicated, a malformation sometimes found in wide crosses. In various external characteristics such as head type and shape, down color and shank color, the turkey-chicken hybrid may be said to have shown the characteristics of the chicken rather than the turkey.

The latest development in poultry breeding for the creation of superior strains is the building up of inbred strains in order to produce successful hybrids by subsequent crossing. It is much more difficult to build up inbred lines of chickens or turkeys than of many plants, since fewer individuals can be used and self-fertilization cannot be practiced.

Although he cannot catalog the characteristics of the turkey, and their mode of inheritance, the scientific breeder might accumulate and purify certain good characteristics by the process of inbreeding, which fixes various good and bad traits of the parents in the different lines of inbred progeny. Sires that show an accumulation of bad traits might be discarded. A line that showed an accumulation of good traits might be crossed with another good line, with the object of producing superior hybrid individuals.

Because inbreeding might play an important role in the improvement of turkeys in some such way as this, an experimental turkey-breeding project was begun in 1931 by the Bureau of Animal Industry at its range livestock experiment station, Miles City, Mont. This project was terminated in 1935 and the results of approximately 5 years' work were summarized. One purpose of the project was to measure the effect of inbreeding on the fertility and hatchability of eggs, the egg weight, and the egg production of Bronze turkeys. In order to make an adequate comparison of the effects of inbreeding, a series of outbred matings were maintained. These outbred matings were made between unrelated or distantly related individuals, and each year the progeny was systematically outbred with the idea of maintaining a line indefinitely without resorting to close inbreeding or the introduction of new stock. This plan of outbreeding included seven matings and constituted a separate experiment that will be discussed later.

TABLE 4.—*Summary of the egg fertility and hatchability and of egg production and egg weight for 773 inbred and outbred Bronze turkeys*

Degree of inbreeding	Coefficient of inbreeding	Fertility	Hatch-ability	Production of eggs to June 1	Average egg weight
		Percent	*Percent*	*Number*	*Grams*
Outbred	0.000–0.063	87.8	67.6	47.7	83.6
Mild	.125– .218	75.4	51.7	42.2	82.7
Close	.250– .411	82.8	52.8	39.0	82.1
Intensive	.500– .672	69.3	34.9	41.4	81.5

The data in table 4 show the results obtained from unrelated turkey matings and from matings of different degrees of relationship on fertility, hatchability of eggs, egg weight, and egg production.

Some general conclusions from this work are as follows:

(1) Mild and close inbreeding had little effect on fertility, egg production, and egg weight when compared to outbreeding.

(2) Mild and close inbreeding had an adverse effect on the hatchability of turkey eggs. The inbred lines averaged approximately 52 percent hatchability whereas the outbred lines averaged 67.6 percent.

(3) Intensive inbreeding adversely affected fertility and hatchability of eggs but had slight effect on production and average egg weight.

These conclusions are taken from the final averages. However, there was considerable variation in the results obtained from various matings within each of the four groups. For instance, some of the mild and close inbred turkeys gave better results in regard to the four factors considered than the outbred turkeys that were used as controls. In other words, it appears that it might be possible with careful selection and mating to obtain lines of inbred turkeys that would be as good as the outbred turkeys in these respects.

Matings were made between unrelated or distantly related individuals each year and systematically outbred with the idea of establishing a line of outbred turkeys without resorting to close inbreeding or introduction of new stock. The method used was briefly as follows:

The start was made with stock purchased from seven different breeders. Seven breeding pens were mated in such a way that the males and females in no two pens were from the same source. The progeny were individually wing-banded, which made it possible to identify the progeny of each mating at any time. The best young hens and the best young tom turkeys were selected in each generation in each pen. The selected young hens from each pen remained together as a breeding unit each year and were placed in the pen previously occupied by their parents, but the selected young tom was placed in the next pen. For example, the selected young hens from the mating in pen 1 were placed in pen 1 the next year. The best young tom available from this mating, however, was placed in pen 2. The young tom turkey from pen 2 was placed in pen 3, and so on, the young tom from pen 6 being placed in pen 7, and that from pen 7 being placed in pen 1. This revolving process was followed each year.

The plan proved to be satisfactory, simple, easily workable, and effective in maintaining the average egg weight and improving the fertility and hatchability of eggs and egg production. The data in table 5 show the results obtained in the operation of this plan for 5 years. It is regrettable that it was necessary to sell the progeny of the 1935 matings before records of egg production and egg weight could be obtained.

Practical breeding operations are well served by basic research, especially in a field so new as turkey breeding. The mode of inheritance of characters, the physiology of reproduction, and the study of mating systems all have a direct application to practical problems. Through these findings, unwise practices may be brought to light and discarded and more efficient methods developed.

TABLE 5.—*Summary of the egg fertility and hatchability and of egg production and egg weight for 390 systematically outbred turkeys*

Year	Coefficient of inbreeding	Fertility	Hatchability	Production of eggs to June 1	Average egg weight
		Percent	*Percent*	*Number*	*Grams*
1931	0.000	72.7	55.2	44.6	84.7
1932	.000	85.0	56.6	47.4	85.0
1933	.031	92.0	71.4	49.6	79.6
1934	.060	85.3	68.7	48.6	84.0

DUCK BREEDING

A. R. LEE, Associate Poultry Husbandman, Animal Husbandry Division, Bureau of Animal Industry

RELATIVELY little information is available on the breeding of ducks and practically no genetic investigations have been made on the improvement of the breeds. Because of the lack of records, no survey of duck breeding has been made, nor has the Department of Agriculture used ducks in its breeding investigations. The same is true of practically all the State experiment stations. On the other hand, although Federal research in poultry breeding has not dealt specifically with ducks, it has dealt with fundamentals in genetics, and principles of management have been worked out that are applicable to all poultry, including ducks. The size and extent of the duck industry in this country seem to warrant careful study of this important aspect of poultry breeding.

Duck raising is conducted as a side line in nearly all sections of the United States, where ducks are kept in small flocks on general farms. These farm flocks are kept primarily for meat production and while the birds have been selected for size and market type, very little attention has been given to careful pedigree breeding. Commercial duck raising has been extensively developed as a highly specialized industry on Long Island, N. Y. (fig. 1) and to some extent on a few commercial duck farms in several other sections of the country. Relatively little has been published on the methods used in the selection and breeding of ducks on these commercial duck farms.

Few ducks have been bred for high egg production in this country because of the lack of demand for duck eggs as food. Relatively few ducks of the breeds especially adapted for egg production have been kept here and few ducks with high egg records have been produced. That ducks can be bred for very high production has been demonstrated in many egg-laying contests in other countries, in which the duck records have equaled or exceeded the best records made by chickens either here or abroad.

PRODUCTION OF GREEN DUCKS

ALTHOUGH most flocks of ducks are small, about 12 million ducks are raised each year in the United States. They are raised in every State, the greatest total farm production occurring in the North Central States. Large commercial duck farms in New York place that State first in total number of ducks raised, Long Island alone producing nearly a million annually. These market ducks from the large commercial flocks are called green ducks. They are hatched in the winter and early in the spring, forced for rapid growth, and marketed

at 9 to 13 weeks of age when they attain a weight of 4½ to 6 pounds each. Ducks produced on general farms are not forced for rapid growth; they are hatched in the spring and marketed in the fall and winter when they are 5 to 7 months old. These ducks from farm flocks, although twice as old when they are marketed, are little if any larger than the green ducks.

The number of ducks raised in this country is about three times the number of geese but less than two-thirds the number of turkeys.

Figure 1.—The Pekin duck is the only breed used for commercial duck farming. A large number of duck farms have been developed along the inlets of Long Island.

Duck production is similar to turkey production in that both ducks and turkeys are raised primarily for market as young birds, and relatively few breeders or mature birds are kept. While chicken and turkey production have shown a marked increase during the last 25 years, duck production is barely holding its own. Ducks are primarily in demand in the large cities, especially among persons of foreign extraction. The number of ducks kept in proportion to the total population is much lower in the United States than in most other countries, where there is a better demand for duck meat and for duck eggs.

ORIGIN AND HISTORY OF DOMESTIC DUCKS

All domesticated ducks, with the exception of the Muscovy, are descended from the wild mallard (fig. 2). While actual references to ducks go back to only a few years previous to the Christian era, it is reasonable to suppose that wild mallards were domesticated at a much earlier period than this. Common domestic ducks of Europe, among which there was a variety of colors, were brought to the United States by the early settlers.

There are three classes of ducks—the meat class, the egg class, and the ornamental class. Only a few representative breeds of each class

will be discussed in this article. In the meat class, the Rouen, Aylesbury, Pekin, Cayuga, and Muscovy are among the well-known breeds.

The Rouen, which has the same color markings as the wild mallard, shows the effect of domestication by its greatly increased size and superior fleshing qualities. This breed originated near Rouen, France, whence it derives its name, but it was greatly improved in England, where it was bred for very large size, the males weighing 9 to 11 pounds alive and the females 8 to 10 pounds. It was brought

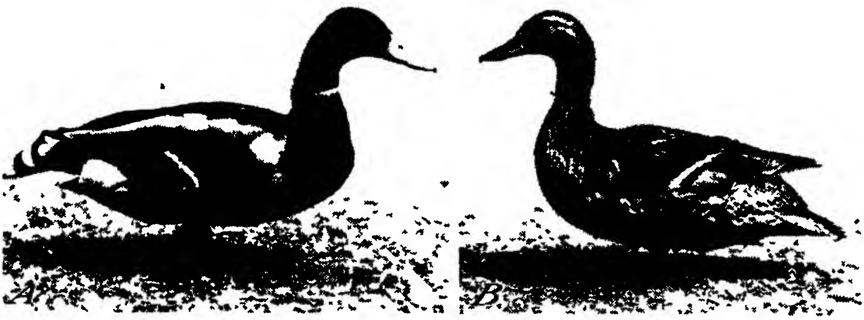

Figure 2.—Wild mallard, drake (*A*) and duck (*B*)—the ancestors of all but one of our domestic breeds of ducks.

into the United States about 1850 and became quite popular but is now kept in this country primarily by fanciers.

The Aylesbury is a white duck that originated in England early in the nineteenth century. It is a large duck with a massive body, that is carried nearly horizontal. The Aylesbury duck was first brought into this country about 1849 and was used on the first duck farms, but was eventually replaced by the Pekin. Duck breeders in this country consider it less hardy than the Pekin.

The Pekin duck (fig. 3) originated in China and little is known of its history in that country. It is a white duck of medium size, more upstanding in type than the Aylesbury, an excellent market bird and noted for its vigor and hardiness. The breed was brought into the United States from China in 1873. It rapidly became popular and soon replaced all other breeds for commercial duck raising. Crosses were made of the Pekin with Aylesbury and other breeds, but the pure Pekin was found to be much better adapted for commercial duck farming and has since maintained this position as the best and only commercial market duck. The first small importations of Pekins, from which most of the present commercial flocks are descended, were very good market ducks, not greatly different in appearance, size, or other economic characters from those of today.

The Cayuga duck (fig. 4, *D*) is of interest because it was produced in Cayuga County, N. Y., and also because it is solid black in color. It was developed about 1850 and was just becoming well known when the Pekin, which was better adapted for the market, came along and replaced it.

138904°—37——87

The Muscovy, or Brazilian, duck is a native of Brazil and is considered a different species from the wild mallard and from the other domestic ducks. The period of incubation for Muscovy eggs is 33 to 35 days, compared with 28 days for eggs of other domestic breeds of ducks. The breed was introduced into the United States between 1840 and 1850. The Muscovy drake is about one-third larger than the duck, while in all the other market breeds the male and the female are practically equal in size.

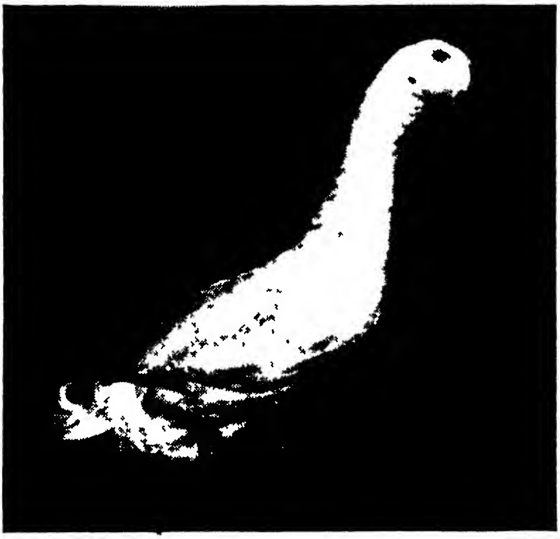

Figure 3.—Most of the commercial flocks of ducks in this country came from two small importations of Pekin ducks brought from China in 1873.

The egg-laying class, of which the Indian Runner (fig. 4, *E*) is the outstanding breed in this country, was brought into United States only about 40 years ago. It is an upright Penguin type of duck noted for great prolificacy. It was named Indian Runner because of its supposed introduction from East India, but the evidence appears to show that it was a selected duck of a type common in Belgium and the Netherlands. Because of its small size it is not so well adapted as the Pekin for meat production. The Khaki-Campbell duck is a popular breed of this class in foreign countries.

In the ornamental class there are ducks of all sizes, types, and colors, which indicates that great variation has been brought about through selection and breeding. The Call (Fig. 4, *A* and *B*) and the Black East India are bred for extremely small size, the White and Gray Calls being miniatures of the Pekin and Rouen, respectively, while the East India is a small-sized Cayuga. The Mandarin and the Wood ducks are the most ornamental of the small breeds of waterfowl. Their plumage contains many brilliant colors and is handsomely marked. In the ornamental class there are also larger ducks, such as the Crested White (Fig. 4, *C*), which is distinguished by a well-developed crest on the top of its head. Figure 4 shows a few of the variations that occur in the breeds of ducks.

Improvement by Breeding

Improvement of ducks of the meat class in this country has been largely confined to the selection of a few individuals notable for size, type, and rapid growth out of the large number raised for market each year. On commercial duck farms 40 or more young ducks are

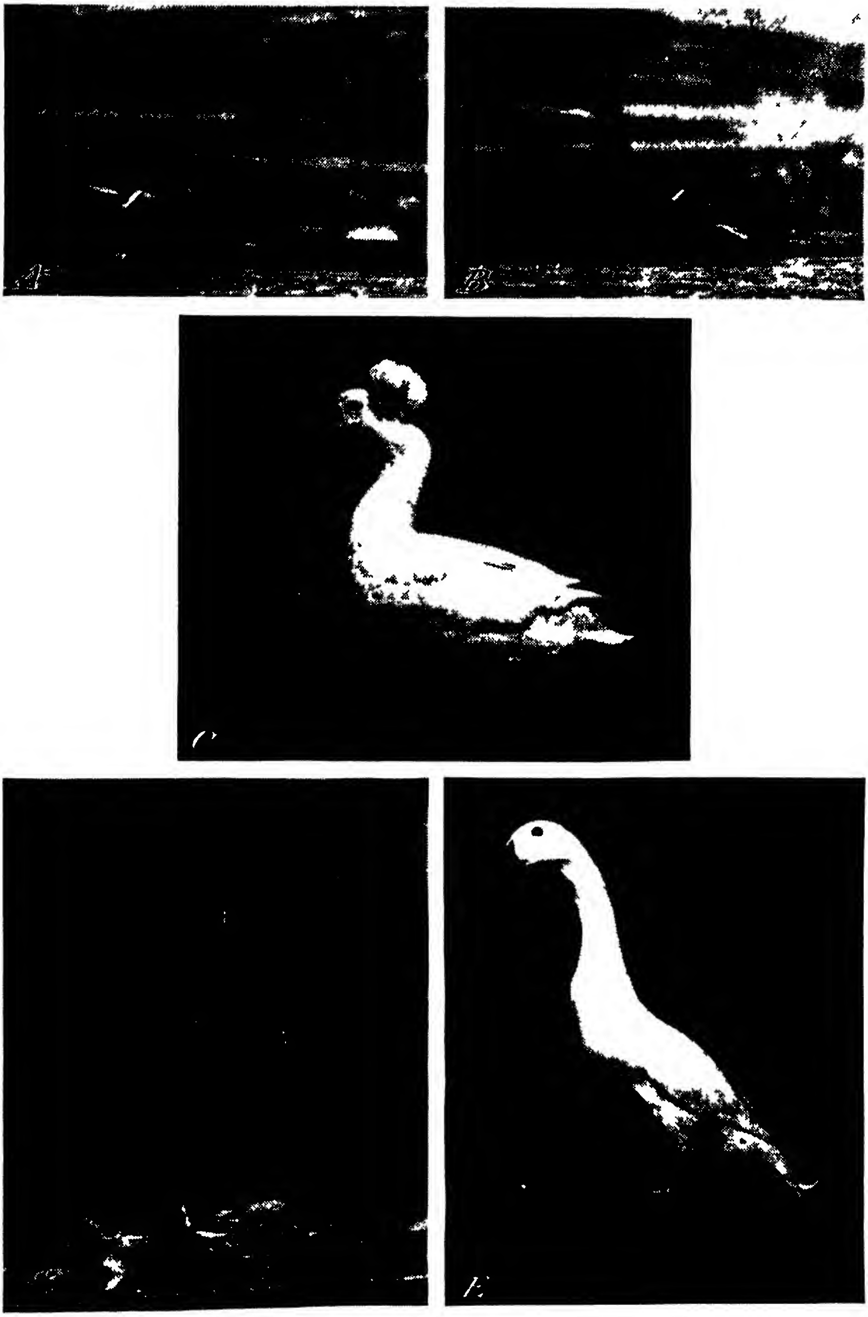

Figure 4.—Great variation has been produced in ducks through selection and breeding: *A*, Gray Call male; *B*, Gray Call female; *C*, Crested White; *D*, Cayuga; *E*, Indian Runner.

marketed annually from each female breeder. Selection of a few of the outstanding birds from a large flock does not give an accurate measure of the breeding value of the flock, but this selection, starting from high-quality stock, has resulted in the production of very uniform flocks of Pekin ducks. These ducks are noted for their rapid growth and for uniformity in size and type. Pekin ducks have not been bred or selected for high yearly egg production but they lay very steadily during the months when eggs are desired for hatching.

Principles of Breeding

An article by Jull in the 1936 Yearbook of Agriculture[1] contains a thorough discussion of the principles of breeding, the use of inbreeding and cross-breeding, breeding for disease resistance, and other aspects of poultry breeding that apply to ducks no less than to chickens. A careful study of the breeding investigations that have been made with chickens and with turkeys should be of much assistance to those interested in improving the breeding of ducks. No attempt will be made to discuss these breeding principles in detail here—for this information the reader is referred to Dr. Jull's article.

Jull stresses the importance of what he calls a three-p program, involving production records, pedigrees, and progeny testing. Production records, he points out, are of great value; yet many good individual producers fail to produce good offspring. Pedigree breeding, in which detailed records are kept of the breeding birds and their offspring, is an improvement over breeding from production records alone, but again there is no positive assurance that a bird with a good ancestry will always produce good offspring. Since ducks are rarely trap-nested, practically no thorough pedigree breeding has been carried on with them. Progeny testing, which is the best method of evaluating any poultry breeding stock, has not as yet been applied to the breeding of ducks in this country.

In fact, ducks offer a virgin field for poultry breeding research, especially in the inheritance of meat characters. The first practical steps in a breeding program would be the use of the production record, the pedigree, and the progeny test. They involve expense, however, in the keeping of records, securing individual egg records, and maintaining breeding ducks beyond the age now customary; and duck breeders apparently do not feel that this expense is justified under present conditions. A very different situation exists among breeders of chickens, who are primarily interested in breeding for eggs.

Breeding for Size and for Quality of Flesh

Ducks are kept and selected primarily for flesh production. Good body type and rapid growth to market size are desired for economical production. But very little research work has been done on the breeding of poultry for meat or flesh production or on the inheritance of body size. W. F. Waters of the Iowa Agricultural Experiment Station has shown that inheritance of body size in chickens is extremely complex, and experiments in crossing a large and a small breed at the National Agricultural Research Center, Beltsville, Md., indicate that a large number of genes are involved.

[1] See list of selected references, p 1377

As already indicated, breeding work with Pekin ducks has been confined principally to the selection of birds of the desired market type, size, and weight, that is, those weighing about 5½ pounds when dressed at 10 to 12 weeks of age. A larger Pekin can easily be produced, but it would not be so well adapted to the market demand; moreover, large heavy ducks are not usually as good breeders as those of medium size. Since only a small percentage of the ducks raised are kept for breeding, it is a relatively easy matter to select good-sized, rapid-growing, and early-maturing birds for the breeding flocks.

Inbreeding and Hatchability

The Pekin ducks have been bred for a longer period without introducing outside stock than have any of the popular breeds of chickens. No work on the use or effect of inbreeding in the egg-laying breeds of ducks has been reported. The results secured with inbreeding chickens for egg production should be applicable to the breeding of ducks. Almost all the Pekin ducks in this country are descended from two small importations. There have been periods when it would appear that many of the flocks on Long Island were being too closely inbred and that this resulted in widespread poor hatchability. From experiments with chickens it has been concluded that hatchability tends to decrease and chick mortality tends to increase with close inbreeding.

Hatchability is an inherited character that can be improved by careful selection and breeding. However, the fact that Pekin ducks are usually mass mated and are rarely trap-nested makes it very difficult to select for hatchability. In these mass matings there is usually one male for every six or seven females. It would be very desirable to select males for breeding on the basis of high hatchability of the eggs of their dam and their progeny.

Cross-Breeding

It is sometimes claimed that cross-breeding produces increased vigor in the offspring. There has been very little cross-breeding of ducks except in farm flocks where the birds are bred indiscriminately. The purebred Pekin is the only breed used on commercial duck farms in this country for meat production. Ducks of the Aylesbury breed were occasionally crossed with the Pekins in this country some years ago, but the reports of this introduction of Aylesbury blood have been unfavorable and these crosses have been entirely eliminated from the breeding flocks. It is reported that outcrosses of the Pekin on the Aylesbury are occasionally made in England to improve the breeding qualities of certain flocks that show poor fertility and lack of vigor. The mule duck, a cross of the Muscovy on the common domestic duck, is occasionally made, especially in the Southern States. The hybrids are not fertile when bred together, but they will breed to some extent with either parent race.

Selection for Disease Resistance

Ducks are considered less subject to disease than chickens, and mortality in commercial flocks, both in the young ducks and in the mature stock, is usually much less than with chickens. Commercial

duck breeders started with good Pekin stock and appear to have kept their ducks relatively free from disease by good management of the breeding flocks. No experimental work has been reported, however, on breeding ducks for disease resistance. There has doubtless been much less chance for the spread of disease than in the case of chickens, since most ducks are very healthy, and commercial duck farming is a highly specialized industry largely conducted on very light sandy soil by a small number of breeders who usually hatch and raise their own

Figure 5.—**Pekin ducks, 12 weeks of age, weighing 6 pounds each, and ready for market.**

stock, while the ducks on general farms are kept in very small flocks and hatched and reared by natural methods with very little trade in day-old ducklings or breeding stock.

Breeding for Meat Production

On commercial duck farms picking out breeders has been almost entirely a matter of selection from appearance and by handling the birds. Ducks have been bred from large flock matings; few if any special matings have been made; the birds are not trap-nested and there has been no selection of outstanding breeders on the basis of individual pedigree records. However, the uniformity of the original stock and the selection of small flocks of breeders from very large numbers of ducks have brought about a much greater uniformity in type and size than can be found in any other kind of poultry (fig. 5). The best flocks of ducks are so highly bred that there is practically only one market grade.

The best-appearing young birds are selected when they are 8 to 10 weeks old and reserved for further selection as breeders. At this age the birds intended for market are changed to fattening rations.

Breeding males are usually selected during June and females during the early part of July. When these selected ducks reach market age they are again carefully examined and only the best are kept. Breeding ducks are selected for good length, width, and depth of body, and for early maturity. While good size and quick growth are desired, stock showing any sign of coarseness is discarded. Heavy birds with very deep keels have a tendency to take on too much fat and are likely to show low egg production, poor fertility, and lack of vigor. Most breeding ducks are kept only through their first laying season, as young ducks are better producers and lay earlier than older ones. The use of only mass matings and this restriction to young breeding stock made it impossible to do any careful pedigree breeding or progeny testing. Retaining a few of the best breeders for a second season and keeping adequate records for these birds would be worth trying.

Young Pekin ducks are efficient producers of meat. The young ducks raised on commercial farms have been selected and bred for rapid growth and at 10 to 12 weeks of age they are nearly as large as they are at maturity. At 12 weeks of age Pekin ducks weigh about 6 pounds, or 50 times their initial weight. Chickens fed for rapid growth and marketed as broilers at 12 weeks of age weigh about 2½ pounds, or less than one-half as much as ducks of the same age, while at maturity the ducks weigh about the same as chickens.

Up to about 1910 market growers exhibited their ducks at the poultry shows and competed to some extent in the sale of breeding stock meeting standard requirements. Since that time commercial duck farmers have shown much less interest in the requirements of the standard, largely disregarding any points that did not meet their own particular market demands.[2]

Breeding for Egg Production

Ducks of the egg-laying class have been selected and bred for very high egg production. Records of individual ducks and of small flocks show egg yields as high in number as the best records made by hens, and higher in total weight. In this country there is very little interest in the egg-producing breeds of ducks, largely because of lack of demand for duck eggs for market. The Indian Runner duck, which is one of the best egg producers, experienced a moderate boom beginning about 1907, but the interest in the breed lasted only for about 7 or 8 years.[3] Duck eggs are usually in good demand only early in the spring, especially around Easter time. There has been some indication of a slightly increased demand during the last year or two in some markets.

Duck egg-laying contests have been conducted in England and other foreign countries, where the egg breeds are kept much more extensively than they are in the United States. Trap nests used in Germany are

---

[2] The first standard for Pekin ducks was published in 1874 and the following year this breed was admitted to the standard of the American Poultry Association. In 1888 the following standard weights were adopted: Old drake, 8 pounds; old duck, 7 pounds; young drake, 7 pounds; young duck, 6 pounds. In 1910 the weights were increased 1 pound in each class and more emphasis was placed on development of ducks with deep bodies and long keel bones.

[3] The Indian Runner duck standard was first adopted by the American Poultry Association in 1898. Relatively few changes have been made in the standard and these changes have been largely confined to minor points. Standard weights are 4½ pounds and 4 pounds for adult drakes and ducks, respectively The standard calls for a long slender bird with carriage approaching the perpendicular. The so-called utility type of Indian Runner duck, bred only for egg production, is less upright in carriage and not so slender as the standard type, which is bred primarily for exhibition.

illustrated in figure 6. The 161 ducks entered in one of the English contests averaged 225 eggs in 48 weeks. The average weight of all eggs was 2.57 ounces, which gives an egg production per duck of 36 pounds, 3 ounces, or about eight times the average weight of the ducks of the egg-laying class. This is a much greater average production per pound of body weight than is made by chickens in the egg-laying

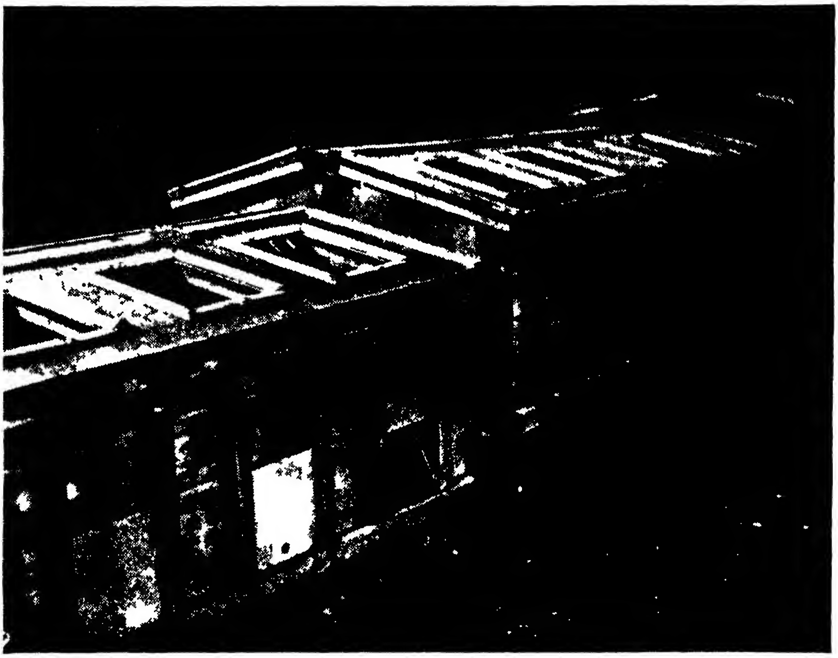

Figure 6.—Trap nests used in Germany in pedigree breeding of ducks for egg production.

contests. Many individual duck records of over 300 eggs per year have been made, while the highest individual production runs over 360 eggs. The use of the single-pen system or of trap nests for keeping records of individual ducks goes back only about 16 years in England, but great progress has been made in improving egg production during these years. Considerable inbreeding has been used, and pedigree breeding and the keeping of production records have been practiced. Progeny testing offers an opportunity for still greater improvement in breeding for egg production.

Improving Size and Color of Eggs

Size and color of duck eggs are inherited so that, where individual records are kept, careful pedigree breeding and selection will lead to material improvement. It is desirable to maintain good egg size in both the egg and the meat breeds. Considerable variation occurs in the color of duck eggs, which have a tendency to show various shades of green. This is natural, since the wild mallard produces eggs with

green shells. Shell colors range from white for the Pekins and well-bred Indian Runners to green for Rouens and dark green or black for the Cayuga. When the Cayuga and Black East India ducks begin to lay, their eggs are almost black, but as production increases the eggs gradually lose their black color and become dark green. White-shelled eggs are desired for market and the popular egg breeds show the great improvement that has been made in selecting and breeding for white eggs. Duck eggs produced by farm flocks on range, which are poorly fed, are not considered to be of as good a flavor as duck eggs produced from well-managed flocks.

Ducks offer a virgin field for poultry breeding research, especially for the inheritance of meat characters, since ducks are used almost exclusively for meat.

GENETIC RESEARCH

VERY LITTLE information has been reported on the genetic composition of the domestic breeds of ducks. The principal plumage-color-inheritance work in this country has been conducted by R. G. Jaap at the University of Wisconsin. A few other research reports on the breeding of ducks will be found in the list of references. Jaap studied the inheritance of three types of white spotting. Two of these types were found to be simple recessive and the third type exhibited incomplete dominance. The dominant type of white markings is found in the Fawn and White and the Penciled Indian Runner varieties and is due to the homozygous expression of a dominant type of white spotting, *RR*, designated "runner." The two recessive types of spotting are found in ducks having white primary wing feathers. One class is due to the heterozygous expression of the genes for runner, *Rr;* the other to a recessive gene, *w*, for white primaries.

Jaap also reported on three allelomorphic genes which produce differences in the mallard-plumage pattern. These three alleles are restricted mallard color, *Mr*, mallard, *M*, and dusky mallard, *md*. Another article describes the effects of a recessive gene which produces a light color phase in mallards. In the juvenile feathering, in the adult plumage of the female, and in the summer plumage of the male the light-phase gene produces a lighter color tone in the ducks that are genetically restricted mallard color, mallard, or dusky mallard color During the summer the adult Rouen male takes on a drab plumage similar to the plumage of the female. After the fall molt the male again assumes his normal bright-colored plumage. Young drakes also have this drab female coloring before they take on their adult plumage.

THE BREEDING OF FUR ANIMALS

FRANK G. ASHBROOK, Principal Biologist in Charge, Section of Fur Resources, Division of Wildlife Research, Bureau of Biological Survey

THE science of breeding can play an important part in conserving and developing the fur resources of the United States in two vital ways. (1) Research is needed to throw light on the breeding habits and gestation periods of wild fur animals so that an intelligent conservation program may be based on the biological needs of the animals concerned. (2) As in the case of domesticated livestock, breeding research is needed to give a more certain foundation for the production of fur animals in captivity—notably the silver fox and the mink. To state which of these two fields is the more important is difficult. Without a vigorous conservation program based on sound scientific knowledge there is great risk of completely wiping out one of the oldest of the valuable resources of the country. On the other hand, fur farming is rapidly becoming an important farm enterprise, and if it is to develop its full possibilities, further information is greatly needed at various points. The industry is all the more significant because it does not compete with any other kind of farming and it utilizes land that is of little or no value for any other crop.

A brief backward glance will show what has happened to the fur resources of the United States to make conservation in the wild so essential and propagation on fur farms a lucrative undertaking of such great promise. In almost every civilization furs have been among the most valued articles of commerce. This was true among the Chinese 3,500 years ago, and later among the Greeks and the Romans. In medieval Europe fur was a luxury much sought after—and incidentally, men made greater use of it for clothing than did women. It was not until after the discovery of North America, of course, that the world fur trade really got into its stride. That it early became an enormously profitable business on this continent is attested by the fact that an Indian trapper could often be induced to part with his winter's catch, worth hundreds of dollars, for a blanket or two and a bottle of rum—and perhaps not very good rum. Among the great fortunes amassed in this game the outstanding example is that of John Jacob Astor.

In these circumstances, with pelts readily obtained and profits large, no attention whatever was paid to the question of the possible exhaustion of this source of wealth that nature distributed with a prodigal hand. The more furs there were on the market, the more popular furs became. The luxury of the rich became the necessity of the moderately well to do. The trap lines were run not less but more intensively, to the profit of everyone—the professional trapper, the landowner,

the farmer who could turn a few extra dollars without much trouble, and a large army of wholesalers, factory owners and workers, and retailers and their employees.

Naturally a depletion of fur resources resulted. This cannot be attributed, however, entirely to overeagerness in trapping. The disappearance of the wilderness, natural habitat of the fur-bearing animals, was a major factor. Nevertheless, even today the trappers and fur farmers of the United States receive $60,000,000 a year for the raw furs they bring to the market. The annual retail turn-over is several times that amount; in 1929, the peak year, it reached half a billion dollars. The United States is in fact the largest consuming market in the world.

PRODUCTION AND DEMAND FOR FURS

TODAY, instead of the United States being the world's chief source of fur supply, this country does not produce enough to meet more than a third of its own demand. Twice as many foreign as domestic furs are now being used in this country, and the demand is increasing rather than decreasing To meet this demand, trappers still take fur animals from the wild with the same extravagant disregard of maintaining or increasing whatever supply is left. It is unquestionable that our natural fur resources will be completely exhausted, unless measures are taken to strike a proper balance between supply and demand.

In this connection there is much need for greater knowledge regarding production. At present no one knows what would constitute

---

BEFORE *the development of fox farming there apparently occurred in the common red fox two distinctly different mutations to black (silver)—one among foxes in Canada, giving rise to what are now called standard silvers, and one among foxes in Alaska, giving rise to Alaskan silvers. Beginning in 1928 the Bureau of Biological Survey conducted research to determine the inheritance of the major color types, and B. L. Warwick and the late Karl B. Hanson worked out a hypothesis according to which two dominant genes, A and B, and their recessives, a and b, accounted for all the principal color variations. The results of experimental crosses and an analysis of a large number of litters from recorded matings made by fox farmers substantiated this hypothesis. By referring to a simple genetic chart, it is now possible to determine the expected results of any method of breeding the nine basic combinations of these two pairs of genes. This research indicates the possibilities in the study of the inheritance of fur color, which is of primary importance in fox farming.*

a proper balance. We do not know, for example, whether we are producing 10,000,000 muskrats a year and trapping 13,000,000 or producing 5,000,000 and trapping 25,000,000. We can be pretty sure that we are trapping more than we are producing; but it is important to find out how many more. Almost every State has some fur resources that are a source of income for some of its citizens. The methods of handling these resources are almost entirely haphazard, and in fact few State game and conservation commissions have given sufficient serious thought to the matter. In most States there is no provision for keeping a record of the furs taken each year. In the case of some of the most valuable fur bearers—martens, fishers, wolverines, and otters—the situation has become so serious that the Bureau of Biological Survey has appealed to all State game and conservation commissions to protect them with a 5-year closed period, as the only way to forestall their extermination.

REPRODUCTIVE CYCLES

THE usefulness of breeding data in this situation may be illustrated by the case of the marten (fig. 1). At its experiment station near Saratoga Springs, N. Y., established in 1923, the Bureau has been studying the breeding and the gestation period of the marten. As a result it has found that a period of 9½ months elapses between the time of copulation and birth. With so long a period of gestation, many pregnant females are bound to be destroyed under the prevailing system of open and close seasons. It is obvious that unless the trapping season for a fur animal corresponds accurately with its gestation-free period, the close season will not accomplish what it is intended to: the prospective generation will be destroyed along with the one trapped. Even this precaution, however, would be ineffective in the case of the marten or the fisher, for their gestation periods are too long. A 5- or 10-year closed period is necessary to prevent local or even general extermination of these two fur animals.

The available information on the reproductive cycles of the wild fur-bearing animals is very meager. A review of the literature shows that very little research has been conducted to determine their actual breeding seasons, postnatal development, and gestation periods. Practically all that is now known has been learned by observing the living animals. Few investigators have studied actual embryological material. The one outstanding contribution to the embryological science of fur animals is that of Hartman,[1] of the Department of Embryology, Carnegie Institution of Washington, at Baltimore, Md. This paper presents a study of the physiology of growth and reproduction, the embryology, the rate of intra-uterine and postnatal growth, and the breeding season. More information of this kind is vitally important to any programs of conservation, restoration, restocking, or transplanting, as well as to the success of any effort to produce fur species in captivity. Conversely, it is also important in successful control of noxious animals, which should be most intensively hunted throughout the period preceding the arrival of the young. Similarly important is definite knowledge of the molting and

---

[1] HARTMAN, C. G. THE BREEDING SEASON OF THE OPOSSUM (DIDELPHIS VIRGINIANA) AND THE RATE OF INTRA-UTERINE AND POSTNATAL DEVELOPMENT. Jour. Morph. and Physiol. 46: 143–215. 1928.

prime-fur cycles, for, with dependable data at hand, trapping may be confined to the time when a given fur has its maximum value. At present this is rather vaguely considered to be the period of cold weather.

This kind of knowledge is fragmentary in comparison with what has been developed in the case of the domestic animals, which have

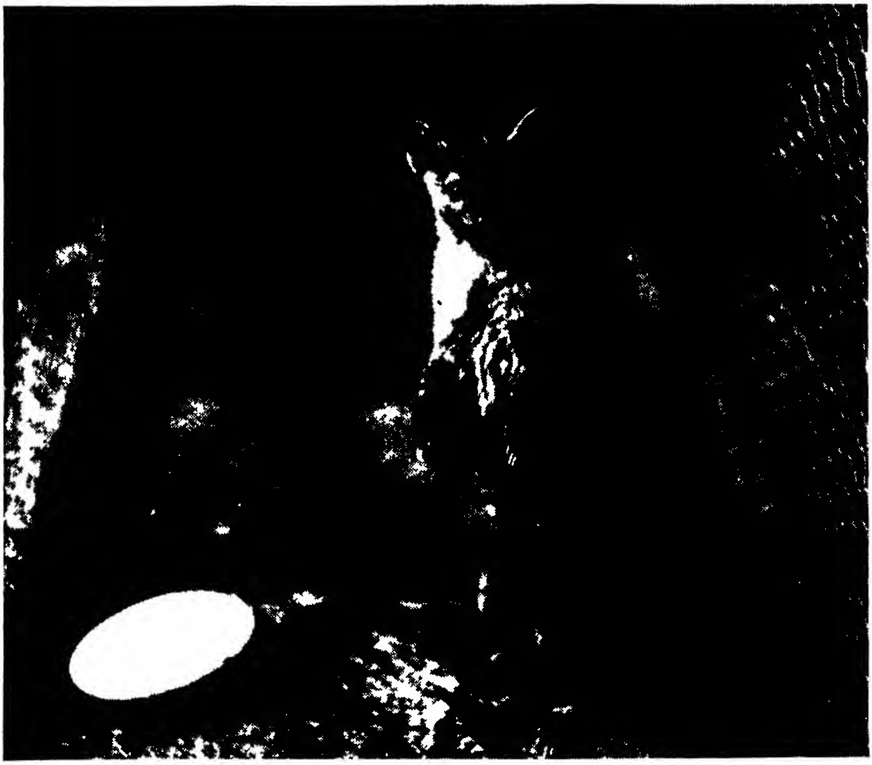

Figure 1.—The marten, one of our most valuable fur animals, is now in danger of extinction.

been under close observation over long periods of time. The place to begin, however, is at the beginning, no matter how elementary it may seem.

RAISING FUR ANIMALS IN CAPTIVITY

Raising animals in captivity as a means of supplying the need for furs is an industry that is both new and not new. The Chinese have for centuries bred sheep, goats, and dogs for their pelts. The outstanding example of a domesticated animal bred specifically for this purpose is the Karakul sheep, which has long been produced for lambskins on the uplands of Bokhara in central Asia. Afghanistan is now perhaps the most important center of this industry, and the annual production of lambskins there is (1936–37) 1,200,000; the

Union of Soviet Socialist Republics is next, with an annual production of 900,000 skins. About 30 years ago Karakul sheep raising was started in what was then German Southwest Africa, and today the farmers of that region are producing annually about 700,000 skins and shipping them to the raw-fur markets of the world. Karakul sheep are also being produced in the United States, but there are few purebred animals in this country. The foundation stock came from small importations from Bokhara in 1909, 1913, and 1914. Further importations are next to impossible. The Federal quarantine regulations prohibit direct importation into the United States, and it is too expensive to make indirect importations by holding the animals for the required length of time in another country.

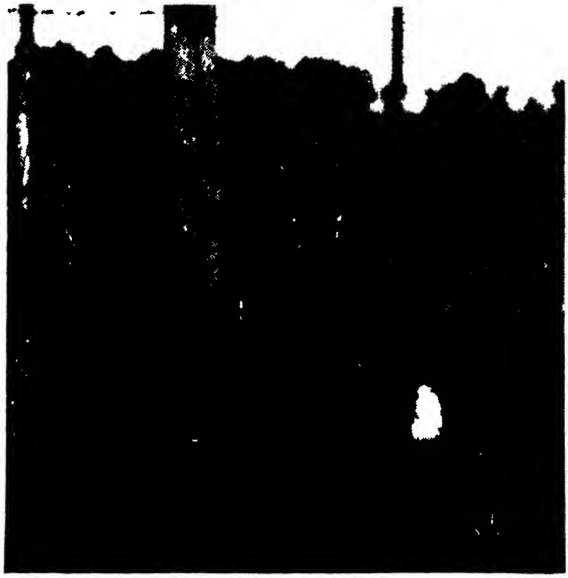

Figure 2.—The production of silver foxes on farms now (1936) exceeds 200,000 annually.

In the face of this situation the Bureaus of Animal Industry and Biological Survey have been cooperating in a breeding experiment that promises favorable results. Since it would be almost impossible to increase the breed to any appreciable extent from present stocks of purebred animals, the Department has been carrying on cross-breeding experiments with Karakul × Black-faced Highland and Karakul × Corriedale at the National Agricultural Research Center, at Beltsville, Md.

The most spectacular and important development in fur-animal production, however, is in silver-fox farming (fig. 2). This development has taken place during the last 40 years, and though brief, the history of the industry has been sensational. Two Canadian farmers on Prince Edward Island, Charles Dalton and Robert Oulton, started to experiment in 1894 with cross and black (silver) foxes, some captured and some purchased. They bred the foxes in captivity and finally obtained some entirely black and silver puppies. The neighbors soon learned of their secret operations and before long several fox farms were established on the island. It was generally understood that Dalton and Oulton were making money, but it was not until the 1910 sales figures were published that the extent of their profits became known. In that year they received for 25 pelts an average price of $1,339. One pelt brought the all-time high price of $2,627. This started a fox-farming boom and sent the prices of

breeding stock skyrocketing. The boom collapsed at the beginning of the World War in 1914, but in 1923 people were again investing anywhere from $500 to $5,000 per pair in foxes, which in some cases they had never seen. By 1927 the unhealthy speculation in breeding stock had died out and ranchers went to work producing the animals for the fur.

Production on Fox Farms

Fox farming today represents the greatest development thus far in raising fur animals under strictly controlled conditions. It can still be considered a relatively new industry, however, since practically all the development in production has taken place since the World War. The number of pelts produced and sold in the United States is estimated to have increased from 6,000 in 1923 to 200,000 in 1935. The total value of the sales increased from $819,429 in 1923 to $7,719,600 in 1928. During the next 3 years prices declined because of the depression and the increased production of skins, but from a low point of $3,472,200 in 1931 they advanced to $7,114,500 in 1934.

Foxes are grown successfully throughout the northern half of the United States, from New England westward to Washington and Oregon, and in the cooler parts of California. The greatest numbers of silver foxes are produced in Wisconsin, Minnesota, and Michigan, and these three States are contributing more than 50 percent to the annual crop of pelts. The largest two companies in the world producing silver foxes operate in Wisconsin. Each maintains about 7,600 breeding pairs. The other principal fox-farming centers are in the Rocky Mountain region, including Oregon and Washington, and in the New England States, Illinois, Ohio, New York, and Pennsylvania.

In Canada, fox farming has had a development similar to that in the United States but on a somewhat smaller scale. In 1923 sales of pelts from Canadian fox farms were slightly greater than in this country. In 1935 the number of Canadian pelts sold totaled 120,465. Furs from farms now play an important part in the fur trade of both Canada and the United States. The value of the pelts from farm-raised animals represents approximately 31 percent of the total annual value of the raw-fur crop in the Dominion and 20 percent in the United States.

Abroad, fox farming has had a phenominal development, particularly in Norway, where the industry has grown like a mushroom. During the season 1934–35 the number of pelts produced was 103,604. Other European countries also are producing silver foxes, and in Japan and South America the industry is well established. The European silver fox pelts, especially those from Norway, must now be considered an important part of the world supply. If silver fox farming develops extensively in South America, the farmers of that continent will have a seasonal advantage in getting the pelts to the markets, for pelting there is in July and August

The world production of silver fox pelts for the season 1935–36 was probably in excess of 500,000 distributed approximately as follows: United States and Canada, 350,000; Norway, 125,000; Sweden, 25,000; Netherlands, 5,000; Denmark, 3,000; Union of Soviet Socialist Republics, 4,000; Germany, 3,000; England, France, Switzerland, Japan, and South America together, 3,000.

It can hardly be doubted that this comparatively new fur-farming industry has become a permanent part of our agriculture. It has met with relatively more success in recent years than most other branches of agriculture, and it promises still greater developments when freed from the artificial restraints and handicaps that at present are retarding its progress. Fur farming fits in well as a side line to general farming

Figure 3.—Many small fur farms like this one in Massachusetts are producing fur as a side line to other agricultural pursuits.

because it can utilize certain parts of the farm not adaptable to growing other crops. It also provides a winter occupation and brings in additional revenue during the season when both are needed to balance farm operations.

In 1926, when the annual production of silver fox pelts in the United States was about 25,000 and the average price for skins was $126, farmers began to worry about the possibilities of overproduction. Many were wondering whether increasing production of furs year after year would not outstrip even the increased demand, including that resulting from the normal population increase. At that time the prices paid for pelts were dropping and the cost of feed was going up. The situation at that time was more alarming to the small than to the large producers.

Today, a decade later, the annual crop of pelts has multiplied eight times, to 200,000. Silver fox fur is fashionable, in fact very fashionable. The average price for raw pelts has dropped to $42, only a third of that realized in 1926. Food costs are increasing rapidly. Some fox farms have grown bigger, others better. Conditions now are not perplexing so much to the small as to the large producers. The reason for this change is that the former does not have all his eggs in one basket—pelt production with him is a side line (fig. 3). Furthermore, pelt production costs him less on the average than it does the

138904°—37——88

large producer and the price he receives for a pelt is on a par with that obtained by the latter. The small producers as a group are today marketing more than 140,000 pelts each year, while the large producers contribute only 50,000 or 60,000 to the annual crop.

Experiments with Other Species

Minks, martens, fishers, skunks, raccoons, and opossums also are being raised in captivity to some extent, the most striking developments having been in mink farming. The number of farm-raised

Figure 4.—Skunks are easily raised but not at a profit.

mink pelts has increased rapidly, and the prices paid have been exceptionally good, reaching their high point during the 1936 season. These favorable conditions have naturally stimulated expansion. Generally speaking it may be said that in the case of fur animals other than foxes and minks more money is invested in feeding, breeding, and management than can be realized from the sale of the pelts. For the present, at least, the production of skunks (fig. 4), opossums, raccoons, martens, and fishers for fur is not a profitable undertaking.

The problems of the fur farmer are fundamentally the same as those of other producers of livestock. They include a knowledge of his animals, their physical needs and temperament, and the requisites of sanitation, feeding, breeding, and disease control. In all of these lines, scientific research has a part to play, but so far research has been of very limited extent.

Present Breeding Methods

During the relatively short period that foxes have been raised by man no particular strains of outstanding characters have been developed. The best of them, however, produce fur of high quality. The problem then becomes one of producing fur of a given character

and quality with greater certainty. In addition, the fox farmer would like to be sure of getting good producing vixens in order to increase his pup crop; and he would like to have greater control of diseases and parasites, some of which are common to domestic livestock and some peculiar to foxes. The disease problem has been paramount, as the losses on fox farms in certain sections of the country have been disastrous, in some instances entire ranches having been wiped out. The application of veterinary science is aiding in developing the industry, although research has not yet developed methods for complete protection against several diseases that are causing heavy losses on fox farms.

The accumulated knowledge developed by plant and animal breeders should be of great value to fur farmers, but the latter have been slow in applying it to fur-animal production. In the past, time given to promotional schemes for selling breeding stock to unsuspecting buyers was much more lucrative than that devoted to the tedious study of basic principles of fox breeding, feeding, and disease control. Then, too, the rapid shift in the market requirements from dark to full silver pelts has kept the farmers busy—and worried—supplying the demands of fashion.

In their breeding operations, fox farmers have primarily stressed the selection of particularly good, true-breeding types and the use of such animals as breeding stock. Increased prolificacy and the production of fur of high quality have been the main objectives. The fur farmer has not advanced so far as the breeder of domestic livestock in the application of definite breeding principles to his problems. Among fox farmers in general, there is as yet no idea of developing a fox strain different from any now in existence and perhaps possessing outstandingly valuable characters. Such good specimens as have been developed have resulted from continued selections for a few desired types.

Market Requirements

It must be said, however, that the vagaries of fashion have had a good deal to do with the failure thus far to set up certain definite long-time objectives. Forty years ago black fox was popular; a few years later the highest prices were being paid for quarter and half silvers; and during the last 4 or 5 years the full silvers have been setting the upper price limits because they are in keen demand for working into short and long capes, short coats, enormous collars, and wide trimmings on fur coats, cloth coats, and dresses. In 1936 the prices obtained in the United States for full silver pelts were 50 percent higher than in Great Britain.

These shifts in market requirements necessitated strenuous efforts on the part of breeders to satisfy present demands, with a minimum of attention to the future. Charles E. Kellogg made an exhaustive study of the silver-fox-pelt markets of the United States and Great Britain covering the 5-year period 1932–36 to determine the effects of trends on the percentages of silver in the pelts. The results showed that about 36 percent of the American offerings in 1936 were full-silver skins, an increase of 225 percent during the 5-year period.

This demonstrates how quickly the majority of farmers produced the maximum of light-silver pelts. Some cautious breeders, however, are retaining some of the darker silvers in the breeding herd as an insurance reserve, in case there should be a sudden return to the half and three-quarters silvers, which are more satisfactory for scarf purposes. Other breeders feel confident that the genetic make-up of silvering is dependent upon so many factors that persistent selective mating toward darker colors would supply such a new demand just as effectively, though perhaps somewhat more slowly. They feel that their method permits maximum concentration on full silvers for the present higher prices. There are no authentic scientific data available to demonstrate that either method is correct, and thus the producers continue to be faced with an important problem that for the present remains unsolved.

RESEARCH IN INHERITANCE IN THE FOX

It is quite generally appreciated that there is still much room for improvement in the color and texture of silver fox fur. The pelts now coming to the market are generally somewhat better in quality than a year ago, but this is true mostly for individual ranches rather than for sections of the country. Since the number of pelts offered for sale is increasing year after year, buyers are naturally becoming more discriminating, especially with the increased competition that now involves other countries as well as the United States. Fox farmers have reached the point where they must exert every possible effort to improve the quality of the fur produced. For the present, close culling of the breeding stock, which means pelting the undesirables, and intelligent and strict selection of breeding animals are the most certain methods to bring about a marked improvement in fur quality.

To meet the need for fundamental information on the genetic basis of silvering, the Biological Survey began an experiment in 1935 at the United States Fur Animal Experiment Station, at Saratoga Springs, N. Y. An attempt is being made to determine, if possible, the genetic factors involved, so that market requirements can be met more promptly. The objective is to determine the relationships between the various degrees of silvering and to work out methods of breeding that will enable the breeder to have more control over them. Only a small number of foxes is available for this experiment, whereas experience proves that a large number must be used to obtain definite results where many genes are concerned. There has been only one other research program to trace the inheritance of fur colors, and this was concerned not with gradations in silvering but with the basic differences between red, cross, and black (silver) foxes. To make this clear, it is necessary to give a brief account of these different types.

Before the development of fox farming, there apparently occurred in the common red fox (*Vulpes fulva*) two distinctly different mutations to black. One of these, namely, that to which the standard or Prince Edward Island silver fox traces its origin, must have occurred somewhere in Canada, probably in the eastern or central part. The other, to which the Alaskan silver fox traces its ancestry, certainly must have occurred in Alaska, most likely in the interior. The so-called cross fox was probably produced by crossing the red and the silver (fig. 5).

Thus foxes of the genus *Vulpes* may have three kinds of pelts: (1) The common red fox, which is primarily red or fulvous with a mixture of gray or brown except for restricted black markings on the feet and ears, a white area at the end of the tail, and certain white-banded hairs on the back and rump; (2) the typical cross fox, in which black predominates on the feet, legs, and under parts, while red or fulvous overlying black covers most of the head, shoulders, and back; and (3) the black (silver) fox, which carries no red or fulvous, the entire pelage being dark at the base and heavily or lightly overlaid with the banded guard hairs that produce the silvery appearance. These guard hairs are not entirely white but are black with a white band, and some are entirely black. Foxes of the third group vary from animals that are almost entirely silver to those that are entirely black except for a few white-banded guard hairs on the back and rump. The fur trade recognizes five classes of silver fox pelts, graded according to the percentage of silver, as follows: Full, three-quarters, half, one-quarter, and slightly silver or dark.

Figure 5.—Litter of pups resulting from cross-breeding a silver with a red fox.

It is believed that what are called standard silver foxes, carrying a factor for silver and black color, were found naturally in many parts of Canada. Few if any of these foxes migrated into Alaska. On the other hand, the progeny of Alaskan silver foxes, also carrying a factor for the silver and black color, probably traveled southward over the mountain range and spread over a large part of Canada. Neither the Alaskan nor the standard silvers migrated to any extent south of the Great Lakes and the St. Lawrence River. The indications are, however, that some foxes possessing either or both of these factors for silver and black must have migrated or occurred naturally south into the northern parts of the States bordering on the Great Lakes.

In the early days of fox farming, red and cross foxes captured in the wild were bred to produce silvers. As more silver foxes became available, they replaced the red and cross foxes on ranches, and silver foxes were bred together to produce silvers. As time went on foxes that would breed true for silver were developed and it became generally understood that silver foxes produced from silver fox parents would always breed true. Later on, however, when silver foxes originating in Canada were bred to silver foxes from Alaska, the young produced proved to be crosses and not silvers.

Genetic Relationships Between Red, Cross, and Black Foxes

Prior to 1928 no scientific research had been conducted to determine the genetic basis of the red, black (silver), and cross coloring in foxes, and consequently there was considerable confusion as to the genetic relationship between the black color in standard and in Alaskan foxes. In 1928 it was decided to include such studies in the program of research for the United States Fur Animal Experiment Station. B. L. Warwick, of the Texas Agricultural Experiment Station, cooperated with the late Karl B. Hanson, of the Fur Animal Station, and proposed a hypothesis that would account for the results obtained. To clarify the discussion somewhat, this hypothesis will be given first. Warwick suggested that genes *A* and *B* and their alternative forms (alleles) *a* and *b* account for red, black (silver), and cross colors in foxes. All the possible combinations of these genes would give the following types:

AABB=Alaskan red.	*AABb*=Smoky red.	*AAbb*=Standard black (silver).
AaBB=Cross.	*AaBb*=Blended cross.	*Aabb*=Substandard black.
aaBB=Alaskan black (silver).	*aaBb*=Sub-Alaskan black (silver).	*aabb*=Double black.

Hanson found that when the standard black and the red foxes were crossed, the offspring were usually a smoky red. Although red was strongly dominant to black, it was not completely dominant; there was some blending that produced the smoky color. Foxes of the first filial generation had larger prominent dark points and more evidence of black than is usually present in the red parents. Segregation into reds, smoky reds, and blacks occurred when the first-generation offspring were bred inter se, that is, bred to their own kind. The ratio of segregation was about 1 red to 2 smoky red to 1 black. When smoky red foxes of the first filial generation were backcrossed to the black parents, the result was a ratio of 1 smoky red to 1 black. These ratios indicated that a single gene accounts for the difference between pure standard blacks and reds.

On some fox farms, however, where supposedly pure standard black foxes were bred with pure red ones, mixed litters of smoky reds and reds in about equal proportions were produced in the first generation. Doubtless the black (silver) parents were not pure but had a hybrid combination of the genes *A* and *a*.

Some red foxes caught in the wilds of Canada, the Upper Peninsula of Michigan, and northern Minnesota and Wisconsin when crossed with pure standard blacks produced mixed litters, with blacks and smoky reds in equal proportions. If these wild red foxes were really hybrids or smoky reds, it would account for the results.

When Alaskan blacks were crossed with red foxes, the first generation were all cross foxes, but no appreciable dominance of black or red was in evidence. When the first filial generation was bred inter se, there was a segregation of 1 red to 2 cross to 1 black (silver). The cross foxes when backcrossed to black parents again produced crosses and blacks in equal proportions. The ratios again indicated a difference of one gene between pure red and pure Alaskan silver foxes.

Hanson then crossed Alaskan and standard black (silver) foxes. The first filial generation turned out to be blended cross foxes. This

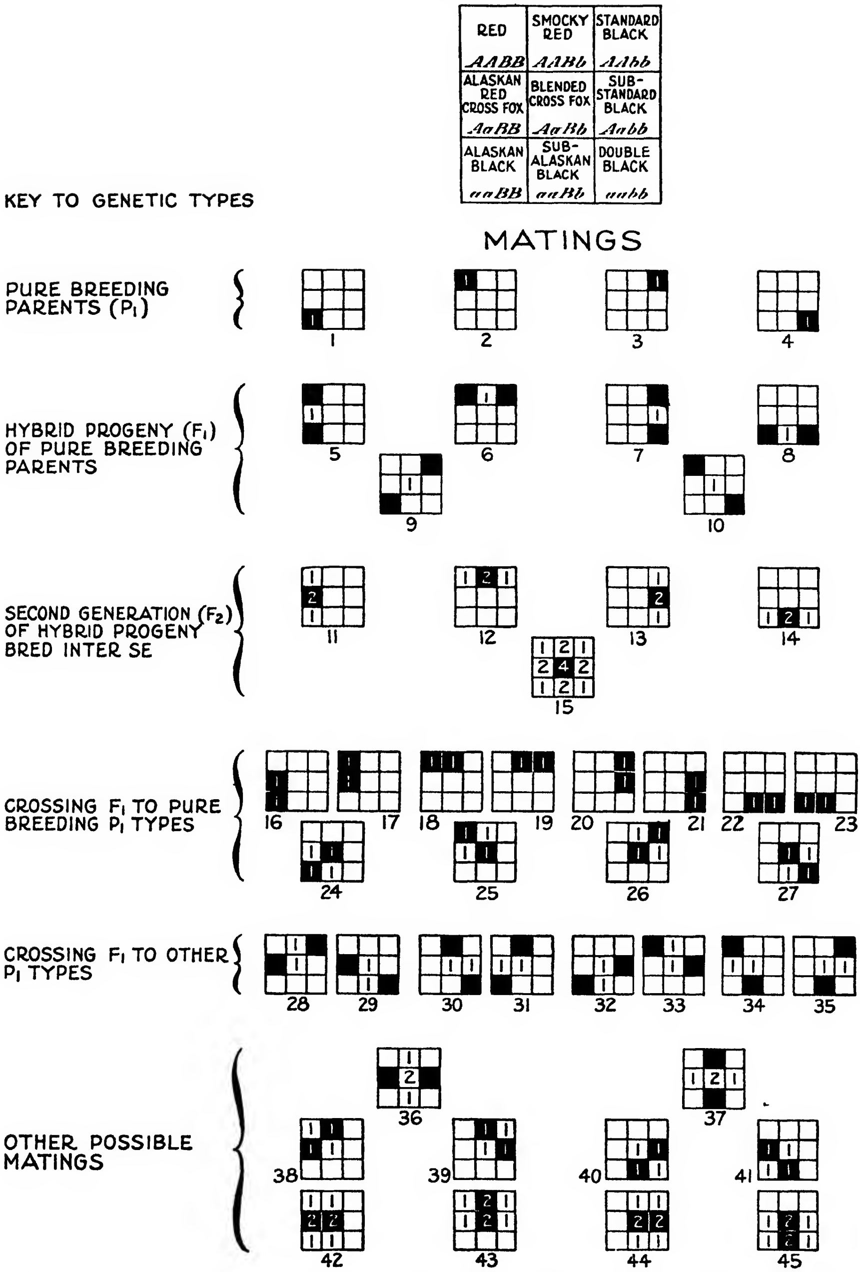

Figure 6.—**Diagram illustrating the genetic types of foxes and the results of various matings on the basis of a two-factor inheritance. Black squares represent matings, and numerals within the squares represent the expected distribution of progeny in proportions.**

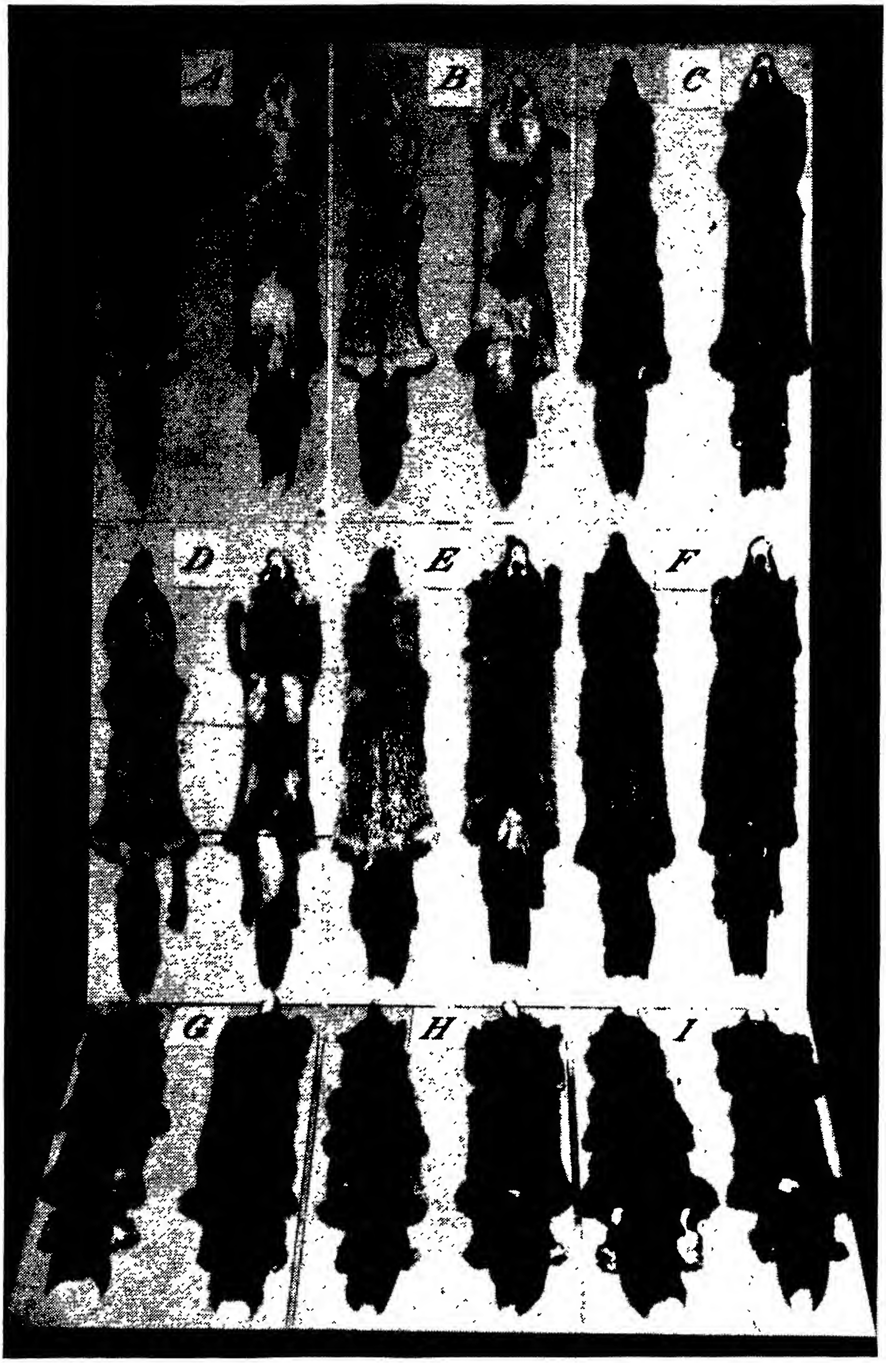

Figure 7. (Legend on opposite page)

indicates that two different genes are involved in Alaskan and standard black foxes.

In some instances when Alaskan blacks and standard blacks were mated, black young occurred in the litters. Check matings demonstrated that the occurrence of black in the first filial generation was due to the fact that one or the other of the parents was not pure but hybrid for either *A* or *B*.

Inadequate facilities and lack of funds made it impossible to maintain a sufficient number of foxes at the Fur Animal Station to make a complete investigation of this kind. Therefore, the research workers had to solicit the cooperation of fox farmers who had been conducting cross-breeding experiments in the United States and Canada. They willingly furnished the data obtained from their breeding operations, and these proved to be most valuable in amplifying the results obtained at the experiment station.

Hanson made a biometrical analysis of these data and found that three principal colors in foxes are inherited in accordance with the factor hypothesis previously mentioned. In 775 litters, including over 3,000 pups, representing 30 different combinations of types, only 4 litters were reported in which the results were contrary to the hypothesis. In at least two of these cases there was some doubt as to whether the vixen was served by two different males or whether the parents were improperly classified as to color.

Hanson designed a chart to illustrate the results of the various matings on the basis of two-factor inheritance (fig. 6). At the top of this chart is a key to the three different colorings and the nine different combinations of genes that result in nine different types. Directly under the key is a series of smaller nine-block squares giving the 45 different mating combinations of these nine types. The black squares in the blocks represent the genetic types mated and the numerals represent the expected distribution of progeny in proportions. Reference should be made to the key at the top of the chart to determine the colors (fig. 7) and genetic make-up of the animals being mated and also the progeny.[2]

As examples of the use of the chart: Suppose Alaskan blacks are to be mated with standard blacks. This mating is given in the set of

[2] In matings producing more than one kind of progeny the result may deviate in the distribution of progeny in individual litters or in a small number of litters, not only among foxes but among other animals also. For example, the expectation from crossing a substandard black with an Alaskan black (fig. 6, square 32) is that the progeny will consist of blended crosses and sub-Alaskan blacks in a 1:1 (50:50) ratio. As likely as not, this mating will produce an equal number of crosses and blacks (silvers). The probable occurrence of different combinations of cross and black foxes in litters of four thus produced is as follows:

Black (silver) foxes	4-3-2-1-0
Cross foxes	0-1-2-3-4
Total	4-4-4-4-4

Although these figures represent the proportion of black (silver) and cross foxes that may occur in litters of four, litters of that size do not always occur. In sufficient numbers there would be produced six times as many litters containing equal numbers of silver and cross foxes as there would be litters of all silvers or all crosses. Likewise the litters with three pups of one color and one of the other would be produced four times as frequently as would be litters of all one color.

Figure 7.—Fox pelts of the nine genetic types, upper and under side illustrated in each case, and grouped as in the square diagram in figure 6: *A*, Red, *AABB; B*, smoky red, *AABb; C*, standard black, *AAbb; D*, Alaskan red cross fox, *AaBB; E*, blended cross fox, *AaBb; F*, substandard black, *Aabb*; *G*, Alaskan black, *aaBB; H*, sub-Alaskan black, *aaBb; I*, double black, *aabb*.

squares numbered 9. The figure 1 in the middle square indicates that all the progeny will be blended cross foxes. Now suppose these blended cross foxes are bred together, as in the set of squares numbered 15. The figures in the squares indicate that every kind of fox will result from these matings, and that in a large number of matings the proportions may be expected to be 4 blended crosses, 2 Alaskan red crosses, 2 smoky reds, 2 substandard blacks, 2 sub-Alaskan blacks, 1 red, 1 standard black, 1 double black, 1 Alaskan black. If an Alaskan black is mated with a smoky red, as in the set of squares numbered 31, the result will be 1 Alaskan red cross to 1 blended cross. If a sub-Alaskan black is mated with an Alaskan red cross, as in the set of squares numbered 41, the result will be equal numbers of Alaskan red crosses, blended crosses, Alaskan blacks, and sub-Alaskan blacks.

A SUGGESTED PROGRAM FOR FURTHER RESEARCH

Fur farmers look to the scientist for leadership in the development both of basic information in fur-animal breeding and of methods of improvement, and they have appealed many times to the Federal and State Governments for assistance Little has been done, however, by public agencies to develop this new and promising animal-production enterprise, and there has been no systematic effort on the part of State agricultural experiment stations or the Department of Agriculture to develop, isolate, perpetuate, or record fur animals of superior breeding ability.

In order to place fur farming on a foundation comparable with that of other branches of agricultural production, fundamental knowledge is essential, and this can be obtained only by inaugurating a comprehensive program of research. Such a program might be conveniently divided into three parts:

1. Research work on reproductive cycles. Most of the study thus far has been concerned with domestic species, and the available definite information on wild animals is very meager, particularly as regards species of economic importance. A more exact knowledge of the reproductive cycles of North American fur animals could be applied in several ways. It would be of great value—(a) in determining the proper trapping seasons for restoring and conserving fur animals; (b) in attempting intelligently to supplement the natural supply by restoring and transplanting; (c) in insuring success in producing fur species in captivity; and (d) in making possible a more efficient and economical control of predatory and other injurious species. The object of research on reproductive cycles would be to establish definitely—(a) the breeding period of valuable fur animals; (b) the number of litters and young produced yearly; (c) the type of embryonic development (whether uninterrupted or with a delay in implantation); (d) the hormone control of the breeding cycle; (e) the feasibility of artificial insemination in those species that might be raised in captivity; and (f) possibilities for producing or maintaining reproductive fertility by hormone or other treatment.

2. Breeding experiments with various fur animals under controlled conditions. These should be conducted to study the inheritance of prolificacy and fur quality, which includes color, sheen, and density.

In all animal breeding it is vital to concentrate on as small a number of objectives as possible. Measurements must be devised to evaluate all these characteristics with greater certainty, especially fur quality. Similarly, there should be measurements for efficiency of feed utilization, since the cost of feeding is a large part of the cost of production. Where genetic factors (genes) might be directly useful, as in the case of coat colors, they should be determined so far as possible. They will doubtless prove to be extremely complex, but the research on color inheritance already described indicates that something may be done to segregate definite traits of this kind and to breed for them. Meantime, to use breeding stock of proved performance, as determined by the progeny test and by dependable records of parental characteristics, would be to approach the problem in the way that has proved to be of such great value in other branches of livestock breeding.

3. Attention to nutrition. This article is concerned primarily with breeding and genetic research, but in any comprehensive research program, nutrition is equally important. Practically no fur-animal research studies have been conducted on digestion and metabolism, the chemical composition of foods, and the part played by various foods in growth, fattening, maintenance, reproduction, and the economical production of pelts of high quality. With few exceptions, all fur animals are meat eaters. The maximum and minimum quantities of red meat that can be fed during the various stages of development should be determined. Some work has been done to determine the value of cereals, vegetables, and protein supplements in the ration, but it should be expanded. These and many more nutritional problems when adequately solved will enable fur-animal breeders to proceed more surely, safely, and efficiently.

Without extensive controlled experiments, all breeding and feeding practices are of a hit-or-miss nature. But experiments with fur animals are exceptionally costly, not only in the matter of equipment, but also in the time involved, for breeding stocks are expensive and practically all species produce only one litter a year. In addition, scientific training and the ability to conduct research are required, and the economic results of any given project are by no means certain. Private breeders therefore are not likely to do much experimenting, because they must confine themselves to operations that are fairly certain to produce immediate profits. Fur-farmers' organizations or wealthy producers might undertake some forms of research work, but men change their minds and associations change their policies, and under these conditions there is no assurance of continuity. There are many reasons why fur-animal research must be conducted primarily by properly equipped public institutions, but this can be done only in response to a sufficient public demand and with the active support of those who have a stake in the industry.

BEE BREEDING

W. J. NOLAN, Apiculturist, Division of Bee Culture, Bureau of Entomology and Plant Quarantine

THE economic importance of bee breeding, measured in dollars, is probably greater than is realized even by the beekeeper. The potential stake of agriculture in the United States in queens alone is over $2,000,000, if a value of 50 cents, the minimum price set by the marketing agreement governing the sale of queens, is placed on each of the

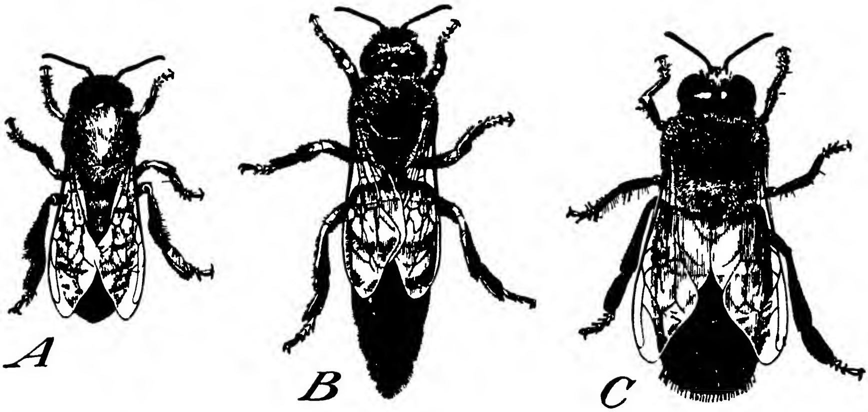

Figure 1.—The three inhabitants of the hive: *A*, The worker, a female with arrested development of the egg-laying organs; *B*, the queen, a female with completely developed egg-laying organs but with undeveloped secondary sexual characters such as those possessed by the worker for secreting larval food, for gathering nectar and pollen, for secreting wax, and the like; *C*, the drone, the male bee. During the height of the season, a bee colony may consist of several thousand workers and a few hundred drones, but it normally contains only one queen at any time.

queens in the more than 4,000,000 colonies of bees in this country. The amount invested in bees, hive and honey-house equipment, and the like is $35,000,000 to $50,000,000 on the conservative basis of $8 to $12 per colony. Whether a fair return is being received by the beekeeper on these sums, plus the amount involved for his time and labor, depends primarily on the blood represented by the queen and by the drone with which she mates (fig. 1).

The public is also directly affected by the breeding problem, not merely from the standpoint of being insured an abundant supply of honey, but from the more important standpoint of having bees that will function as efficiently as possible in the pollination of many of

our crops. For example, clover crops, which are so fundamental in the dairy and livestock industries, apples and other fruits, and truck crops in greenhouses are now more or less wholly dependent on the efforts of the honeybee. There is interest also in increasing the supply of native beeswax, which at present comes so far short of meeting domestic demands that large quantities are imported annually. The bee is far more valuable to American agriculture through all these other activities than through its honey production. As a matter of fact, the activities of the honeybee are so varied and so useful that practically every person benefits by them in some way or other, and so will benefit, indirectly at least, by any improvements that result from scientific breeding.

FACTORS LIMITING PROGRESS OF THE BEE BREEDER

In spite of its importance, bee breeding is only in its infancy, one reason being that promising methods for mating queens and drones under laboratory conditions had not been worked out until within the last few years. Prior to the development in 1923 of the Quinn-Laidlaw technique discussed later in this article—whereby, through the agency of the operator, the drone organ is everted in proper position in relation to the queen for insemination to take place, and in

SEVERAL *desirable characters have been commonly recognized among the varieties of honeybees used in the apiary, but the breeder during past years has been able to do little in combining these in one bee because in nature queen and drone mate only on the wing. These characters have to do with disease resistance, color of comb cappings, size of body parts, constancy of color markings, disposition, and swarming propensity. Because of recent work that shows the feasibility of accomplishing the insemination of queen bees by laboratory methods, the breeder is now in a position, however, to utilize the characters already available in the germ plasm of bees and to start at once toward the goal of breeding bees better adapted to present agricultural demands. It would be a great and perhaps not impossible achievement to breed a bee with the long tongue of the Caucasian, capable of reaching sources of nectar not now available to most honeybees; the gentleness of the Caucasian and the Carniolan; the white comb capping made by the black bee and the Carniolan; the reduced swarming tendency, and the resistance to common hive enemies and European foulbrood, of the Italian; the uniform marking of the Cyprian; and the industriousness of the Italian or Cyprian.*

1926 of the Watson technique for the artificial insemination of queen bees through the transfer of sperm from drone to queen by means of a microsyringe (fig. 2), the bee breeder was forced to trust to luck in his work, because he had to rely on chance natural matings in midair, since in nature the honeybee mates only while on the wing away from the hive. A successful method for obtaining natural matings of queen and drone in confinement still remains to be developed.

Figure 2.—L. R. Watson, who developed the Watson method for the artificial insemination of queen bees, seated at his instruments.

Another reason for the backwardness of bee breeding is the fact that only since the application of biometric methods in studying the body parts of individual bees, a development of recent years, has progress been made in working out a method whereby the breeder can readily identify the race or strain with which he is working. Mendel, the father of modern genetics, lacked a means of distinguishing between strains when he endeavored to work out problems of bee genetics in addition to those of the genetics of peas, which brought him fame (*9, pp. 142–157*).[1]

The first investigator to make a comprehensive biometric study of the honeybee was Kozhevnikov (*12*), who in 1900 endeavored to separate the various races on the basis of physical measurements made with the aid of a microscope. He included such measurements as hooks on the wing, tongue length, length of leg segments, length of abdominal segments, length of wings, and the like. Since that time Russian investigators have been particularly active in this field.

However, the problem of checking differences between various crosses, strains, and races of the honeybee on the basis of the physical characteristics of individual bees, or even of the productivity of colonies, and then utilizing the results in breeding, is far more complicated than with other farm animals. This is due not only to the small size of the honeybee, but also to the fact that honeybee productivity represents the collective efforts of the thousands of individuals making up a colony. It is even hard to define a standard colony for purposes of any comparative experiments, since, even under the same natural conditions outside the hive, within the hive the physiological ages of the individual bees differ. Furthermore, the honeybee cannot carry on its life functions indefinitely in confinement, as can cattle, poultry, rabbits, or even pigeons.

Advances in scientific bee breeding are also limited by the variety of demands on the breeder. Queens must be reared and tested; drones must be reared; mating of queen and drone must be accomplished;

[1] Italic numbers in parenthesis refer to Literature Cited, p 1537.

progeny must be tested for colony characteristics and production, as well as for physical characteristics of individuals; and results must be evaluated. The scientific breeder should possess a working knowledge of the biology of the honeybee, including an intimate knowledge of its various races and strains, and of genetics, biometrics, and supplementary fields as well. In short, he should be a combination beekeeper, laboratory technician, biometrician, and geneticist, or know how and where to utilize the services of specialists in the various fields involved.

Another situation faced by the bee breeder is the fact that worker bees cannot be bred, and the queen and drones, mating but once in a lifetime, cannot be used in line breeding involving parent-offspring crosses. Furthermore, since queen and drone function only in reproduction, progeny tests—in other words, the collective colony behavior exhibited by the worker progeny—must be relied upon exclusively in testing the inheritance of the queen and drone for such economically important characters as honey gathering, wax secretion, pollinating activity, and the like. Even when a parent queen is bred pure for the same color factors as the drone with which she mates, her color pattern may differ from that of her worker daughters, since in some races, the Italian being one, the causes that lead to the development of worker structures in a larva, with a resultant arrest in the development of its reproductive organs, also lead to a modification of its color pattern.

MORE KNOWLEDGE REGARDING REPRODUCTIVE PROCESS NEEDED

The advantageous employment of present mating methods, or their improvement, whether natural or artificial insemination is involved, will be facilitated when the physiological processes preceding and accompanying mating are better understood, since much remains to be known regarding the conditions most favorable for mating. For example, the consensus of opinion is that the queen mates when about a week old or shortly thereafter, but a queen 56 days old has been artificially inseminated with success. A knowledge of the external signs, if there are any, that queen and drones are ready for mating should go far in increasing the usefulness of methods of artificial insemination and also be of advantage in work involving natural insemination.

As a matter of fact, until recent years little was known about reproduction in the honeybee. Knowledge that drones are produced from unfertilized eggs (parthenogenesis), at least in European varieties of the common honeybee, dates only from the middle of the last century, and the origin of queen and worker and the fact that the queen mates on the wing outside the hive has been known for only about 150 years.

More has been done in studying the mating processes in the drone than in the queen. The most complete study on the drone is that by Bishop (*4*), who found that usually the drone is not sexually mature until the ninth to twelfth day after emergence, but that some drones are apparently incapable of mating at any age. Bishop also found the function of the mucus, which the male organ contains in addition to sperm. During mating the sperm is merely transferred from the

drone to a temporary storage place in the vagina and oviducts of the queen. The spermatozoa collect within the spermatheca during the next few hours and may live there for 6 years or more. While still in the oviducts and vagina, however, the sperm might all escape through the genital opening were not this opening filled with the mucus from the drone when the last of the sperm has entered. This mucus quickly hardens on exposure to air, and thus forms a temporary stopper in the genital opening.

The anatomy and the physiological responses of the queen in relation to mating are being studied by Harry Laidlaw, formerly in the employ of the Department but now a graduate student at the University of Wisconsin. This study includes the structure and functioning of the queen's genital organs, a subject on which little is known, but a knowledge of which is demanded for the further successful development of methods, not only of artificial insemination but even for obtaining natural matings in confinement. Laidlaw has found that a membranous fold arising from the floor of the vagina fits so snugly in the genital passage as to be able to thwart attempts to inseminate queens artificially by his method or perhaps sometimes to defeat efforts to insert the glass syringe by the Watson method.

MATING STATIONS AN EARLY STEP IN THE BREEDING PROGRAM

In spite of many handicaps, the bee breeder has not been idle. During the period when he was attempting to bring the mating of the honeybee under laboratory control, he made such use of natural matings as he could by establishing mating stations in isolated bee-free localities, taking virgins and drones of desired stock there to mate. The possibility, however, that the queen may mate with a stray drone, even in a locality thought to be well isolated from local bees, reduces the value of mating stations in a scientific breeding program.

The first reported use of isolated localities in an endeavor to obtain pure matings of bees was that by Baldenstein (*2*) in Germany in 1848. Breeders in a number of European countries are now carrying out investigations by means of bee-mating stations. In Switzerland the association of German-speaking beekeepers has for a number of decades conducted a well-supported movement, inaugurated by the Swiss beekeeping leader Kramer, to maintain and improve the native Swiss bee by having selected queens mate in isolated localities at stations stocked with drones of desired strains. The mating stations are in charge of personnel from the beekeepers' association. Beekeepers bring virgin queens or queen cells in mating nuclei to these stations and take back the mated queens. The method resembles the use of community-owned sires in cattle breeding.

On this side of the Atlantic such stations have not been used so much in scientific investigations. The notable exceptions are the breeding experiments conducted a number of years ago in Texas by Newell (*21*), and those by Sladen (*34*), of Canada, in progress on an island in Lake Ontario at the time of his death in 1924. Even commercial queen rearers have made little use of mating stations, because in this country isolated locations free from wild swarms or colonies of neighboring beekeepers are not easily accessible to most queen

rearers. In Colorado, however, a strain of the Caucasian race was maintained for at least 25 years through natural matings in an isolated locality (*1, p. 40*). Certain commercial queen rearers in this country have attempted insofar as possible to duplicate conditions found in an ideal mating station by endeavoring to rid the territory in the immediate vicinity of their mating yards of undesirable colonies of bees. Their methods have consisted of buying up colonies found in the neighborhood, requeening colonies nearby with desired stock free of charge, paying rewards for wild swarms, and similar measures.

OBJECTIVES OF THE BEE BREEDER

What are the immediate objectives of the bee breeder? He may attempt to standardize the various strains now existing that are of economic importance. He may even attempt to develop strains that are more gentle, more disease-resistant, capable of carrying larger honey loads, or capable of flying longer distances than strains now available. He may attempt to develop strains with tongues long enough to secure nectar from floral sources not now available to the honeybee. For some regions it would seem desirable to develop strains that fly at lower temperatures than do bees now commonly found in the United States. This is of particular importance to those interested in bees as pollenizing agents.

The breeder need not await the occurrence of mutations, or an exhaustive survey of existing strains, to find some definite character of economic importance with which to begin work. On the contrary, he is able to start at once toward his goal, a bee better adapted to present agricultural demands, since not one but several desirable characters have already been identified among the varieties of honeybee now used in the apiary. Other desirable characters may exist, while still others are to be expected from future mutations occurring either naturally or under experimental conditions.

What are the characters in the available germ plasm with which work may be begun immediately? They are related to disease resistance, color of comb cappings, size of body parts, constancy of color markings, disposition, swarming propensity, and the like. For instance, the breeding of a bee in which are incorporated the long tongue of the Caucasian, the gentleness of the Caucasian and the Carniolan, the white capping made by the common black bee and the Carniolan, the reduced swarming tendency and resistance to common hive enemies and European foulbrood of the Italian, the uniformity of marking of the Cyprian, and the industriousness of the Italian or Cyprian would be a big achievement. Some commonly accepted worker characters, desirable and undesirable, and the races in which they are found are given below:

Character	Race
Resistance to European foulbrood	Italian.
Fighting wax moth	Italian, Cyprian.
Hive cleanliness	Italian.
Clinging to frame during manipulation	Italian, Cyprian.
Running on frame during manipulation	Common black, European brown.
White cappings on honey	Common black, European brown, Carniolan.
Water-soaked cappings	Cyprian.

Character	Race
Tongue length over 6.75 mm	Caucasian.
Tongue length under 6.25 mm	Common black, European brown.
Long legs	Caucasian.
Uniformity of markings	Cyprian.
Yellow scutellum	Do.
Gentleness	Caucasian, Carniolan.
Viciousness	Cyprian.
Reduced swarming tendency	Italian.
Excessive swarming	Common black.
Propolizing tendency	Caucasian.

BEE BREEDING IN THE UNITED STATES

Investigations of the Department of Agriculture

The Department of Agriculture was a pioneer in providing the American beekeeper with new breeding stock. It began this work by bringing in bees from Europe in an effort to have better blood than

Figure 3.—Multiple set-up devised in the Department of Agriculture for inseminating each equipped with a microsyringe and apparatus to hold the queen during the opera

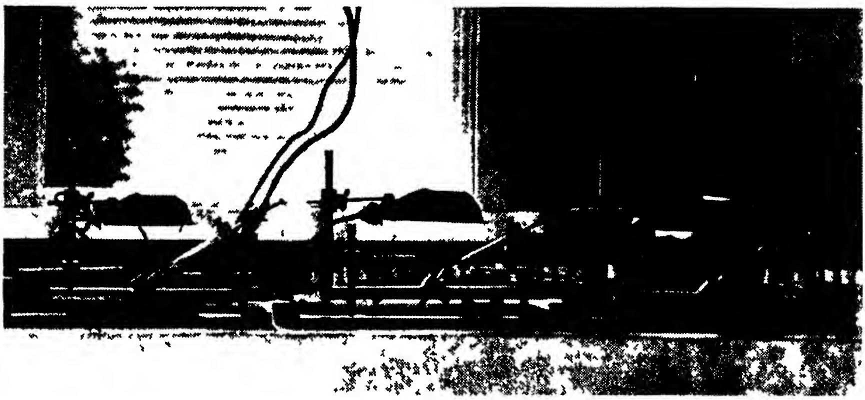
that represented by the common black bee, introduced about the middle of the seventeenth century, and as a result is credited with having established the Italian race in the United States through importations made in 1860.

In 1905 the Department sent a specialist around the world, primarily to secure the introduction of *Apis dorsata* Fab., the largest honeybee known, but the effort was unsuccessful. At that time the Department was distributing queens of the Cyprian, the Carniolan, and, more especially, the Caucasian race. During the last few years it has given further attention to a study of various races. As a result of this work and observations made by beekeepers in general, the recommendations of the Department as to an all-around bee for this country, for anyone other than the bee specialist or fancier, are usually limited to the Italian or Caucasian race.

The Department also led the way in this country in attempts to develop methods for the artificial insemination of queen bees. As early as 1885, the date when it employed its first full-time specialist

in beekeeping, it set forth as one of his duties: "To make experiments in the methods of artificial fertilization and, if possible, demonstrate the best process by which the same may be accomplished." Some slight success was reported from this early venture, and a method described in which a fine-pointed syringe was employed, as in the present Watson method, but this early work was not followed up. In 1907 the Department conducted unsuccessful attempts to obtain the mating of queens on the wing within enclosures.

Within the last few years the Department (*23*) has greatly simplified the technique and equipment for the Watson method, reducing the cost of equipment and making it possible to operate on several queens more or less simultaneously, thus increasing the output (fig. 3) Some of the special features of this new equipment differentiating it from that developed by Watson are as follows: Only one microscope is needed in using a large number of syringes; a cheap and easily made manipulator is provided for the microsyringe; the queen is held in a



several queens more or less simultaneously The set-up shown consists of 6 separate units, tion. One microscope serves the entire set-up, being moved from unit to unit as needed.

glass tube with only her abdominal tips projecting, instead of being bound by thread to a small wooden block hollowed out to fit her body; and the queen's abdominal tips are spread apart by a pair of metal hooks held mechanically instead of by forceps held by hand (fig. 4). With this equipment the genital opening of the queen can be found quickly under the miscroscope, and the microsyringe then can readily be brought into correct position for discharging the sperm without injury to the queen.

A durable microsyringe, all metal except for the minute plunger tube of glass that holds the sperm, has been developed from an automatic pencil by substituting a fine wire plunger for the lead and attaching the plunger tube to the point of the pencil. The earlier syringe consisted of a piece of glass tubing drawn out to proper shape for holding the plunger and plunger mechanism, as well as for attaching the plunger tube.

Sperm to fill the syringe is obtained by causing partial eversion of the drone organ by pressure on the drone, after which the bulb con-

taining both sperm and mucus is pulled loose with a pair of forceps. With the bulb still held in the forceps, the end containing the white mucus is cut away and the remainder, forming a minute sac containing the cream-colored sperm, is slipped over the point of the syringe. The sperm is then drawn into the plunger tube.

The Department has also modified the Quinn-Laidlaw method for artificial insemination, commonly referred to as a "hand-mating"

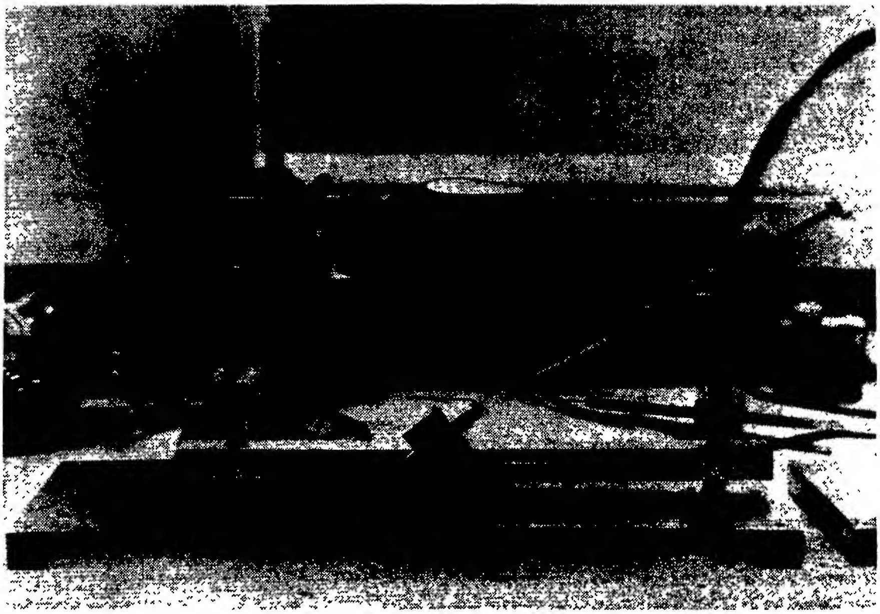


Figure 4.—Separate unit of the multiple set-up, showing queen and microsyringe in position. The microsyringe differs somewhat in construction from the original Watson type but works on the same principle. A less fragile microsyringe, all metal except for the glass point and with the movement of the plunger in and out caused by direct action, has since been devised in the Department.

method, by using a glass tube to hold the queen and a small spring placed inside her abdominal tips to hold them apart (*14*). A microscope is now used during the process. As when the method was first developed, the drone is so held by hand as to cause partial eversion of its genital organs and is then so placed in relation to the queen that the transfer of sperm will be accomplished after complete eversion has taken place.

Biometric data on common races of the honeybee and on the progeny of various crosses made by controlled matings are being collected by the Department to determine racial or strain characters of a quantitative nature and their behavior in crosses. The data collected so far consist mostly of linear measurements of various parts of the head, thorax, and abdomen. The specimens are mounted on slides under a microscope and the measurements are made on projected images (fig. 5). Those of head parts (fig. 6) include

tongue and scapus (the long joint of the antenna). On the thorax they cover counts of hooks on the hind wing and dimensions of the fore wings (fig. 7, *A*) and hind legs (fig. 8). On the abdomen the measurements deemed important are width of the third tergum (the upper surface of the third segment), longest width of third sternum (lower surface of third segment) across its left wax plate, and longest dimension of the wax plate itself. The first two abdominal segments, because of their shape and lack of wax plates, do not lend themselves to such measurements (fig. 9).

Figure 5.—Apparatus used in the Department of Agriculture for measuring external parts of bees. A micrometer eyepiece with a movable scale is attached to the microscope.

The size of the foregoing parts is of economic interest as well as of value in distinguishing races or strains, because nearly all of them function directly in the gathering of nectar and pollen and in the production of wax. The tongue, for instance, is of importance in nectar gathering. The wings are important in all activities taking the bees away from the hive. The hind legs carry pollen. The abdominal segments contain the wax plates, and may serve to limit the size of the honey sac.

Characters of a qualitative nature are also being studied. These include gentleness, industry, disease resistance, and the like. At the present time the Department is engaged in a cooperative undertaking with the States of Iowa, Texas, Wisconsin, and Wyoming, to search for stock resistant to American foulbrood, and then to combine the factor for resistance, if any be found, with other desirable factors by breeding.

During the past year the Department has employed a trained geneticist for the first time in its beekeeping work. His immediate genetical problem is to determine whether heritable factors affect supersedure, especially the premature supersedure of queens sold commercially. By "supersedure" is meant the replacement of the queen by another reared by the colony apparently for that purpose.

If heritable factors play a part in this behavior, they may lie in the behavior of the queen alone—lack of fecundity, for example—or they may lie in the behavior of the workers—for example, undue hostility to a queen reared in another colony.

State Bee-Breeding Work

Only a few States have been engaged in breeding work. A number of years ago Shafer (*30*), at the Michigan Agricultural Experiment

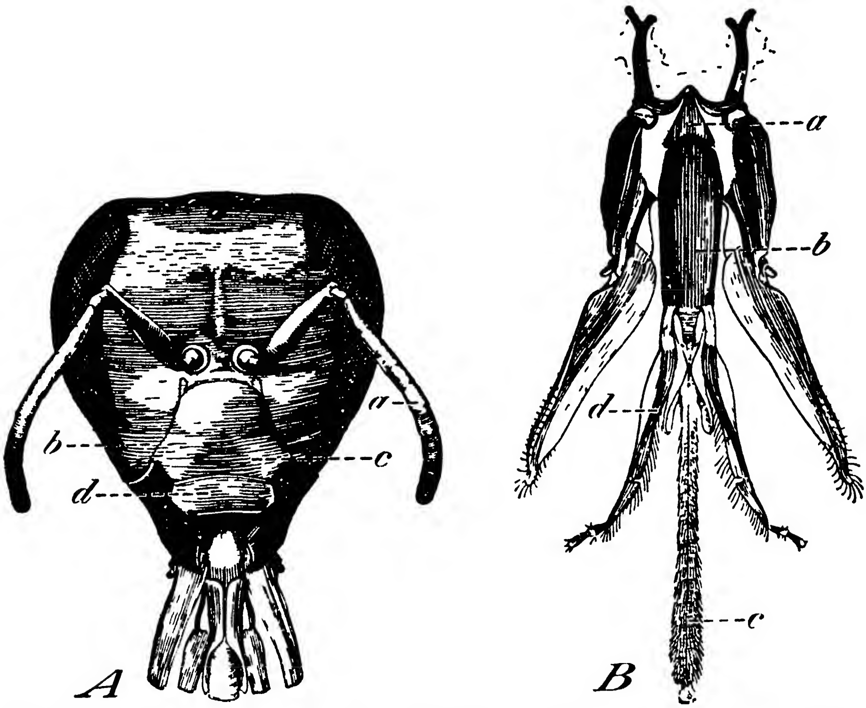

Figure 6.—*A*, Head of bee, showing: *a*, Antenna; *b*, gena; *c*, clypeus; and *d*, labrum. Tongue is shown extruded but cut off. *B*, Extended tongue, showing: *a*, Submentum; *b*, mentum; *c*, ligula; and *d*, labial palpus. (Drawing by Snodgrass.)

Station, made an unsuccessful attempt to obtain controlled matings of queen bees by natural insemination. The New Jersey Station conducted bee-breeding work in an isolated location for a number of years in connection with a study of disease resistance. More recently the Iowa Station, in cooperation with the American Bee Journal, has been engaged in a program to find stock resistant to American foulbrood and to breed for this character. The Texas Station is endeavoring to breed a bee that will better withstand Texas weather and possess greater honey-gathering ability than present strains. The College of Agriculture of the University of California is studying the correlation between physical characters of queens and their productivity, and is also studying environmental factors that influence the development of queens. The College of Agriculture of the University

of Minnesota a number of years ago conducted work on the artificial insemination of queen bees by the syringe method, with some slight success. In this work, performed by Jager and Howard (*10*), the sperm was diluted with salt solution.

Merrill (*16*), while in charge of apicultural work at the Kansas State Agricultural College, became the American pioneer in the biometric study of the activities of the colony as a whole. He attempted to correlate honey production with tongue length, size of honey sac, and other physical characters. A few years ago Munro (*19*), while a student at this college, made a study of color inheritance, using natural matings. At present E. J. McNay, a graduate student at the same institution, is making use of the Watson method in breeding work.

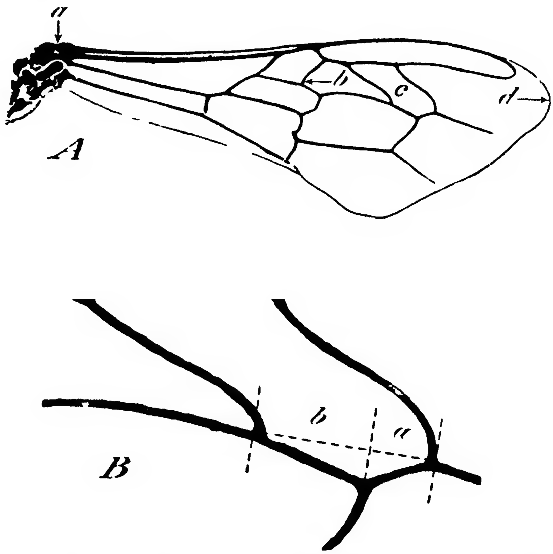

Figure 7. *A*, Front wing of honeybee, showing: *a–b*, Proximal length measured; *b–d*, distal length measured; *c*, third cubital cell. *B*, Cubital cell enlarged to show method of measuring cubital index (*a*/*b*). (Drawing by Snodgrass.)

Work by Private Breeders

The outstanding bee-breeding work of a private nature is that by Watson (*36*, *37*), who developed the method for the artificial insemination of queen bees that bears his name, and who now holds a Guggenheim fellowship for the study of bee breeding. He is making a survey of tongue lengths of various strains in an endeavor to develop a longer tongued bee than is now available. He is also trying by artificial insemination to perpetuate the "Albino" bee, a mutation of the Italian that appeared in this country about 50 years ago but has now apparently disappeared except for stock in Watson's apiary. This bee is marked by an unusually large quantity of long gray or white hairs, especially on the abdomen.

Jay A. Smith is using the Watson method in an endeavor to breed a more yellow and gentler bee. In a private communication he reports success in diluting the sperm with a saline solution before taking it into the microsyringe.

About 25 years before the present methods for the artificial insemination of queen bees were developed, Root (*26*) greatly stimulated interest in bee breeding through publicity given a "red clover queen" of the Italian race, from which was bred progeny said to have exceptionally long tongues for Italian bees. This strain soon disappeared. Among present-day workers in this country who are endeavoring to

breed bees by natural insemination may be mentioned Ralph Benton and Erwin Alfonsus, the latter formerly with the University of Wisconsin.

Balinkin (*3*) and Clifford Muth have pioneered in this country in the application of ultraviolet rays to young queens, but details of their method have not yet been published. An increase in egg laying and progeny with better dispositions were reported, but it was not claimed that this modified behavior is transmissible.

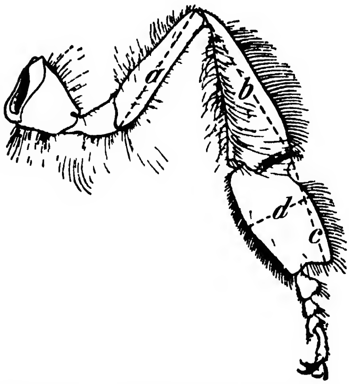

Figure 8.—Hind leg of worker bee, showing measurements made: *a*, Length of femur; *b*, length of tibia; *c*, length of metatarsus; *d*, width of metatarsus. (Drawing by Snodgrass.)

BEE BREEDING IN FOREIGN COUNTRIES

Numerous foreign workers are interested in bee breeding (see the appendix). The work of the German-speaking beekeepers' association in Switzerland has already been mentioned. Breeding along the same lines is in progress in Germany and elsewhere in central Europe. Zander (*40, p. 193*), assisted by A. Himmer, for years used isolated mating stations to breed an improved strain of the European brown bee, as part of the program of the bee-research institute at Erlangen. Armbruster (*2*) is another German investigator who has worked in this field.

Gotze (*7*), also of Germany, has been engaged in a biometric study of progeny of crosses obtained at mating stations. He has reported unsatisfactory results in the use of artificial insemination. He places considerable reliance upon certain indices, which are based on proportions involving certain wing cells, as a means of identifying various strains with which he works. The most important of these is the cubital index, which is the ratio of the two parts into which the line joining the two corners of the third cubital cell of the front wing on the side bounded by the cubital vein is divided when a perpendicular is dropped from this line to the second recurrent vein (fig. 7, *B*, illustrates this measurement).

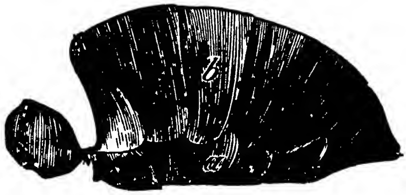

Figure 9.—Lateral view of worker abdomen showing the six abdominal segments, including a portion of the thorax at left: *a*, Left end of third abdominal sternum; *b*, left end of third abdominal tergum. (Drawing by Snodgrass.)

Alpatov (*1, p. 24*), of the Union of Soviet Socialist Republics, has perhaps made a wider use of biometrical indices in studying the differences of races or strains than has any other investigator. Some indices used by him are the proportion between width of the first wax gland and width of the sternum that contains it, length of the hind metatarsus and width of third abdominal tergum, length of hind tibia and width of third abdominal tergum, length of hind femur and width of third abdominal tergum,

distal length and proximal length of front wing, and width and proximal length of front wing (figs. 7, 8, and 9).

Jaroslav Rytiř, of Czechoslovakia, has made observations on the inheritance of measurable characters of various strains, including "strain 47". This strain was developed, or rather perpetuated, by the Austrian queen breeder Sklenar (*31, p. 5*) from a colony that had been outstanding in his apiary. Sklenar thinks the strain is descended from a mixture of the Carniolan and Italian races, although the workers show no yellow color. They are usually gray but occasionally one is reddish brown. Rytiř (*27*) has also studied inheritance of amount of coloration on abdominal segments, and has devised a workable system for obtaining quantitative data on this characteristic.

A few years ago Mikhailoff, of the Union of Soviet Socialist Republics, reported considerable success with the Watson method. From the same country also came the Malyschev method (*15*). This differs from the Quinn-Laidlaw method in that the drone organ is first dissected out under the microscope and then placed in position in the queen. Prell (*25*), of Germany, working independently, reported success with a method like that of Malyschev.

GEOGRAPHICAL STATUS OF DEVELOPMENT OF BREEDING TECHNIQUE

In the United States successful methods for the controlled mating of queen and drone under laboratory conditions have been developed and existing races of the honeybee have been tried out. In western and central Europe workers have made praiseworthy attempts at the improvement of bees by selective breeding in isolated mating stations. In the Union of Soviet Socialist Republics breeding work has centered largely around biometric studies in an endeavor to reduce the characteristics of races and strains to some sort of mathematical formula whereby each can be more easily distinguished. Some work has been carried out with artificial insemination.

CYTOLOGICAL STUDIES [2]

Too little is known concerning the cytology of the honeybee. For a long time the work of Nachtsheim (*20*), which seemed to show that the diploid number of chromosomes (that of queen and worker) is 32 and that the haploid number (that of drones) is 16, has been accepted as standard. In recent work, however, Sanderson (*29*) has questioned whether Nachtsheim has reported the normal numbers or whether they are not 16 and 8 for queen and drone, respectively. The characteristic shape of any of the chromosomes has not yet been determined.

Even the type of sex chromosome and the method of sex determination in the honeybee are still undetermined. Nachtsheim holds that the sex chromosomes are of the X type, the female possessing two and the male but one, since the drone arises from an unfertilized egg. Likewise the female possesses twice as many other chromosomes (autosomes) as does the male. Consequently, according to Nachtsheim, sex is determined on a quantitative basis—doubling the sex

[2] The following sections are written primarily for students and others professionally interested in breeding or genetics, although some of the results discussed are also of general interest

chromosome and autosome complement results in a female instead of a male. This view is not in accord with the theory of genic balance that is now applied to so many organisms. According to this theory, sex is not determined on a quantitative basis, but is the resultant of a tendency towards maleness or femaleness in genes of the autosomes taken as a group and an opposing tendency in genes of the sex chromosomes.

In contrast to Nachtsheim's theory of sex chromosomes in the honeybee, Whiting (*39*) holds that in the parasitic wasp *Habrobracon juglandis* Ashmead, another hymenopterous form in which males develop parthenogenetically, the two sex chromosomes of the female are of the XY and not of the XX type. Consequently two types of haploid males develop, depending on whether they contain a single X or a single Y chromosome. Outwardly they appear alike, but they can be identified genetically. They are produced in equal numbers. Of even greater interest, two types of biparental males are to be found and these contain either two X or two Y chromosomes. Biparental males, like the females, carry two sets of autosomes, but cannot be distinguished from the ordinary parthenogenetic males unless the parent male possesses a factor that is dominant to the homologous factor carried by the homozygous mother.

Whiting (*39*), basing his conclusions on experimental evidence, explains sex determination in *Habrobracon* by assuming that the X chromosome carries the factors $F.g$ while the allelomorphs ($f.G$) of these two factors are carried by the Y chromosome. The presence of both F and G, classed as "complementary factors" by Whiting, is necessary for the development of a female, otherwise only a male will result. The dominants F and G would both be present, of course, whenever fertilization of the egg represents the union of X and Y, since the egg would then carry the factors $F.g/f.G$. The union of a sperm and an egg each of which has an X chromosome, or each of which has a Y chromosome, could only result in a biparental male, because in either event the fertilized egg would contain only one of the two dominant complementary factors necessary if a female is to result. The factors in the one case would be $F.g/F.g$, and, in the other $f.G/f.G$. Whiting's line of reasoning would hold, whether F and G each represents only a single dominant gene or whether they are the symbols of a group of dominant genes carried in their respective chromosomes (X and Y).

Whiting (*38*) first encountered biparental *Habrobracon* males in a culture headed by a female homozygous for orange-colored eyes but mated to a male with black eyes, the dominant color. Instead of all the sons having orange eyes, a few resembled the daughters in having black eyes. Such males usually proved sterile, although in certain instances in which they were mated with females homozygous for orange-colored eyes a few daughters were obtained, some with orange eyes and some with black eyes. A knowledge of whether or not Whiting's results on *Habrobracon* hold good for the honeybee awaits further work.

The fact that the drone is haploid seems to have led to the impression that drones from a heterozygous queen will be only of two kinds,

corresponding to the queen's maternal and paternal inheritance. Such a conclusion holds only if one pair of unit factors or linkage groups is under consideration. For example, normally half the drones from a queen heterozygous for color say, yellow and black—would carry the factor for yellow and half of them the factor for black if these were unit factors. Her drones would fall into four types, however, if their inheritance of any two pairs of unlinked factors is considered. Thus, if it is assumed that the characters for tongue length and those for color are not linked, but that each is determined merely by a unit factor, a queen heterozygous for these two factors would produce long-tongued yellow drones, short-tongued yellow drones, long-tongued black drones, and short-tongued black drones. The greater the number of pairs of unlinked factors that are under consideration, the greater will be the number of types into which the drones can be classified.

RESULTS OBTAINED FROM BEE BREEDING

It is unfortunate that Mendel's detailed records have never been brought to light. His studies were not confined to one race of the honeybee, since it is reported (*9*) that he worked on the heather or Dutch bee, the Italian, the Carniolan, the Egyptian, and the Cyprian, in addition to the native bee of his region.

Since so much of the work concerned the development of a technique for breeding the honeybee under controlled conditions, and a biometric study to determine measurable physical characters of individual members of a colony as well as characteristic colony behavior marking races or strains, strictly genetic results are scanty as yet, and often of a somewhat general nature.

The work of the Department has verified the fact that honeybees can be successfully carried from generation to generation by means of artificial insemination, seven successive generations having been obtained in three seasons' work. Allowing the queen 16 days to develop from egg to adult, 7 days in which to mate, and 3 more in which to begin egg laying, there should theoretically be a laying queen of each successive generation every 26 days, but the normal hazards and delays of beekeeping have greatly increased this period in actual practice.

The Department has verified Watson's feat (*37*) of transferring sperm from the spermatheca of one queen to that of another. The queen from which sperm was transferred had been dead for several hours. This procedure makes possible a type of line breeding, involving crosses of a drone with his offspring, although on an extremely limited scale, because the supply of sperm from the original drone cannot be replenished but will be diminished when transferred from queen to queen.

The work of the Department also indicates that color and tongue length can be inherited independently of each other and that each race has its own size characteristics, which are inheritable and more or less constant within fairly definite limits. Judging from preliminary data, some correlation exists between tongue length and number of wing hooks, and also between tongue length and length of scapus. Götze's statement (*7, p. 227*) of the correlation between tongue

length and length of labial palpi also seems borne out by the work thus far.

A hitherto undescribed mutation, involving a yellow coloration on the face of the bee—principally on the clypeus, genae, labrum, and, at times, bases of antennae (fig. 6, *A*)—was found in an Italian strain in the Department's apiary formerly at Somerset, Md., and an attempt is being made to obtain a homozygous strain. However, it appears to be a recessive character.

The development of stock especially resistant to European foulbrood was announced as the result of selective breeding experiments in New Jersey (*6*). In describing the first season's work of the Iowa Agricultural Experiment Station to find stock resistant to American foulbrood, Park (*24*) concluded that variation in resistance to American foulbrood exists. Some evidence of the inheritance of number of egg tubules has been reported in a private communication from J. E. Eckert, describing work at the University of California.

Since the World War an independent breeder, Henry Brown of New Jersey, has developed a light-colored strain, reputed to be very gentle, by crossing the Cyprian and Italian races, according to a private communication.

Even years before Brown's work the "golden" Italian bee, a strain with the anterior portion of each of the first five abdominal tergites marked with a golden band, instead of only each of the first three as in the ordinary Italian, was developed in this country, supposedly by crossing the Italian with the Cyprian. This golden Italian, while held to be gentle and a beautiful bee, had little repute as a honey gatherer. Sladen (*32*) developed a "British golden" by crossing the English strain of the common black bee, the Italian, and the "American golden." By continued selective breeding in an isolated locality, a bee was obtained which Sladen claimed combined the hardiness and industriousness of the black with the prolificness of the Italian, although its area of golden coloration was not so extensive as that of the "American golden." No attempt was made to increase the area of golden coloration, however, since this character was used merely to provide breeding stock with drones of such a color that their progeny could easily be distinguished from that of the common black drone, which prevailed elsewhere in the locality.

Jay A. Smith reports in a private communication that in crosses obtained by the Watson method no correlation seemed to exist between color and gentleness.

The reports of the work in Switzerland are of especial interest to beekeepers, since rather extensive records are kept showing the returns from improved (veredelte) stock, meaning that developed at the mating stations, as compared with those from ordinary or unimproved stock. Thus from 1915 to 1928, according to a survey of certain apiaries which contained colonies of both types of stock, the honey crop of the improved stock averaged larger per colony each year than that of the unimproved stock, ranging from 20 percent more in 1923 to 100 percent more in 1924 (*13, p. 30*).

Mikhailoff (*18*) used the Watson method of insemination to demonstrate that the spermatozoa from white-eyed drones are active,

and he succeeded in obtaining white-eyed workers and queens. White-eyed drones apparently do not see and do not mate in nature. That the gene for white eyes is recessive to the normal eye color is shown by the fact that with natural mating a queen laying eggs from which white-eyed drones arise gives only workers with normal eye color.

In the Department apiary formerly at Somerset, Md., half of the drones from an Italian queen that produced white-eyed drones were white-eyed and half were black-eyed, a proportion also observed by other investigators. A few of the white-eyed drones were seen to fly off into the air, but none was seen to reenter the hive. Some, on leaving the hives, made short hops or flew in small circles away from the hive entrance. In the fall only black-eyed drones were found in the hive with this queen. Whether at this season the workers removed the white-eyed drones before emergence is problematical, since no white-eyed drone pupae were found in any of the sealed cells. A number of virgins were reared from this queen, but attempts to inseminate them with sperm from the white-eyed drones were unsuccessful. One of these virgins inseminated with sperm from a normal drone, however, produced some white-eyed drones. Part of the worker progeny of the original queen were a lighter yellow on their abdomens than the ordinary Italian bee.

As for the inheritance of quantitative characters, Mikhailoff reported (*17*) that a Caucasian queen from a colony with a tongue length of 6.9393 mm was mated with a central-Russian black bee with a tongue length of 6.1729 mm, and the resulting cross gave a bee with tongue length of 6.705 mm. Twelve percent of these hybrids had tongue lengths of 7.0282 mm, this being greater than that of either parent race. Two Caucasian queens that were inbred with "brother" drones had progeny with shorter tongues than those of their worker sisters. Other quantitative data are included and, although they represent a very scanty number of colonies, they are of interest because they are the first statistical data to be published that are derived from controlled crossing of the honeybee.

Alpatov (*1*) has concludedas a result of his studies in the Union of Soviet Socialist Republics that, in the area covered, absolute size of body and of wings, relative size of the wax gland, and the color of the abdomen seem linked. The same is true concerning length of tongue and length of hind legs. He (*1, p. 40*) has pointed out that the constancy of color of the yellow and the black races in the United States shows that color is an inherited racial characteristic.

Watson (*37*) has stated that the albino bee is dominant over the common black bee.

Newell (*21*) crossed yellow Italians and black Carniolans and found yellow dominant. Watson (*37*) crossed a black virgin and a yellow drone and obtained all black offspring. It may be assumed that Watson used the common black or Dutch bee. Sladen (*33, p. 64*), in crossing a golden queen with pure black drones, obtained "intermediate" workers that had black bands on the posterior margins of the second to fifth abdominal tergites, increasing in width from tergite to tergite toward the rear. The sixth tergite was black As a matter of fact, the last abdominal tergite is black in all varieties of

the European honeybee, no mutation showing a different color having yet been reported.

In work at the Department (*22*) a daughter of a European brown bee crossed with a yellow drone produced workers that might have been taken casually as a dark strain of three-banded Italians, possibly because of the blackness of the posterior bands of each of the first three abdominal tergites. Practically the same results were obtained later with Caucasians and Italians.

Mikhailoff (*17*), in crossing queens of the central-Russian black bee with golden Italian drones, found yellow to be the dominant color in 90 percent of the progeny.

Götze (*8*) holds that the yellow scutellum, such as occurs in the Cyprian and other eastern races, is the expression of a dominant unit factor. He found that a golden queen mated to a black drone gave workers with yellow scutella. These workers, however, as regards abdominal coloration, were not golden, but had abdominal segments with decided black edges, as in the work by Sladen and the writer. Götze (*8, p. 71*) therefore calls the F_1 an "intermediate form" and further assumes that a separate gene is responsible for the black edges on the abdominal segments.

Götze has found in various colonies both black and brown drones as well as some termed by him "leather-colored." To account for these various colorations he assumes a basic color factor, *N*, which requires the presence of an activating factor to give rise to color. He assumes that not one but two activating factors or their allelomorphs are carried. These are *M*, a factor for black, and *B*, a factor for brown. *B* is inhibited by *M*. When only their allelomorphs *bm* are present, leather-colored individuals arise. Gotze states that *m* is a factor for leather-colored but does not give the nature of *b*. A black drone, according to this scheme, would have the genic composition *NBM* or *NbM;* a brown drone, *NBm;* and a leather-colored drone, *Nbm*. In addition, Götze found that certain eggs did not hatch, and he holds that they had the genic combination *nbm*, which he assumes is lethal. In an actual count, omitting the supposed lethal cases, he found 110 black, 48 brown, and 21 leather-colored workers.

Stucki (*35*) has suggested the possibility that certain definite excesses or deficiencies from the normal wing venation may be characteristic of certain strains of Swiss bees, although he postpones definite conclusions until more material is accumulated. Like Casteel and Phillips (*5*) and others, he found drones especially variable. Rytiř (*28*) reports, as a result of crossing the Iskra strain of bees from Czechoslovakia with the Nigra strain of the European brown bee—the latter strain having a lower cubital index (fig. 7, *B*)—that the lower index is completely dominant over the higher.

The dominance or recessiveness of certain characters of the honeybee that have been reported as heritable is shown below. It is to be remembered that most of the data need further confirmation before being accepted and that, while many of the characters listed seemingly have little or no direct economic importance in themselves, yet, if they happen to be linked with characters of economic importance, perhaps they may ultimately prove of use as an index to the presence of such characters.

Dominance or recessiveness as shown in F_1 generation

Dominant factors	Recessive factors	Reported by—
Eye color normal	Eye color white	Mikhailoff (*18*).
Abdominal marking:	Abdominal marking:	
Italian	European brown	Mikhailoff (*17*).
Do	Carniolan	Newell (*21*).
Common black	Italian	Watson (*37*, *p. 40*).
Albino	Common black	Do.
Cubital index low	Cubital index high	Rytiř (*27*).
Scutellum yellow	Scutellum black	Munro (*19*).
Clypeus, genae, and labrum dark	Clypeus, genae, and labrum yellow.	Nolan (this article, *p. 1534*).
Use of wax for sealing crevices, etc. (Carniolan).	Use of propolis for sealing crevices, etc.	Newell (*21*).

Some crosses in which dominance or recessiveness is not shown for certain characters by F_1 generation

Cross	Character	Reported by—
European brown × Golden	Abdominal coloration	Götze (*8*, *p. 71*).
Common black × Golden	do	Sladen (*33*, *p. 64*).
European brown × Italian	do	Nolan (*22*).
Long × short	Tongue length	Götze (*8*, *p. 73*).

Some linked characters

Characters	Reported by—
Absolute size of body and wings, relative size of wax glands, color of abdomen.	Alpatov (*1*, *p. 48*).
Tongue length, labial palpi	Götze (*8*, *p. 227*).
Tongue length, number of egg tubules	Komarov and Alpatov (*11*).
Yellow color, light weight (drones)	Munro (*19*).
Black color, heavy weight (drones)	Do.

Now that a notable advance in the technique of accomplishing matings has been made, methods for obtaining biometric data have been worked out, and germ plasm that possesses a number of desirable characters is available, the way appears open for a worth-while advance in bee breeding, although quick results should not be expected.

FUNDAMENTALS OF HEREDITY FOR BREEDERS

E. N. BRESSMAN, Scientific
Adviser, Office of the Secretary [1]

THE preliminary articles in the 1936 Yearbook included some discussion of the fundamental nature of genes and chromosomes, but very little about how the chromosomes, the carriers of the genes that are the determiners of hereditary traits, are distributed among the descendants of two parents used as breeding stock. This distribution occurs in certain genetic ratios, which were first discovered by Johann Gregor Mendel and gave the clue to the orderly operation of heredity. Before explaining them, it is necessary to consider what happens when two reproductive cells unite to produce progeny.

WHAT HAPPENS WHEN THE CELLS UNITE

THIS has been well described by A. H. R. Buller in his account of the discovery of Marquis wheat. Buller not only understood the facts of his science of botany; he had a feeling for its poetry as well. The following description is taken from his book. Telling how all Marquis wheat plants came originally from a single kernel or seed, the offspring of a cross between Red Fife and Hard Red Calcutta selected by the famous Canadian plant breeder, Charles Saunders, Buller wrote: [2]

> Pollen dust from some stamens removed with forceps from a few flowers of [Red Fife] was placed on the two feathery stigmas of a flower of [Hard Red Calcutta]. The pollen grains germinated, each grain producing a single pollen tube. The pollen tubes, which were exceedingly delicate cylindrical structures, grew down the stigmas and made their way, by elongating at their apices, into the ovary below. This ovary was a tiny chamber containing a single ovule or potential seed attached laterally to its wall. One of the pollen tubes, guided by chemotropic stimuli, directed its course toward the ovule, entered at its mouth or micropyle, and penetrated into its interior as far as the ovum or egg-cell. The egg-cell having been reached, the wall at the tip of the pollen tube liquefied and broke down, and from the opening so produced there were emitted two exceedingly minute dense rounded masses of gelatinous protoplasm known as male nuclei. One of these nuclei, carried by forces as yet not perfectly understood, advanced through the general protoplasm of the egg-cell toward the female nucleus situated in its center. The male and female nuclei, after coming into contact, brought their affinity for one another to a climax by mingling together and forming one whole; and this nuclear fusion, this formation of a single nucleus from two others of opposite sex, marked the completion of the act of fertilization. * * * With-

[1] Many workers in the Department have made contributions to this article. The writer is indebted particularly to George Haines, senior animal husbandman, Office of Experiment Stations, and W. V Lambert, senior animal husbandman, Bureau of Animal Industry, who have been very generous with suggestions and help on animal genetics, not only in this article but elsewhere in the Yearbook.

[2] R. Buller, A. H. ESSAYS ON WHEAT, INCLUDING THE DISCOVERY AND INTRODUCTION OF MARQUIS WHEAT, THE EARLY HISTORY OF WHEAT-GROWING IN MANITOBA, WHEAT IN WESTERN CANADA, THE ORIGIN OF RED BOBS AND KITCHENER, AND THE WILD WHEAT OF PALESTINE. 339 pp., illus. New York. 1919. See pp. 219–220.

out fertilization, the egg-cell would have * * * withered and died; but, its fertilization having been accomplished, a most extraordinary future was opened to it. Further development became irresistible, with the result that, in the course of a few years, its products became in numbers like the stars on a clear night, or the grains of yellow sand upon a sea beach.

To round out the description, it is necessary to add that when the male and female nuclei fuse, the resulting single nucleus becomes the embryo of a new plant. But this embryo is not the whole seed. It will be noted that there were two male nuclei, only one of which united with the female nucleus. But there was also more than one female nucleus, for this one was attended by two much smaller bodies known as the polar nuclei. During fertilization, these two polar nuclei united with the other male nucleus and from this separate union came the endosperm, the starchy part of the seed, the function of which is to furnish food for the embryonic plant during the initial stages of its growth. This union of a male nucleus with two female polar nuclei is peculiar to plants, and it accounts for the fact that the male parent may immediately impress certain characters on the endosperm and embryo of the seed—a phenomenon known as xenia. Except for xenia and metaxenia, the inheritance from the male parent does not appear until the new plant has grown and produced seed in its turn.

This immediate effect of the two polar nuclei, visible in the endosperm, is commonly seen in corn. When a pollen grain from purple corn pure for this characteristic fertilizes an egg cell of white corn, for example, the resulting seed is purple. In some other seeds, like wheat, the effect of xenia is not evident because the endosperm is covered with female tissue known as the pericarp; but even though it is not always observed, xenia occurs in all seed plants. It might be added here that certain other tissues associated with the seed may sometimes be affected in a similar manner by the male parent. This happens in the case of date fruits, and the phenomenon, which has been called metaxenia, is discussed in the date section of the article on subtropical fruits.

The details of the process of fertilization in animals differs somewhat from that in plants although the end result in each case is a new individual which received half of its heredity from the male parent and half from the female parent. In animals the male reproductive cells, known as spermatozoa, are produced literally by the millions in the testes or sex glands of the male. They are microscopic, motile cells, which are propelled by long hairlike tails. The larger part of the head of the spermatozoon is composed of the nucleus, the part of the cell that carries the hereditary factors. The female reproductive cells, known as ova, are produced in the ovaries or sex glands of the female. They are much larger than the male reproductive cells and are nonmotile.[3] They contain a microscopic nucleus that corresponds in size to the nucleus of the spermatozoon. The remainder of the egg consists largely of food material intended to nourish the young embryo until food connections are established with the tissues of the mother, or in the case of birds and other forms in which development takes

[3] The yolk of the hen's egg is the true egg, the remainder of the contents within the shell are secreted by the glands of the oviduct or "egg bag." Most of the yolk consists of food material. The eggs of mammals are much smaller than the eggs of birds. Most mammalian eggs are of a size that makes them barely visible to the naked eye.

place outside of the body of the female, food to nourish the embryo throughout its entire development.

In contrast with plants, the spermatozoon, which corresponds to a pollen grain, and the egg cell, which corresponds to the ovule of the plant, are ready to function in fertilization without further nuclear divisions. The sperm cells are deposited by the millions in the reproductive tract of the female at the time of mating. From the point of deposit they move in a swarm to the innermost part of the reproductive tract (the fallopian tubes) of the female, where they are ready to unite with the egg or eggs as soon as they are freed from the ovary. Normally only one spermatozoon enters the egg and takes part in fertilization although thousands of spermatozoa surround an egg. When the spermatozoon enters the egg its nucleus unites with the nucleus of the egg, and this joining of the two nuclei into a single new nucleus is what is known as fertilization. The new nucleus, which received half of its heredity (genes) from the male parent and half from the female parent, constitutes a new individual. All animals and plants begin their life as such single cells. From that point growth proceeds by a continual process of cell division and as it proceeds the new cells are formed into the tissues and organs of the body of the new animal. The processes of growth are similar in both plants and animals. The embryo observed in the seed of plants is a partially developed plant since it contains many cells that arose by the division of the fertilized ovule.

Now we must consider another aspect of those male and female nuclei whose union was described by Buller for wheat plants.

It is generally recognized that the chromosome number for a given species is constant. For example, every nucleus in each body cell of the Red Fife and Hard Red Calcutta parents contained 21 pairs of chromosomes, or 42 altogether. But the nucleus of each reproductive cell—as distinguished from the body cell—contained only 21 chromosomes, not 21 pairs. (This reduction in number occurs when reproductive cells are formed, as described by Kempton.)[4] These 21 chromosomes in the male Red Fife reproductive nucleus contained a complete set of genes capable of reproducing all the Red Fife characteristics; and the same thing was true for the female Hard Red Calcutta nucleus. The two joined, promptly lost their individual identity, and formed a new nucleus with 42 chromosomes containing all the genes of both parents, and therefore capable of producing their characteristics. From that cell came a new plant, the first-generation or F_1 hybrid[5] between the two.

Under ordinary circumstances, if the two parents are pure, all the F_1 or first-generation plants of the cross are exactly alike, for each individual offspring contains a full set of genes from the mother and a full set from the father and it expresses the dominant characteristics of both of them. Very often also these F_1 hybrid plants are unusually vigorous in size or productiveness or other characteristics, especially if the parents were considerably unlike one another. This is the well known "hybrid vigor" or heterosis, for which several explanations have been suggested.

[4] KEMPTON, J. H. HEREDITY UNDER THE MICROSCOPE. U. S. Dept. Agr. Yearbook 1936: 165–182, illus. 1936.

[5] F_1 is pronounced eff-one. The F stands for filium or filial, depending upon whether it is used as a noun or an adjective, and the subscript numerals indicate which generation is meant—first, second, third, etc.

One of these explanations is that all the dominant genes from both parents have a chance to express themslves in the hybrids. To take an imaginary example, suppose one parent had a dominant gene for height so that it was tall, but it had small leaves because of a recessive gene. Suppose the other parent had large leaves because of a dominant gene, but that a recessive gene for dwarfness made it a short plant. The F_1 hybrid would then be tall because of the dominant gene for height inherited from one parent, and it would have large leaves because of the dominant gene for leaf size inherited from the other parent. A number of such dominant genes might express themselves and in combination make the F_1 hybrid seem unusually vigorous. Or, to consider another characteristic such as disease resistance—each parent might have certain dominant genes that increase resistance. When all of these genes came together in the progeny, it might be more disease-resistant than either of the parents.

Another suggested explanation of hybrid vigor is that it is the result of physiological stimulation, which somehow comes from the mixing of unlike protoplasm from the egg and the sperm.

SEGREGATION OF CHARACTERISTICS IN THE PROGENY

But hybrid vigor is not the immediate point of this discussion. We are not concerned here with what happens in the first hybrid generation, but with what occurs in the second generation, which breeders call the F_2. This is well illustrated in figure 1.

We shall assume that both the original parents have been bred pure, and that the F_1 generation is then inbred or fertilized by its own pollen to produce the F_2 generation- the grandchildren of the original parents. What happens to the chromosomes in the F_2 progeny?

Perhaps this can best be visualized for the present by concentrating on a single pair of genes, let us say a pair governing height. Now genes have alternative forms, called allelomorphs or alleles (allelomorph comes from two Greek words meaning "alternative form"). Suppose that a gene for height in the original male parent was one that made the plant tall. Suppose that the gene in exactly the same place on the corresponding or homologous chromosome in the original female parent was an allel or alternate that made the plant short. The F_1 hybrid would receive both chromosomes, making a pair, with the gene for tallness in one and the gene for shortness in the other. These two genes would be present in every body cell of the F_1. But the time would come when reproductive cells were formed, and this would involve the separation of the two members of a pair of chromosomes, since each reproductive cell receives only one chromosome where there were two in the body cell. Thus whenever an original cell divided to form two male reproductive cells, one of them would be bound to receive the chromosome containing the gene for tallness and the other would be certain to receive the chromosome containing the gene for shortness. If several thousand male reproductive cells were produced by the plant, half of them would have the tallness gene, half the shortness gene. And the same thing would be true of the female reproductive cells.

Next this plant is to be self-fertilized; its own male nuclei are to join with its own eggs to form the primary cells of F_2 plants, the next generation. Obviously there could be four kinds of these new cells.

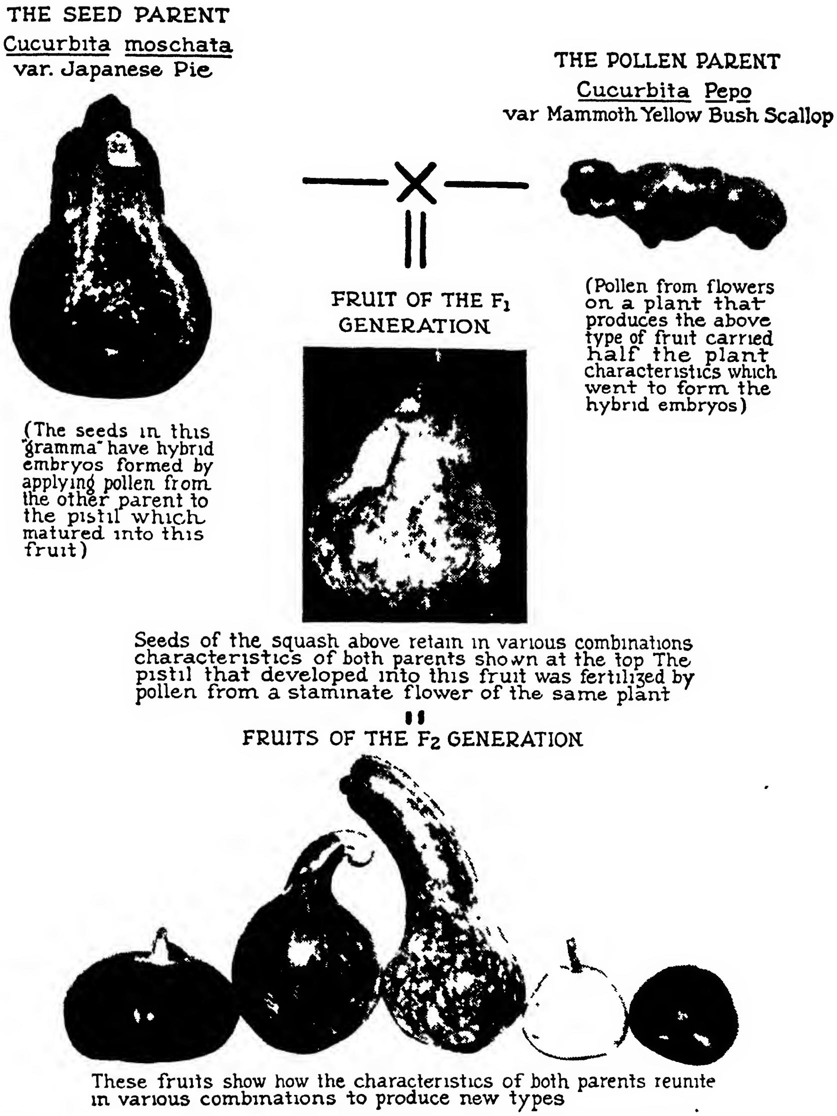

Figure 1.—**A cross between two species of cucurbits widely differing in appearance. Typical fruits of the parental types; the first generation, which exhibits dominant characteristics; and the second generation, which exhibits characteristics of both parents in various combinations. This is a typical example of the operation of Mendelism. (Courtesy of New York (State) Agricultural Experiment Station.)**

(1) A male nucleus with a tallness gene might join a female cell with a tallness gene, giving "tallness-tallness."

(2) A male nucleus with a tallness gene might join a female cell with a shortness gene, giving "tallness-shortness."

(3) A male nucleus with a shortness gene might join a female cell with a tallness gene, giving "shortness-tallness."

(4) A male nucleus with a shortness gene might join a female cell with a shortness gene, giving "shortness-shortness."

Since there are as many reproductive cells that carry the tallness gene as there are reproductive cells that carry the shortness gene and fertilization of the two kinds of eggs by the two kinds of pollen grains occurs entirely by chance, there would be equal numbers of these four different kinds of new cells if large numbers were produced. But group (2) and group (3) above would be exactly the same in effect, since each is a tall-short combination. Thus the proportions in the total population would be 1 tall-tall to 2 tall-short to 1 short-short. This is a simple Mendelian characteristic, the probable breeding behavior of which is expressed as a 1 to 2 to 1 or 1:2:1 ratio.

Thus the plants in the F_2 generation are not at all like those in the F_1. In the F_1, all are alike; in the F_2, with exactly the same basic characteristics, there are three different kinds of plants, with respect to this pair of genes, and they occur in definite proportions. That is, they occur in definite proportions if the population is large enough and is considered as a whole. If only a few plants were produced, these proportions might not hold; out of any four individuals selected at random, there would obviously be a very small chance that one would be a tall-tall, two tall-short, and one short-short. But for large numbers, the ratios hold well. This might be compared to the fact that any given family may have more boys than girls, or vice versa, but that on the whole the male and female population is about equal.

Segregation Ratios

This splitting up into several combinations of characteristics in the second generation is what is technically called segregation, and the generation in which it occurs is often called the segregating generation. Segregation occurs even in pollen grains as is shown in figure 2. It should be noted that segregation may occur in the F_1 if the parents are hybrids rather than bred pure. For example, if the hybrids in this example were the original parents, segregation would begin in the first generation after they were selfed or crossed. But this would be merely a change in names; what was really the F_2 would now be called the F_1. It is important to remember, however, that whenever hybrid material is used to start with—as it often is in practice—segregation is apparent in the first generation. In fact, this is the test that proves whether the parent material is hybrid or pure. If a breeder takes a plant the ancestry of which he does not know, selfs it, and finds the progeny in the next generation segregating into different types, he knows the original plant must have been a hybrid. This is what happens, for example, with ordinary open-pollinated varieties of corn. Upon being selfed, the progeny begins to segregate into types immediately.

Before going on with the discussion of segregation ratios, it might be well to consider what happens on further inbreeding of these F_2 plants. We derived three kinds—the tall–tall, the tall–short, and the short–short. When reproductive cells are formed in the tall–tall plant, obviously every one of them must receive a tallness gene, since there is no other. Thus when such plants are selfed all the descend-

ants of the tall–tall plants will also have the tall–tall combination, and this will go on indefinitely as long as they are selfed. Likewise, the short–short plants will produce only short progeny. Whenever an organism has exactly the same genes for a certain character on both members of a pair of homologous chromosomes, it is said to be homozygous for that character Ordinarily, it will go on breeding true for that character indefinitely as long as it is selfed. From a genetic standpoint, this is what pure breeding means. Often the effort of the plant breeder is to produce plants that, for practical purposes, are homozygous for all characters. Then he can continue reproducing them indefinitely with the assurance that the progeny will be like the parents. His basic procedure—though there are many necessary modifications and complications—is commonly the one given here.

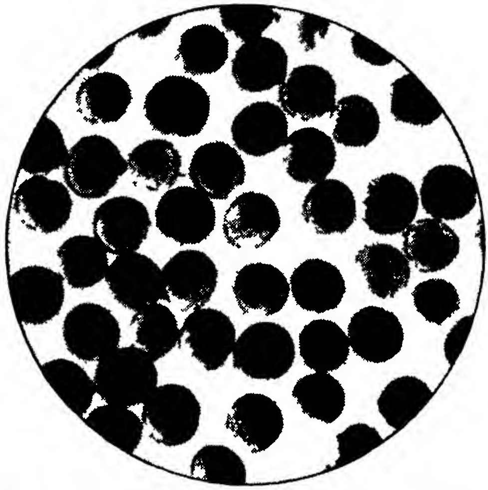

Figure 2.—An early effect of a gene on a characteristic is shown in these pollen grains from a sorghum plant heterozygous for the waxy gene. One-half of the pollen grains are waxy and stain red (light) with iodine, while the remainder are starchy and stain deep blue (dark). (Courtesy of Journal of Heredity.)

But what about the third type mentioned above— the plants with the tall–short combination in their cells? Here we have exactly the same combination we had in the F_1. In each cell of this type there is a chromosome containing the gene for tallness and one containing the gene for shortness. One-half of the reproductive cells, then, would get the gene for shortness and one-half the gene for tallness. Thus when the plants with the tall–short combination are inbred, they again segregate in the next generation into 1 tall–tall, 2 tall–short, 1 short–short. When an organism has two alternative genes for a certain character in its homologous chromosomes, it is said to be heterozygous for that character, as opposed to homozygous.

Effect of Dominance

So far, we have dealt only with what are called the genotypes of this tall–short combination in breeding. The segregation in the F_2 really took the form of 1 tall–tall, 2 tall–short, 1 short–short so far as the actual cells of the progeny were concerned. But it happens that with these particular characters of tallness and shortness there is a complication, namely, that tallness is a completely dominant characteristic and shortness a recessive. This means that when a cell contains the gene for tallness in one chromosome of a pair and the gene for shortness in the other, the tallness gene will dominate in the growth of the plant, and the shortness gene will, as it were, recede into the background.

We know that the cell actually contains both genes, but the plant does not show it so far as appearances go; it is a tall plant. In breeding terminology, its phenotype, which literally means its appearance type, is tall; its genotype, which literally means its breeding type, is tall-short. The genotype designates the actual genic constitution regardless of expression. The phenotype is the type that results from the interaction of the genes among themselves, as well as with the environment.

Thus in this case the phenotypic and genotypic ratios are not the same. All the plants with the tall–tall combination in their cells will of course be tall, but so will all the plants with the tall-short combination, because tallness is dominant. So far as the phenotype is concerned, then, the ratio becomes 3 tall plants: 1 short plant (the one with the short–short combination). This also is a simple phenotypic ratio, which is really only a modification of the genotypic 1:2:1 ratio and is produced whenever complete dominance is involved. Where there is no complete dominance, the segregation of the phenotype as well as of the genotype is 1:2:1. This occurs, for example, when the hybrid pink four o'clock, a flower, is selfed. The progeny segregates in the ratio of 1 red:2 pink:1 white.[6] Red in this case is partly dominant, but not enough to make plants with the red-white combination red in appearance. They are pink instead.

Another ratio that is a variation of the 1:2:1 was obtained by Cuènot, crossing yellow and black mice. The dominant gene, designated *Y*, produces yellow, and its allel, *y*, produces black.[7] Now it happens that when a cell received the homozygous combination *YY*, it could not live; that is, this gene was lethal for any cell that received it in both chromosomes of the pair. With only one *Y*, however, the cell could live. Thus in the segregation 1 *YY*:2 *Yy*:1 *yy*, the *YY* perished, leaving a ratio of 2:1. Since yellow (*Y*) was dominant, the phenotypic ratio was 2 yellow mice (*Yy*) to 1 black mouse (*yy*). There are many lethal genes in animals and plants that would give the same sort of results, but in most cases the lethals are recessives rather than dominants.

Such ratios are useful to the breeder in two ways. If he knows that a certain character is governed by a single pair of genes, he can tell what proportion of each type he will obtain in a large segregating progeny. When he does not know how many genes are involved in a certain character, he can find out, or obtain an estimate, at least, by figuring the ratio in the segregating progeny. If the character segregation is 1:2:1, he concludes he must be dealing with a single pair of genes and that complete dominance is not involved. If it is 3:1, he assumes it is a single pair of genes involving complete dominance. If it is 2:1, he knows it may be a single pair of genes, and that one of the alleles in the double condition is lethal.

[6] Knowledge of the 3:1 phenotypic segregation preceded that of the 1:2:1 as a phenotypic ratio. One of the first reports of the latter was made by Correns—German botanist and one of the rediscoverers of Mendel's original paper—working with the hybrid pink four o'clocks mentioned. There is no gene for pink, but the color is produced by the interaction of the whiteness and the redness genes in the same cell. The same result is obtained in the blue Andalusian fowl, which is produced by crossing a splashed white with a black. The segregation in the F_2 is 1 splashed white:2 blue:1 black. This ratio also occurs in commercial double carnations, produced by crossing the burster and the single varieties.

[7] The genetic formula is somewhat simplified. The designation is in accordance with the practice of designating a recessive gene by a lower-case letter and its dominant allel by the same letter capitalized.

Ratios With More Than One Pair of Genes

The situation becomes much more complicated when there are two pairs of genes and their alleles to be taken into account instead of one pair. Corn has been a favorite plant for studies of this kind. Figure 3 shows same heritable characters in corn.

Consider a pea plant with a pair of genes for tallness (*T*— dominant) and a pair of genes for red blossoms (*R*—dominant) crossed with a plant that has alleles (*t* and *r*) of these two genes and is dwarf (recessive) and white-flowered (recessive). The genotypic segregation, including all possible combinations of these two characteristics, would be like this:

Parents. Tall-tall red-red ×[8] dwarf-dwarf white-white The first parent indicated here would produce only gametes (germ cells) carrying genes for tall and red, while the second parent would produce only gametes carrying genes for dwarf and white. The progeny, F_1, of course, would carry both kinds of genes, that is, genotypically they would be tall-dwarf red-white; but in phenotypic appearance they would all be tall and red.

F_1: tall-dwarf red-white × tall-dwarf red-white. The gametes produced by each of the parents here would be of four kinds—tall-red, tall-white, dwarf-red, and

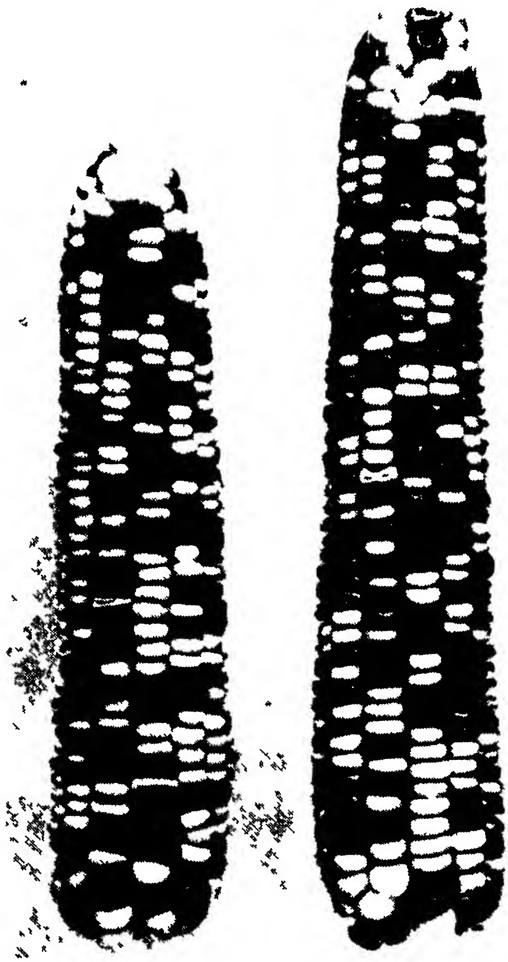

Figure 3.— Segregation for more than one character is shown on these ears of corn. It will be noted that there is not only a variation in color of the kernels but also a difference in the development of the kernels. Studies of heritable characters of this kind have enabled geneticists to increase their knowledge of heredity greatly beyond the fundamental laws formulated by Mendel. (Courtesy of Journal of Heredity.)

[8] The symbol × stands for "crossed with"

dwarf-white. These four kinds of gametes would unite by chance to give the various F_2 progeny. Possibly the best way to show the formation of these F_2 genotypes is by what is commonly known as the checkerboard square, presented below. The gametes produced by each parent are shown at the top and side of the checkerboard square. The genotype of each of the progeny formed by the union of all the different kinds of gametes is shown within the squares.

F_2.

Parent (gametes)

Parent (gametes)	*TR*	*Tr*	*tR*	*tr*
TR	*TTRR*	*TTRr*	*TtRR*	*TtRr*
Tr	*TTRr*	*TTrr*	*TtRr*	*Ttrr*
tR	*TtRR*	*TtRr*	*ttRR*	*ttRr*
tr	*TtRr*	*Ttrr*	*ttRr*	*ttrr*

Progeny (zygotes)

This F_2 checkerboard square adds up to the following genotypes: 1 tall-tall red-red: 2 tall-tall red-white: 2 tall-dwarf red-red: 4 tall-dwarf red-white: 1 tall-tall white-white: 2 tall-dwarf white-white: 1 dwarf-dwarf red-red: 2 dwarf-dwarf red-white 1 dwarf-dwarf white-white.

But tall is dominant to dwarf and red is dominant to white; that is, every plant with the tall-dwarf combination in its cells would be tall in appearance, and every plant with the red-white combination would have red flowers. Thus in the F_2, the segregation from the standpoint of phenotype or appearance would be

Tall red —9 (1 tall-tall red-red + 2 tall-tall red-white + 2 tall-dwarf red-red + 4 tall-dwarf red-white).
Tall white —3 (1 tall-tall white-white + 2 tall-dwarf white-white)
Dwarf red —3 (1 dwarf-dwarf red-red + 2 dwarf-dwarf red-white)
Dwarf white—1 (dwarf-dwarf white-white)

This 9:3:3:1 is the basic phenotypic ratio when two independently inherited dominant genes with their two recessive alleles are concerned.

Modifications of Basic Ratios

The basic ratios are modified in various ways. Interaction between the genes accounts for many of the modifications. It will be enough here to analyze five of the most common of these modifications through interaction.

(1) One dominant gene may have no visible effect unless a member of another pair is present. There is an example of this in corn, in which many color genes have been identified by R. A. Emerson and his associates at Cornell University. The dominant gene *R* governs red color, and its recessive allel *r* produces white. The dominant gene *Pr* produces purple, but only if *R* is present; otherwise it has no

effect. Suppose we have corn with the genes *r* and *Pr* (expressed as *r Pr*). This is white because, though it contains the gene for purple, *Pr*, it does not at the same time possess *R*. Let us cross this with a variety containing the genes *R pr*, which is red because it contains the *R* without the *Pr* that would modify it. Since the F_1 would have all the genes from both parents, its constitution would be *R r Pr pr*. It would be purple because it would have both *R* and *Pr*. The genotypes would work out in the 9:3:3:1 ratio already given—that is:

9 *R–Pr–*[9] (purple, because *R* and *Pr* are both present).
3 *R–prpr* (red, because *R* is present but not *Pr*).
3 *rrPr–* (white, because though *Pr* is present, it has no effect without *R*).
1 *rrprpr* (white—double recessive).

Thus the phenotypes add up to 9 purple: 3 red: 4 white, and we get 9:3:4 as the typical ratio for this kind of gene interaction.[10]

(2) Sometimes two dominants have a complementary effect on one another, but neither exerts any visible influence alone. Again we may turn to corn for an example. The dominant gene *C* and the dominant gene *R* produce colored (red or purple) kernels if they are both present, but neither has any effect alone. The recessive alleles, *c* and *r*, produce white. Suppose we have a variety with the composition *CCrr*, which is white because only one of the dominant genes is present, and another variety *ccRR*, white for the same reason. The F_1 contains the two dominants and the two recessives—*Cc Rr*—and is therefore colored. All the possible combinations would give us the following genotypes in the F_2:

9 *C–R–* (colored, because both dominants are present).
3 *C–rr* (white, because only one of the dominants is present).
3 *ccR–* (white, because only one of the dominants is present).
1 *ccrr* (white—double recessive).

Here the phenotypes add up to 9 colored: 7 white, and one concludes that 9:7 is the typical ratio for this kind of interaction.[11]

(3) Sometimes one dominant hides the effect of the other when both are present. In oats, the gene *G* produces a gray seed coat and the gene *B* a black seed coat, but the effect of *G* is always hidden if *B* is present. The gene *Y* produces a yellow seed coat, but only if neither *B* nor *G* is present. Suppose we cross a variety *BBGGYY* (black because *B* hides *G* and *Y*) with a variety *bbggYY* (yellow because *Y* is present but not *B* or *G*). The F_1 is *BbGgYY* and is therefore black. All possible combinations would give in the F_2:

9 *B–G–Y–* (black because *B* hides *G* and *Y*).
3 *B–ggY–* (black because *B* hides *Y*).
3 *bbG–Y–* (gray because *G* can show its effect without *B*).
1 *bbggY–* (yellow because *Y* is present without *B* or *G*).

This gives a phenotype ratio of 12 black, 3 gray, and 1 yellow—12:3:1 being the typical segregation for genes interacting in this way.

(4) Sometimes when there are two dominants, one acts as an inhibitor of the other. For example, in corn, *R* produces red kernels;

[9] The small dash (-) in the symbol stands for the presence of either the dominant or the recessive gene In this case, *R–* stands for *RR* or *Rr*, while *Pr–* stands for *Pr Pr* or *Pr pr*.

[10] In this particular example, there are really four other known genes present, A_1, A_2, *C*, and *i*. Together, these genes produce color when *R* is present, but they have no effect when *R* is not present. The real composition of the white parent, then, is $A_1A_1A_2A_2CCrrPrPrii$, of the red parent $A_1A_1A_2A_2CCRRprprii$, and of the purple F_1, $A_1A_1A_2A_2CCRRPrPrii$. Since A_1A_2Ci is the same in all three cases, it is omitted to make the analysis clearer.

[11] This example is also somewhat simplified in the genetic formula.

r white kernels; *I* prevents the action of *R*; *i* has no effect. Stated in another way, the recessive (*ii*) must be present to allow the gene *R* to be effective. Suppose a variety *rrii* (white, the double recessive) is crossed with *RRII* (also white because, though *R* is present, it is inhibited by *I*). The genotype of the F_1 is *RrIi* and is white. The F_2 segregates as:

9 *R–I–* (white because *I* inhibits *R*).
3 *R ii* (colored because *R* can act with *i*).
3 *rrI–* (white because *R* is not present and also because *I* is present).
1 *rrii* (white because R is not present).

The phenotypes here add up to 13 white: 3 colored.[12] This 13:3 phenotypic ratio is commonly called the inhibitor ratio, and the larger number always represents the gene that acts as the inhibitor.

(5) Finally, there may be two dominants, each having the same effect as the other, or as both of them together. In the common shepherds-purse, the seed capsule is triangular in shape if the dominant gene *C* or the dominant *D* is present—and also if both are present. If both the recessives of these genes, *c* and *d*, are homozygous, the seed capsule is top-shaped. Dr. Shull of Princeton crossed a variety *ccdd* (top-shaped) with a variety *CCDD* (triangle-shaped). From the triangular F_1 (*CcDd*) he obtained in the F_2:

9 *C D* (triangular both dominant genes present).
3 *C–dd* (triangular—one dominant gene present).
3 *ccD* (triangular—one dominant gene present).
1 *ccdd* (top-shaped—double recessive).

This adds up to 15 triangular: 1 top-shaped, giving a 15:1 ratio.

Other modifications of the ratio for two pairs of genes are: 9:6:1, 4:11:1, 1:11:4, 7:4:4:1, 1:7:4:4, 1:8:4:2:1.

When three genes with their alleles are involved instead of two, the ratios become still more complicated,[13] and they will not be illustrated in detail here. The basic phenotypic ratio in the case of three pairs of genes is 27:9:9:3:9:3:3:1. If the genes are considered as *ABC* and *abc*, this ratio is 27 *ABC*: 9 *ABc*: 9 *AbC*: 3 *Abc*: 9 *aBC*: 3 *aBc*: 3 *abC*: 1 *abc* Some variations in this basic ratio produced by the interaction of genes are 27:37, 27:9:28, and 63:1.

With more than three pairs of genes, the ratios become even more complicated, especially if there are complex interactions among the genes. It is evident that large numbers of progeny would be needed to furnish a population with proportionate representation of all classes. This need for large numbers of progeny is one of the difficulties in animal genetics, where there is reason to believe that many genes, interacting in a very complex way, are involved in what appears to be a simple characteristic such as high or low milk production.

Backcrossing and the Backcross Ratio

The backcross ratio is different from any of those previously explained. The backcrossing technique consists chiefly in crossing an F_1 or later progeny back to one of the original parents or to an individual recessive for whatever characteristic is under consideration.

[12] In this case also, the genes A_1A_2C are present in all the combinations, but they can be disregarded for the sake of simplifying the analysis

[13] It will be noted in the above examples that three pairs of genes are sometimes involved, or even more, but only two of them in both the dominant and recessive forms— that is, only two genes with their alleles.

The ratio is now being used to advantage by both the geneticist and the breeder. The genetic make-up of the sow shown in figure 4 is being tested by the backcross method. The geneticist uses it primarily to test for linkage, a phenomenon explained in the next few pages. The breeder uses it chiefly for two purposes—(1) to test whether a given character exists in a pure (homozygous) form or in a hybrid

Figure 4.—A backcross ratio obtained in a litter from a cross-bred Berkshire-Yorkshire sow by a Berkshire sire. The ratio is 7 white: 6 black with some white. Two of the latter type died. (Courtesy of Journal of Heredity.)

(heterozygous) form in one of the parents used in the backcross and (2) to transfer a valued characteristic such as disease resistance into an otherwise desirable variety that lacks it.

Suppose the breeder is dealing with a gene *B*, which produces black in Aberdeen Angus cattle and is dominant to its allel *b*, which produces red. He is not sure whether a given black animal is homozygous or heterozygous, since both *BB* and *Bb* produce exactly the same appearance. It is necessary for him to know, however, if he wants to go on breeding pure black animals, because if he picks two that are heterozygous the progeny will keep on segregating into blacks and reds. In order to test the composition of an animal by this method, he backcrosses it to a red individual, which, of course, has the double recessive, *bb*. In the following generations one of two things must happen. (1) All the progeny will be black, in which case he knows that the animal he was testing must have been homozygous, with the composition *BB;* for *BB* crossed with *bb* would give every offspring a *B* and a *b*, or *Bb*, which would make every animal black. (2) He might get an equal number of blacks and reds, in which case he knows that the uncertain animal must be heterozygous, or *Bb;* for *Bb* crossed with *bb* would give 1 *Bb:* 1 *Bb:* 1 *bb:* 1 *bb*, or 1 black: 1 red. In the first case, he can keep on using the animal he has chosen with the assurance that it will breed true. In the

second case he will have to discard the animal and its progeny if he wants a herd pure for black.

Backcrossing, especially with plants naturally selfed, is seldom resorted to for the purpose of determining whether they are homozygous for a given gene. A few progeny from selfed plants are all that are needed for this purpose, and, of course, in self-fertilized plants it is much simpler to self a plant, grow a few progeny, and note whether they segregate.

The 1 : 1 is a so-called backcross ratio, and it always appears when a recessive is crossed with a heterozygous individual. The backcross method therefore can be used to test the purity of any stock that exhibits a dominant character. Backcross ratios also have been worked out for two and three pairs of genes with their various interactions. For example, in the case of two genes, *A* and *B*, with their alleles, *a* and *b*, a heterozygous plant with the composition *AaBb* crossed with the pure recessive *aabb* would give 1 *Aa Bb:* 1 *Aa bb:* 1 *aa Bb:* 1 *aa bb.*

The second use of the backcross is to transfer a certain valued character to an otherwise desirable variety. Suppose the breeder has a plant, A, that has good commercial characteristics but is susceptible to a disease, such as bunt in wheat, and a plant, B, that is worthless commercially but has bunt resistance, a dominant characteristic. He crosses them, determines by suitable tests that the F_1 is resistant, inbreeds the F_1, and finds that the F_2 segregates into disease-resistant and disease-susceptible plants. He may backcross the F_1 to A, the double recessive for bunt resistance, and obtain the backcross ratio of 1 resistant to 1 susceptible. A second or third backcross may result in successfully retaining bunt resistance and at the same time getting all of the desirable characters of the susceptible parent, A. This backcross method is most successful when only one dominant factor is involved. When the resistant reaction is recessive, the backcross method of breeding is not so successful.

The important thing for the breeder to keep in mind here is that B contributes worthless commercial characteristics as well as the valuable one of disease resistance, and he must use skill in selecting the particular disease-resistant plants for backcrossing on A. They must have as many A qualities as possible, but, of course, lack susceptibility to disease. Too much emphasis cannot be placed on the importance of wise selection, especially in view of the fact that usually many genes are involved in even the simplest characters, rather than one dominant gene as in the above example.

LINKAGE AND CROSSING OVER

ALTHOUGH the discussion of ratios has dealt with genes, it should be kept in mind that the genes are located in chromosomes. Just what genes or chromosomes are, or by what means they exert their fateful control over the characteristics of organisms, remains an unsolved mystery of science. A chromosome may be thought of as merely an aggregation of genes that stick together, like a chain composed of a series of links, each somewhat different from the others; or as a spiral of protoplasm inclosed in a matrix and divided into sections, each section being a gene; or as a package containing

genes, like a druggist's vial containing pills. The point is that genes occur in groups; and since they do, all of the genes on one chromosome and the characters controlled by these genes tend to be inherited together in what is known as linked-inheritance or linkage.

This is quite different from the idea held by Mendel, the father of modern genetics. One of Mendel's laws was that all characteristics assort independently of each other in inheritance—the theory of independent assortment. As a matter of fact, apparently all the characteristics Mendel studied in peas were so located that they did assort independently. This was one of the most lucky of scientific accidents. If Mendel had happened to deal with linked characteristics or those involving the interaction of genes, the results might have been so complicated that he could not have worked out his clear-cut laws with the knowledge then available.

It was about 1905 when Bateson and Punnett in England discovered characteristics that did not assort independently but remained together in inheritance. As more evidence of this kind accumulated, various theories were proposed to account for it. The one finally accepted was that genes for certain characteristics tend to be linked together in what were called linkage groups. When Sutton in 1902 showed that chromosomes, the existence of which was known through microscopic studies of the cell, play the dynamic role in inheritance, it took only one more step to demonstrate that the genes in a linkage group are carried on a specific chromosome and the number of linkage groups and chromosomes is the same. Corn, for example, has 10 chromosomes and 10 linkage groups. However, it is not possible by looking at a chromosome to tell what genes it contains. The breeder must first discover by actual test what characteristics tend to be linked together in inheritance; then he assumes that the genes determining these characteristics are located in the same chromosome. In some cases, notably the pomace fly and the corn plant, it has been possible by such breeding tests to assign a large number of genes to definite chromosomes.

But the situation is not so simple as this account might indicate. A given gene does not always stay in the same chromosome. Kempton's article in the 1936 Yearbook described how a pair of homologus chromosomes become twisted together during the formation of reproductive cells, and how they may exchange equal portions during this process. This is called crossing over, and it is equivalent to saying that genes are exchanged between the two chromosomes. Thus the original linkage group is changed and a new combination within the linkage group is formed.

Suppose, to take an imaginary example, that on one chromosome there is a gene *A* determining resistance to a certain disease and not far from it a gene *B* determining broad leaves. In the corresponding places on the homologous chromosome of the pair, there is a gene *a* determining susceptibility to the disease and a gene *b* determining narrow leaves. When these chromosomes segregate in inheritance, every plant that is disease-resistant will have broad leaves and every one that is not resistant will have narrow leaves, since *AB* are located in one chromosome and *ab* in one chromosome. But suppose that in the reproductive cells of one plant, *A* and *a* are exchanged by crossing over. Now *Ab* will be in one chromosome and *aB* in the

138904°—37——91

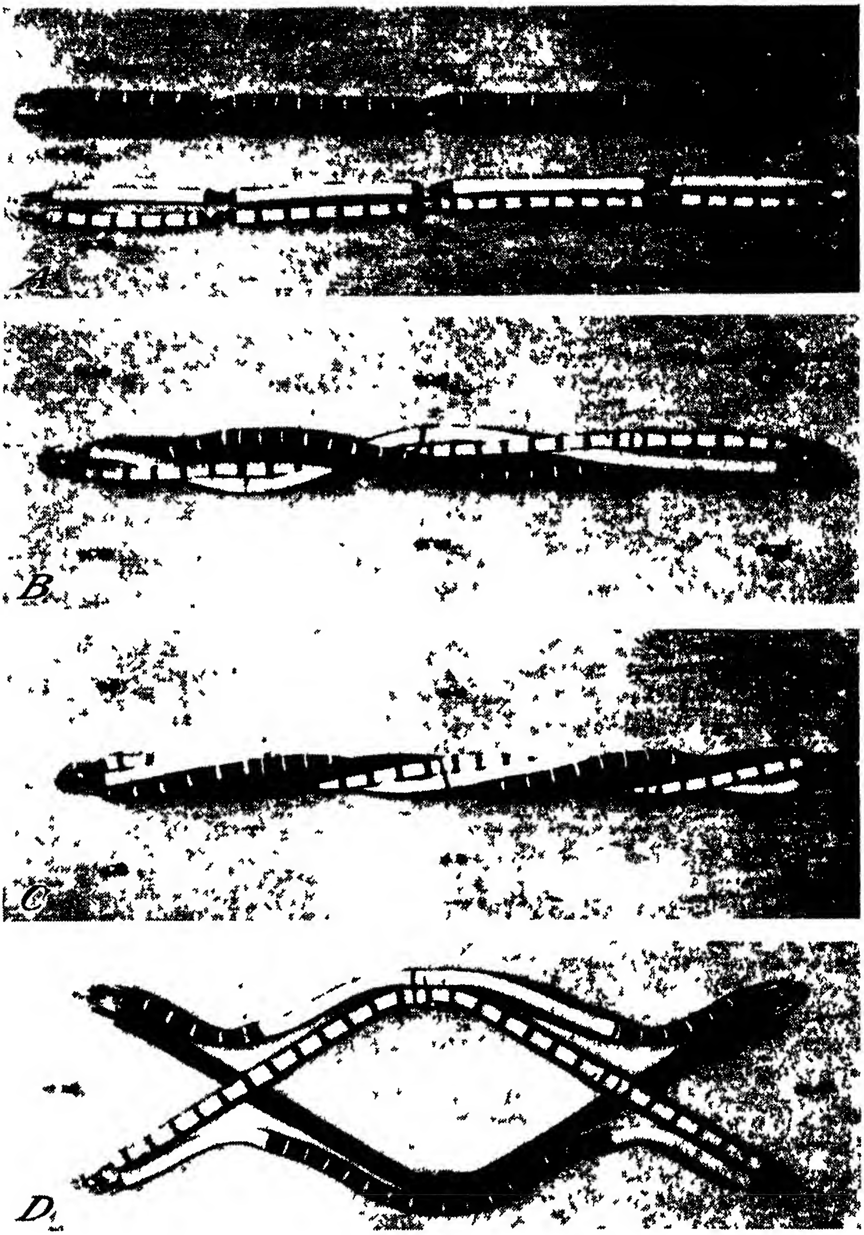

Figure 5.—Models of chromosomes (*A*) broken into "chromatids" (longitudinal sections), showing two ways (*B, C*) in which the sections might wrap around one another to produce the cross-overs shown in *D*. These chromosome models were prepared by H. B. Newcombe and G. B. Wilson, of the Department of Genetics, McGill University, Montreal, Canada. (Courtesy of Journal of Heredity.)

other, and there will be an opportunity to obtain new true-breeding strains as a result of these recombinations. Figure 5 illustrates two ways in which linkage groups are broken up by crossing-overs.

If the genes were very close together, the break would obviously have to occur within a very narrow range to bring about an exchange, and if they were next to each other it would have to occur exactly between them. In other words, the closer the genes are on a chromosome the less likelihood there is that a break will occur in the right place to make an exchange possible. Geneticists have taken advantage of this fact to locate the position of genes on chromosomes without actually seeing the genes. For example, if in a case of linkage 20 recombinations are obtained out of every 100 progeny, the two genes are said to be located about 20 units apart on the chromosome, for the number of new combinations that are obtained when linkage is involved depends upon the amount of crossing over, and this in turn depends on the distance of the genes apart. In this case the genes would be said to have 20 percent linkage, since the degree of linkage is designated by the amount of crossing over. Cross-overs are extremely frequent and they may make breeding operations either more difficult or easier, depending upon a breeder's desire for new combinations.

It is this physical fact that enables the geneticist to draw maps showing the locations of genes on chromosomes. First, by appropriate tests he determines that two genes, *A* and *B*, are located on the same chromosome. Then, by breeding many progeny, he determines the percentage of cases in which there is crossing over. By getting a whole series of percentages for other genes—*C*, *D*, *E*, *F*, *G*, *H*, etc.—in relation to both *A* or *B*, he can determine how close these are to the genes already located. Without ever seeing or identifying any of the genes, he can determine mathematically their relative position on the chromosome, and knowing the percentages of crossing over between them, he can make a genetic map of a chromosome showing the approximate locations of the genes. Other techniques are available for aiding in chromosome mapping.

Effect of Linkage on Segregation

The effect of linkage on segregation ratios may be illustrated with the fowl. Landauer and other investigators have demonstrated a linkage between the creeper characteristic, which causes a marked shortening of the long bones of the wings and legs (the fowl seems to creep), and single comb. Rose comb (*R*) is dominant, and single comb (*r*) is recessive. Creeper (*Cr*) is dominant, and normal or noncreeper (*cr*) is recessive. To show how this linkage affects ratios an example of an actual cross is given. One parent is normal and rose-combed (*cr cr RR*), the other is creeper and single-combed (*Cr cr rr*). The "creeper" parent is heterozygous for this condition because when homozygous it is lethal, the embryos dying at about the seventy-second hour of incubation. When these parents are crossed, one-half of the F_1 progeny have all four genes and are of the genotype $\frac{cr\ R}{Cr\ r}$[14]. They are creeper and rose-combed because of the effects of the two

[14] This form is used in linkage studies to designate which genes are linked. In this case *cr* and *R* are on one chromosome and *Cr* and *r* on its homologue.

dominants. Now the F_1's of this type are backcrossed on double recessives, that is, fowls with single comb and normal wings and legs, $\frac{cr\ r}{cr\ r}$. If the creeper and single-combed condition were assorted independently, we would get the normal backcross ratio—1 creeper rose comb: 1 creeper single comb: 1 normal rose comb: 1 normal single

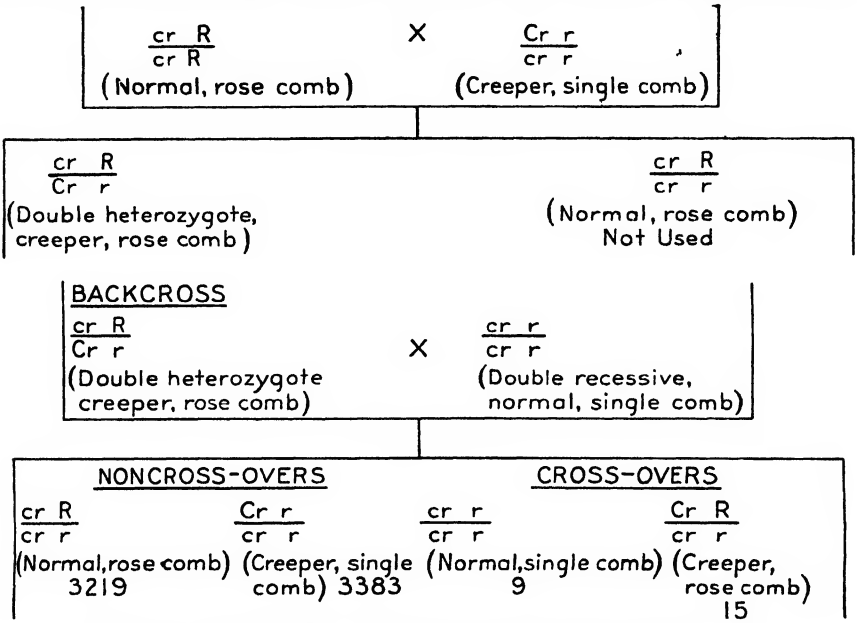

Figure 6.—Test for linkage between rose-comb and creeper genes.

comb. But this does not occur. Instead the following proportions, as shown by Landauer, are obtained—normal rose comb 3,219: creeper single comb 3,383: creeper rose comb 15: normal single comb 9. In other words, the normal rose comb and creeper single-comb birds (parental types) are enormously in excess of the number expected. The conclusion therefore is that the genes for normal wings and legs and rose comb are on the same chromosome, and those for the creeper condition and single comb are on its mate or homologue. When the chromosomes segregate, the original combination of genes stays together, and the few cases of the opposite combination are due to crossing over. Without crossing over there could not be a creeper bird with rose comb, or a normal one with single comb. Since 0.36 percent of the progeny were of these types, there must have been crossing over between the genes on the chromosome carrying the creeper rose comb characters and their alleles in 0.36 percent of the gametes produced by the parent heterozygous for both characteristics. This is referred to as 0.36 percent crossing over. The matings and segregations are shown in figure 6. The proportions were obtained by Landauer.[15]

[15] LANDAUER, W. STUDIES ON THE CREEPER FOWL. V. THE LINKAGE OF THE GENES FOR CREEPER AND SINGLE COMB. Jour. Genetics 26: [285]–290. 1932.

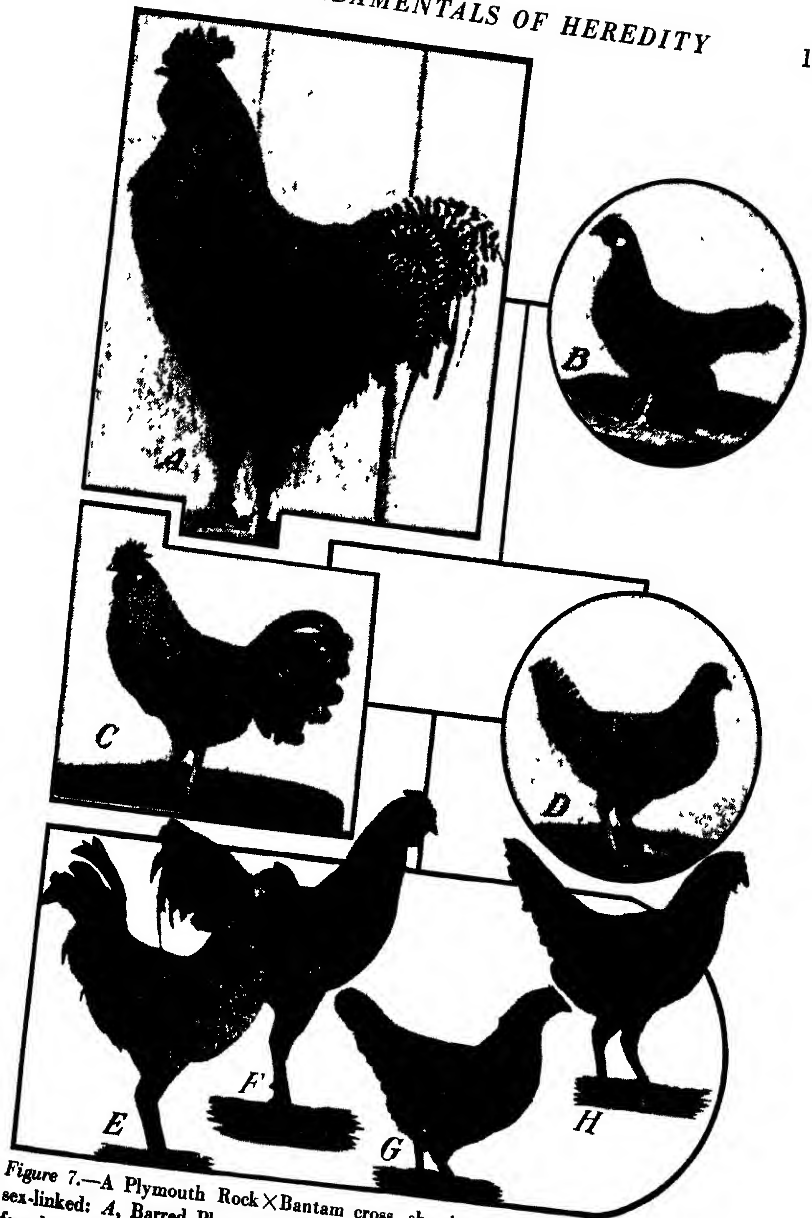

Figure 7.—A Plymouth Rock×Bantam cross, showing the barring gene, which is sex-linked: *A*, Barred Plymouth Rock male parent; *B*, Rose Comb Black Bantam female parent; *C*, *D*, first generation; *E*, *F*, *G*, *H*, second generation. Note that barring is dominant (no black birds in the first generation) and a 3:1 ratio is obtained in the second generation. There are, however, no black males in this generation.

Sex Linkage

A special case of linkage of particular importance is the linkage associated with sex. Maleness and femaleness may be considered to be characteristics just as truly as any others. If they were determined exactly like other characteristics, however, the world would be very different than it is. Suppose, to take a hypothetical case, that in animals there was a gene *M* for maleness and an allel *m* for femaleness. Whenever a male and a female—*MM* and *mm*—crossed, all the progeny would be *Mm*. If *M* were dominant, they would all be males, and no further reproduction would be possible. If neither gene were dominant, all the progeny would be male-female, that is, hermaphrodite. Neither of these conditions occurs; instead, in the population at large, males and females are born in approximately equal numbers. If sex is determined by a gene, then, it does not operate like other genes.

What actually does determine sex is another of the unsolved problems. It is known, however, that in many animals, sex is associated with a chromosome peculiarity. In the dog, the cat, the pig, the cow, the horse, and some other animals it is believed that the female has one more chromosome than the male. In these cases the male contains all the chromosomes contained in the body cell of the female, and in addition one so-called *X* chromosome—not a pair. The female, who has a pair of these *X* chromosomes, therefore always has one more chromosome than the male with *X*. In some species of *Drosophila*, each sex has a pair of sex chromosomes, but they are different in males and females. The odd chromosome found in the male is designated as *Y*, so that the female has the composition *XX* and the male the composition *XY*. In moths and birds, this situation is reversed; the male has a pair of sex chromosomes called *ZZ* and the female a single *Z* chromosome and a *W* chromosome. The effect of a typical sex-linked gene-barring is shown in figures 7 and 8.

If sex is determined by a gene (or even a number of genes in combination) on a sex chromosome, this arrangement would bring about a segregation that accords with the facts. Let us say the female is the one homozygous for sex, with the combination *XX*. The male is heterozygous, with the combination *XY*. When the chromosomes are reduced to form reproductive cells, every reproductive cell produced by the female has an *X* chromosome. Out of every two reproductive cells produced by the male, however, one has an *X* chromosome and one has a *Y*. When a female cell met an *X* male cell, the union would give the combination *XX*, which would become a female organism. The female cell that met a male *Y* would have the combination *XY*, which would become a male organism. In the *WZ* type of sex determination males are homozygous, *ZZ*, and females heterozygous, *WZ*. In both cases, males and females would be produced in approximately equal numbers in the population as a whole.

On the other hand, it is possible that sex is not determined by a gene or genes. One theory is that it is determined by a certain balance between all the chromosomes. There might well be a different

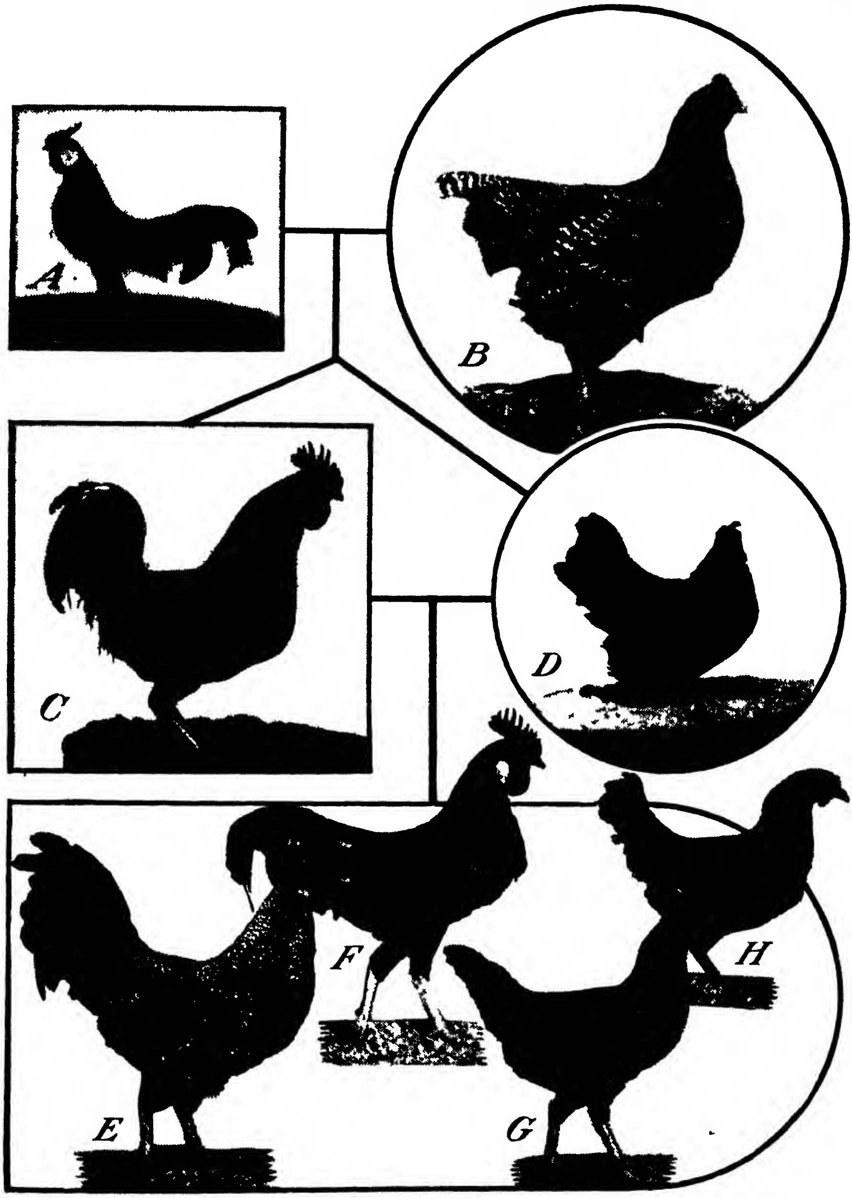

Figure 8.—The reciprocal of the cross shown in figure 7: *A*, Rose Comb Black Bantam male parent; *B*, Barred Plymouth Rock female parent; *C*, *D*, first generation; *E*, *F*, *G*, *H*. second generation. Note that in this cross the Black Bantam is a male and the Plymouth Rock a female. The color factors show typical sex-linked inheritance—also what is known as "criss-cross inheritance." The latter is common in cases of sex-linked inheritance. In this cross it is readily seen when the parental and first generation types are compared. The black color of the male parent is shown only in the female of the first generation and the barred characteristic of the parental female is shown only in the male. In the second generation there is an equal number of barred and black males and females, respectively.

balance between an organism with one *X* or one *Z* chromosome and an organism with two.

The sex chromosomes do more than determine sex (granted that they do that). They also carry genes determining other less unique characteristics such as barring, mentioned above. All the genes on a sex chromosome, naturally, are in a single linkage group, and they are associated with sex in inheritance. How does this work out?

As an example, we might take the type of color blindness in man that renders a person unable to distinguish between red and green. This is a sex-linked characteristic; it is recessive and its determining gene is located on the *X* chromosome. Now it has been shown that when an *X* chromosome from a female cell combines with a *Y* in the male cell, the result is a male organism, a son, On the other hand, when an *X* from a male cell combines with an *X* from a female, the result is a female, a daughter. This is another way of saying that a son can receive the *X* chromosome only from his mother. The father's *X* chromosome, on the other hand, can go only to the daughter. Thus if the father's *X* chromosome contains the gene for color blindness, it will go to his daughter but will be expressed only if both father and mother transmit color blindness, since the two recessives must come together. A son who is color blind could have inherited the trait only from his mother, from whom alone he receives the *X* chromosome.

A sex-linked characteristic, it should be noted, is quite different from a sex-limited characteristic. A sex-limited characteristic is one that can be expressed by one sex only; genes for it may be contained in the other sex, but there is something that inhibits its expression. Thus milk production may conceivably be inherited by both males and females, but its actual expression is limited to females. Horns in Rambouillet sheep are limited to males; presumably there is something in the glands of the females that inhibits the expression of horns, or perhaps something in the glands of the male that compels the expression.

MUTATION OF GENES AND CHROMOSOMES

OTHER phenomena in addition to linkage and crossing over affect the orderly transmission of a given set of genes to offspring. In a broad sense these phenomena may be classed as mutations. Gene mutations involve a change in one or more genes, and they are now understood to be caused in any one of a number of ways, as by heat reaching the cell at a certain stage of its development, or by radiations of certain wave lengths. In the latter case, it has been suggested that a gene may be altered by a direct hit from an electric particle. In any case, once a gene in a reproductive cell has mutated, it is thereafter inherited in the new form, unless there is another mutation, It is now commonly believed that many, perhaps most mutations, are harmful to the organism.

Polyploidy brings about similar results. This is an increase in the number of chromosomes in the cell, beyond the number that is normal for the particular organism. Polyploidy frequently occurs when organisms only distantly related are crossed. Presumably some or all of the chromosomes from the two parents are so unlike that they are

unable to join in pairs, with the result that the number cannot be reduced in the regular way when reproductive cells are formed. The unpaired chromosomes are then left over to increase the regular number in the reproductive cell. Sometimes there is only one extra chromosome, sometimes several, sometimes a whole extra set, or more than one extra set. The phenomenon is treated at greater length in Dr. Blakeslee's article, which appears in a separate of this Yearbook.

Naturally geneticists deal with other concepts besides Mendelian ratios, linkage, sex-linked factors, lethal factors, multiple allelomorphs, and other phenomena discussed in this article. They are paying considerable attention to such things as chromosomal aberrations, translocations, gene frequency, epistasis, and genetic tensions. As yet the real importance of some of these newer concepts is not known. Some may have a profound effect upon our knowledge of heredity, others may be of little importance or may prove to be another way of stating something that is already known.

The influence of environment on the expression of genes cannot be ignored. For instance, in the case of animals it is only under certain specific conditions of feeding, care, and management that genes for rapidity and economy of gain, or for high milk production, can be fully expressed. Taking production as an example, it is conceivable that one strain of dairy cattle might have genes that would enable it to produce at a high level on a diet that would reduce the production of another strain to a very low level. In other words, there is no universally optimum environment but an optimum for a specific gene or genes. Temperature and nutrition have been found to produce important effects even on such characters as coat color in rabbits and rats. In certain kinds of rabbits low temperatures cause new hair to come in black, whereas at higher temperatures the hair developing on the same parts of the body is white. Thus it is evident that the geneticist must consider the interaction of the genes with the environment in accurately describing their expression.

GENETIC ANALYSIS—PLANTS AND ANIMALS COMPARED

INTENSIVE study of one animal form, the small pomace fly of the genus *Drosophila*, principally by Thomas Hunt Morgan and his students, has contributed very largely to the understanding of the mechanism of heredity. Because of its short life span (it lives only 13 days on the average), its minute size, which permits hundreds of flies to be grown in small vials, its small number of chromosomes, and the presence in the species of a large number of different characters, it has proved to be remarkably good material for genetic study. But even with *Drosophila*, progress has been made at the cost of much painstaking labor, and probably over 25,000,000 flies have been raised and examined with meticulous care by students of this species.

With the laboratory rodents and the fowl progress has also been relatively rapid. The manner of inheritance of many traits, such as color and various defects of structure and function, has been clearly determined and it has been shown that the types of inheritance (independent, linked, and sex-linked) are the same for these forms as for *Drosophila* and many plants. And the masterful analysis by Wright

of the results of many years of inbreeding of guinea pigs by the Department of Agriculture has contributed much to what is known of the consequences of inbreeding, cross-breeding, and various other systems of mating, in both plants and animals.

With the larger animals progress has not been so great and the criticism is frequently made that genetics has contributed little of importance to animal breeding. Much of this criticism is unjustified. While the direct contribution to breeding practice has not yet been great, genetics has contributed in a large way to an understanding of the basic principles of breeding, and many concepts and superstitions, such as telegony (an alleged effect of a sire on later progeny of the same dam by another sire) and maternal impressions, have been discarded as a result. It is now possible more readily to eliminate undesirable hereditary traits from breeding stock. Application of this knowledge has been employed especially in the elimination of such abnormalities as lethal conditions, which have been found to be inherited to some extent in most classes of animals.

The way in which the breeder of dairy cattle, for example, is today shaping some of his breeding methods on the basis of genetic principles is greater than is ordinarily realized. Within a period of 10 years breed associations have adopted herd tests for the purpose of securing records on all animals in a herd instead of the best ones only—a recognition of the fallacy of selective testing. They are publishing daughter-dam records for sires in recognition of the need of determining the genetic make-up of outstanding sires. Great emphasis is being placed on the sire that has proved through the progeny test that he possesses a superior inheritance. Finally, many courses for the study of the principles of Mendelian inheritance as applied to dairy cattle are now held regularly.

In a negative way also genetics has contributed to practical breeding. A knowledge of Mendelian laws has brought an understanding of the consequences of the various systems of mating that have shown the limitations of selection and certain other breeding practices.

In plant production it is usually possible to obtain large numbers of progeny in a relatively short time and at little expense. The segregation by classes permits a determination of the ratios between them, and this makes it possible to formulate a hypothesis to explain the mode of inheritance and the genotype of the parents in a rather conclusive manner for most qualitative and some quantitative characteristics. By the application of the principles of Mendelism it has also been possible to work out the genetic basis for the more simply inherited unit characters in animals, explain the occurrence of unexpected progeny, and predict the frequency with which they may be expected in the future. With a background of such information the breeder can decide whether he wishes to continue to breed a dam that produces progeny meritorious in some such character as conformation even though a certain percentage of her progeny have a very undesirable characteristic and must be culled.

An understanding of the mechanism of sex determination was also largely dependent upon genetic discoveries. Cytologists had postulated the sex chromosomes as the basic sex-determining mechanism, but it remained for the discovery of sex-linked characters and the genetic

analysis of such characters to furnish final proof of the correctness of this hypothesis. In poultry a large number of sex-linked genes have been studied and the facts obtained from some of these studies have been put to practical use in certain crosses to determine the sex of chicks at the time of hatching. There is also some evidence that certain genes affecting such characters as maturity and rate of winter egg production are sex-linked, and, if these observations are substantiated, the information should eventually enable the poultryman to incorporate these genes more easily into his flock.

Aside from such rapid-breeding forms as *Drosophila*, Mendelian analysis with animals in the sense of locating individual genes or finding the number of genes that determine a given character will always be more difficult than with plants, and a complete analysis with the larger animals will probably never be made.

Why Progress in Animal Genetics Is Slow

There are numerous reasons why animal genetics has not made and cannot hope to make as rapid progress in working out a complete genetic analysis as has been possible with plants. Some of these reasons will be discussed below.

(1) The male and the female are different individuals. Thus self-fertilization, an important method used extensively in plant breeding, is not possible in the breeding of livestock. The progeny always has genes contributed by both parents, and since each parent has a different set of genes this greatly retards the rate of production of genetically pure forms. Progress in plant genetics has been aided by the ability to determine the genotype through the segregation of progeny produced by self-fertilization. The mating of brother and sister or of a parent to his or her offspring is an approach to the self-fertilization method used by the plant breeder, but the progeny test, as shown in figure 9, is being more and more widely used as a method of determining the genotype in animal breeding.

(2) The rate of maturity and breeding is relatively slow. In most plants with which genetic progress has been made, it is possible to obtain at least one generation a year. An animal— for example, a calf— must often be kept 2 years before it produces any progeny. In turn, the female progeny must be kept 2 years before it produces milk, in case this is the character to be measured. Another year is required to get the complete lactation. If the first calf happens to be a female, at least 5 years are required to get the first record of production on dam and daughter. Further records on other progeny will be needed to determine the genotype of the dam.

(3) The number of progeny of any pair of individuals is usually too small to be sure of the genotype of the parents. Earlier in this article, it was pointed out that the genotype of the individual is determined by the type of progeny it produces. Backcrossing to the homozygous recessive strain was found to be the easiest way to determine the genotype. Applying this to a dairy animal, let us assume that dominance is involved in inheritance of milk yield. If the animal in question were a cow and if a bull carrying the recessive factors were available, so many years would be required to get sufficient milk records on the female progeny of this cow in order to have data on which

sound conclusions might be based regarding the genotype of the dam that the procedure would be impracticable. Moreover, only half of the calves would be females, and not all of these would be raised so that milk records could be obtained for them.

A case of polled condition in cattle involving a single pair of genes will help to explain this, although it should be kept clearly in mind

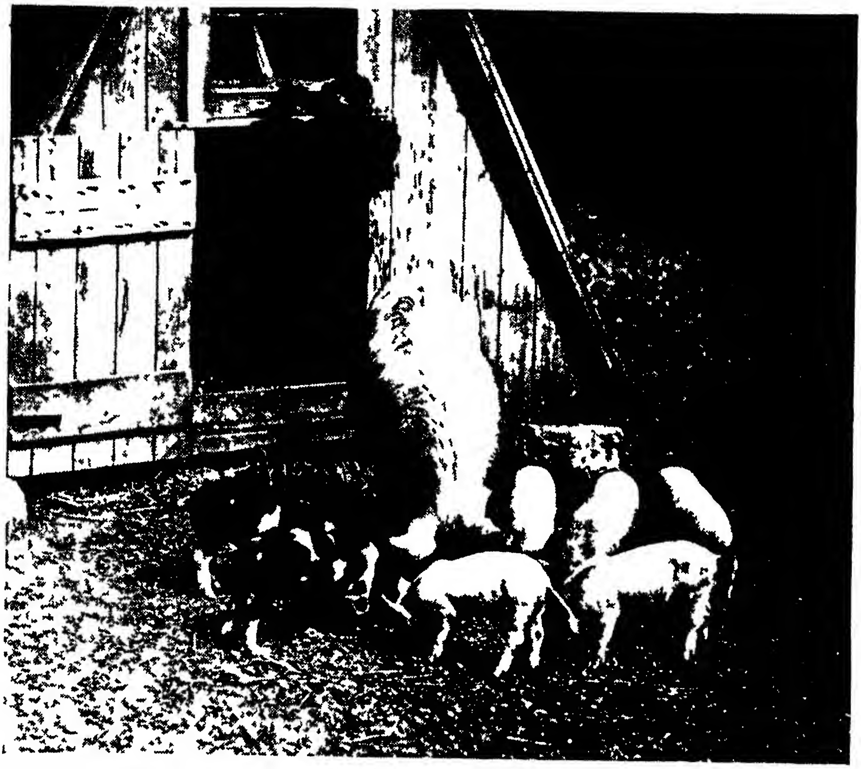

Figure 9.—Brother and sister matings are the closest approach that the livestock breeder can make to the self-fertilization method used by the plant breeder. Here is shown a cross-bred Berkshire-Yorkshire sow with pigs by a Yorkshire-Berkshire sire. The ratio is 7 white pigs: 2 black with some white. Both of the latter type died. (Courtesy of Journal of Heredity.)

that milk production is probably due to several pairs of genetic factors. In cattle the polled condition (*P*) is dominant and horns (*p*) recessive. Suppose a polled cow produces a polled heifer calf, but in later matings produces a horned bull calf (simple recessive). It is desired to know if the genotype of the polled heifer calf is *PP* or *Pp*. In the former case, the heifer might advantageously be kept for breeding purposes, but in the latter case, it might be undesirable to do this in view of the fact that she would transmit the gene for horns to one-half her progeny. Of course, she could be used for breeding purposes and produce no horned calves if mated to a *PP* sire even though the gene for horns would be transmitted to one-half her progeny.

After reaching sexual maturity, the polled heifer (*P*–) is mated to a horned bull (*pp*). If she carries horns, one-half of the calves should be horned. If all the calves are polled, it will be necessary to produce four to six calves to obtain a reasonable degree of assurance that the polled heifer does not carry the gene for horns. Here, it has taken several years to determine the genotype of the polled heifer for one pair of genes, which may be expressed in calves of either sex. Consider how much more complex the problem becomes when the characteristic concerned is due to the action of several pairs of genetic factors, expressed only by females and not by them until they have reached sexual maturity, as in the case of milk production or egg production. Further, a cow that has produced four to six calves will not be available very much longer for breeding purposes.

The case of horns involving the action of only one pair of genes is the simplest kind that will be encountered. Suppose we are concerned with the inheritance of characters behaving like comb type in fowls. Here, two pairs of genes are involved. The double recessive for both pairs of genes results in a single-combed bird. The dominant gene of one of the pairs produces pea comb and the dominant gene of the other, rose comb. When the dominant genes are present in both pairs, a walnut comb results. The ratios to be expected in cases where two pairs of factors are involved have been pointed out in the previous discussion. At least 16 individuals would be necessary to represent the segregating groups in the proportion in which they occur in the F_2 generation.

Warwick has suggested that inguinal hernia in swine is due to the operation of at least two pairs of recessive genes. This characteristic does not ordinarily appear in sows, although sows transmit the genes for it. To determine whether a sow transmits hernia, it would be desirable to mate her with a herniated boar (backcross) and ascertain if any of her male pigs were herniated. The ratios expected would depend somewhat on the genotype of the sow. If she did not transmit both recessive factors, none of the pigs would be herniated. Still we would not know whether she transmitted the recessive gene of one of the allelic pairs. If she were heterozygous for one pair of factors and homozygous recessive for the other pair—that is, with the constitution *Aa bb*—one-half of her male progeny from the herniated boar would have hernias. If she were heterozygous for both pairs of factors, with the constitution *Aa Bb*, one-fourth of the male progeny would be expected to have hernias. Modifying factors may still further complicate the situation. Therefore, it is usually considered advisable, instead of testing the individual concerned in a definitely planned experiment, to go ahead with the usual breeding operations, and if the parents produce herniated pigs, to assume that both parents transmit the undesirable characteristics, and discard them so as to eliminate the possibility that their progeny will carry an undesirable recessive to still more descendants.

The difference between high and low milk production certainly is due to the operation of several pairs of genetic factors. Estimates of different investigators have ranged from 3 to nearly 20 pairs of genes. This increases the number of animals necessary to give a complete segregating population beyond any possibility of a single pair of par-

ents producing sufficient progeny to determine the genotype accurately. With 10 pairs of genes, which has been suggested by Turner as the minimum number controlling milk production, 1,048,546 animals would be required to give a complete F_2 population and 1,024 progeny to give a complete backcross generation. Obviously, it is impossible to get enough progeny from matings between the same two individuals, yet genotypes of a pair cannot be ascertained otherwise. Moreover, to allow for chance variations, it is usually considered necessary to have at least three times as many individuals as are needed for the complete segregating population.

(4) Animal-breeding research is very costly. It is much more expensive to produce a single individual than would be required in the case of a single plant. Special care, feeding, management, and adequate space are required. The progeny of any single mating is small as contrasted with the large number of seeds produced by most plants. The cost of keeping the numbers of animals needed to work out a rather complex ratio involving several pairs of genetic factors is almost prohibitive.

(5) Many of the characteristics of economic importance do not readily group by classes. Color, horns, and many of the more obvious characteristics are inherited in a relatively simple manner, but the genetic basis for characteristics concerned with the production of milk, meat, eggs, wool, etc., is more complex. The genes determining milk-producing capacity may act in a cumulative manner, or dominance may govern their expression to a greater or lesser extent. It is probable that if several pairs of genes are involved, various kinds of gene interactions occur, which adds to the complexity of determining the mode of inheritance of such characters.

In cases where a large number of genes are operative in determining a quantitative characteristic such as yearly butterfat production, different genotypes may give rise to the same phenotype. For example, with genes *A*, *B*, and *C*, assuming that *A* was responsible for 150 pounds; *a*, 25 pounds; *B*, 75 pounds; *b*, 25 pounds; *C*, 100 pounds; and *c*, 25 pounds, one might have an individual producing 350 pounds of butterfat with the genotype *Aa bb Cc*, or *aa Bb CC*. Such conditions make the identification of the effect of the different genes very difficult, if not impossible. When a large population is needed in order to have representatives of the different types, the difficulties encountered in studying quantitative characters, which includes so many of those of economic importance, are apparent.

(6) Modifying factors, which play an important part in the inheritance of many characters, tend to spread the classes so that one grades into another. The mode of inheritance of these factors is similar to that of the other genes concerned, yet their presence may completely change the results obtained. For example, in some poultry there is an inhibiting gene preventing the appearance of any color. The presence of this gene results in the white of the White Leghorn. Yet the White Leghorn may carry many color genes, expression of which is inhibited until suitable crosses with other breeds permit their expression in the absence of the inhibitor. In quantitative characters, such genes may increase or reduce the expression of another gene, as in the case of the relative amounts of color and of white in spotted animals.

(7) Environmental effects may prevent the expression of certain genes. The characters of economic importance in livestock are influenced to a considerable extent by environment. For example, it is well known that a dairy cow may not produce up to her inherent capacity if she receives an insufficient food supply. To be sure, the plant is subject to environmental influences also, but ordinarily plants are placed under more adequate control, or at least the effect of environment can be evaluated more easily and at less expense. The identification of the role of the individual gene becomes practically impossible unless the environmental effects are known and kept constant.

Breeding Programs and the Future of Animal Genetics

Fortunately there is a brighter side to this picture. It is not necessary to know how many genes affect each character nor the effect of each individual gene entering into the final expression of a given quantitative character in order to make progress in animal breeding. Again we may use the inheritance of milk yield as an example. We now know that the cow that produces 350 pounds of butterfat cannot be depended on to transmit the inheritance for that level of production to all her offspring. But if a herd of such cows are mated to a certain sire and all or most of the daughters produce 400 to 450 pounds of butterfat under the same environmental conditions, then we know that the sire possesses a genotype for a higher level of production than did the dams to which he was mated. Furthermore, the continuous use of sires that have demonstrated through the progeny test that they possess a genotype for higher levels of production will result in concentrating the factors determining the higher levels of production in the germ plasm of the herd. (The genotype of the dam as well as that of the sire can be determined by the progeny test, but the time required is so much greater and the inheritance of the individual dam is transmitted to so few progeny that it is much more feasible to work through the sire.) Thus progress is made in animal breeding by working with the end result of numerous genes, even though the number of genes involved is not known, nor the part that an individual gene plays in bringing about the end result.

Research work is gradually bringing about a knowledge of the extent to which some of the more common environmental variations may influence the expression of a character. In dairy cattle, for instance, knowledge is being accumulated concerning the effect on production of a number of factors, including age; the use of box stalls as compared to stanchions; the number of milkings per day; different ratios of grain or the all-roughage ration. Such information helps in evaluating a sire when, as frequently happens, the dams and daughters did not make their records under entirely comparable conditions, since suitable corrections can be made. However, more knowledge is needed to solve many of the problems that confront such a system of breeding as that outlined above. For example, when a sire is mated to dams with a very high level of production and the daughters of that mating have a somewhat lower level of production than the dams, it is difficult to determine what the genotype of the sire is, unless he has also been mated to cows possessing a lower level of production to see whether

he raised it or not. Likewise, when a sire is mated to dams with a level of, say, 350 pounds of butterfat and his daughters prove to be considerably above that level, it is impossible to know whether he has a genotype that will enable him to improve the germ plasm of a herd of cows with an average level of, say, 600 pounds, perhaps made under different environmental conditions than the record of the first herd.

The so-called proved-sire system of breeding progresses most rapidly where (1) the sire is mated at an early age to a large group of females, so that there is a sufficient number of female progeny to make possible the evaluation of his genotype before he reaches too advanced an age; (2) there is no selection of the daughters and their dams on the basis of high records; (3) records are made under environmental conditions that are comparable for both daughters and dams; and (4) environmental conditions are sufficiently good to enable the animals to express levels of production approaching their inherent capacity.

The difficulties encountered with the breeding of larger animals as contrasted with the progress made with insects, plants, and laboratory animals lends support to the idea that it never will be practicable, or perhaps possible, to identify the action of each gene in animal breeding. Genetic principles may be worked out with laboratory animals or insects that may be kept at much less cost and will reproduce rapidly. In experiments with larger animals, the genes will not necessarily have to be identified, but evaluations may be made by methods analagous to those employed in proving dairy sires in order to determine transmitting ability. It makes little difference to the dairyman whether 350 pounds of butterfat is produced because the animal was of the genotype *Aa bb Cc*, *aa Bb CC*, or what not, except that crosses of strains of certain genotypes would be expected to produce animals superior to either parent. In practice, it probably would be more satisfactory to test the complementary action of the genes from different animals by trial crossing rather than to attempt to discover the specific genes carried by each animal and the part they play in determining and transmitting characteristics

The complementary action of unidentified genes has been successfully used with corn Strains have been inbred to insure that they were homozygous, and by trial and error it has been found that the progeny from certain crosses are superior to ordinary varieties. The practice of similar methods would appear to offer promise in animal breeding, though experimental evidence will be needed in order to determine whether the results would be superior to, or more reliable than, those obtained by the proved-sire system. Then too, when close inbreeding in animals results in a loss of efficiency in characteristics of economic value, as is often the case, the cost of maintaining these closely inbred strains for crossing will be much greater than is the case with inbred strains of corn. Not all inbred strains of corn respond with marked hybrid vigor when crossed, and many strains have to be crossed in order to find those that result in increased yields. If this same amount of work is necessary with livestock, the expense of this method of breeding appears quite formidable, particularly in the case of cattle and horses. With smaller animals, like swine, the limitation is somewhat reduced and in fact experimental work of this kind is rapidly getting under way.

With the larger animals it is apparent that breeding progress will come about largely through what might be called a mass determination of the genotype. By the application of the progeny test and the use of sires proved in that manner, it will probably be possible to produce strains of animals in the various species containing combinations of genes that will give better average production than any strains now in existence. This method, combined, perhaps, with some inbreeding to produce greater homozygosity of the desired characters, holds great promise for the improvement of all forms of livestock. Progress obviously will be slow, however, owing to the difficulties that have been enumerated.

That genetics has not contributed more to livestock-breeding practice is not surprising. As a science it is less than 40 years old, and many of the basic discoveries have been made in the last 20 years. But the principles underlying breed improvement have been determined, and progress in the future should be more rapid. While Mendelian analysis has taken first place in some forms of life, it is certain that with the larger animals such an analysis will remain secondary to the testing of various breeding systems with the aim of synthesizing better and better strains.

VEGETATIVE REPRODUCTION

J. R. MAGNESS, Principal Pomologist,
Division of Fruit and Vegetable Crops
and Diseases, Bureau of Plant Industry

ALL of the important fruit-crop plants in the United States, many of the ornamentals, a few crops like potatoes, and some of the nut and forest trees are multiplied or propagated for commercial production by vegetative means. This means that a new plant is developed from a vegetative portion of a mother plant, such as a cutting or bud, instead of from a seed, as is the case with most of the cereal, forage, and vegetable crops. This fact is extremely important from the standpoint of the principles and methods employed in the improvement of fruit crops by breeding.

As was explained in detail in the article on Heredity Under the Microscope, in the 1936 Yearbook, the seed in the ordinary plant develops from a single cell, the fertilized egg, which has received in the fertilizing process chromosomes from both the female or seed parent and the male or pollen parent. These chromosomes transmit the hereditary factors or genes from both parents, and the offspring that develops from this cell, therefore, inherits the characteristics of both. If the germ cells from the two parents carry genes that are alike for all characteristics, the plants that develop from the seeds will be very similar to these parents. On the other hand, if the parents transmit unlike genes for various characters, many of the offspring will vary widely from either parent because of the effects of dominance, recessiveness, or modifying factors.

In vegetative propagation the new plant also develops from a single original cell. Although the bud or other propagative tissue may consist of thousands of cells, at one stage of its development only a single cell was involved. This cell carries the same genes as the mother tissue from which it was developed, and the genetic characteristics of the new tissue correspond to those of the mother plant, except in the case of vegetative mutations, to be discussed later in this article. From the hereditary standpoint it may be said that the vegetative offspring of a plant is a part of that plant itself rather than a new individual.

The Winesap apple, for example, originated as a seedling about 200 years ago. The original tree has probably been dead for more than a century. Before that tree died, however, buds taken from it were grafted into other apple roots and these buds developed into new individual Winesap trees, the tops of which are genetically a continuation of the parent trees. Many generations of trees have been grown from this original Winesap, yet the characteristics of the Winesap

trees and fruits today are but little, if at all, changed from those of the original tree.

Varieties of European wine grapes exist today that are believed to have originated several hundred years ago. These grapes have come down to the present time practically unchanged in character because vegetative portions of the vines rather than the sexual portions or seeds have been used for propagating them. The Wilson strawberry, originated in 1852, is still grown to some extent in Oregon. It has been propagated by runner plants ever since its origin and after many vegetative generations is today apparently similar in all respects to the parent plant.

CELL DIVISION IN VEGETATIVE TISSUES

In many respects the division of a cell to form two daughter cells in vegetative tissue is quite similar to that described in the article on Heredity Under the Microscope for germ cells. Each vegetative cell consists of the cell wall, the cytoplasm, and a nucleus. The nucleus, while the cell is in the resting stage—that is, not in the act of dividing—contains numerous chromatin granules, just as the germ cells do. In the beginning stages of cell division these chromatin granules collect in threadlike bodies, which are the forerunners of the more definitely organized chromosomes. These threadlike bodies are usually more or less separate, though in some cases they appear to be arranged end to end. Later they break up into independent chromosomes.

At this stage one very important step occurs that does not occur in the same way in the germ cell. After the chromosomes are formed in the vegetative cell, each chromosome appears to split longitudinally into two parts, giving twice the original number. Each of these parts appears to function as an independent chromosome. After that, the process is like that in the germ cell. The two halves of each original chromosome migrate, one to each of two poles on opposite sides of the nucleus. These two groups of chromosomes, one at either pole, now reorganize as separate daughter nuclei, each similar to the original one. A cell wall is formed between the two daughter nuclei, and there are two complete cells instead of the original one. Each of these cells, however, has the same number of chromosomes as the original, whereas if they were germ cells they would have half the original number.

Apparently the genes, which are the carriers of hereditary factors in the chromosomes, are also divided in this process of longitudinal splitting of the chromosomes, and this gives each daughter cell exactly the same hereditary factors. If it were possible at this stage to isolate each daughter cell and develop from it a wholly new individual, the new individuals would be exactly alike genetically and both would be exact genetic replicas of the parent plant.

However, it is, of course, never possible to grow two plants and have them exactly alike even though they have exactly the same genetic make-up. The final size and shape of a plant depends upon two factors—its genetic make-up and its environment. It is never possible to have exactly the same environment for two individuals. Variations in nutrition, light exposure, moisture relations, or in other

factors in the environment will always make some difference in the ultimate development of individuals. Genetically, however, plants that develop from these vegetative daughter cells will have the same make-up that was contained in the parent cell from which they were derived.

But, even in the most nearly perfect mechanism there is always the possibility that it may not function exactly the same in every case. Thus in the division of thousands of cells there is the possibility that certain cells may not divide so as to give the daughter cells exactly the same genetic make-up. In the splitting of the chromosomes, for example, it might occasionally happen that certain genes would fail to split, in which case one daughter cell might have a certain gene while the companion daughter cell might lack it.

There is ample evidence in the horticultural field that abnormal cell division occasionally occurs in the vegetative development of the plant. When it does occur, if the cell concerned is one from which major portions of the plant develop, a so-called bud sport branch may arise, showing a different character, and this sport or mutant may be propagated by vegetative means. Thus, in an apple variety a gene for fruit color may be added to or taken from a chromosome in a dividing cell at the tip, giving rise to a "color sport branch."

In certain plants shoots arise, not from the continued division of a single cell at the tip, but rather from the divisions of many cells in a group. In such cases the mutant cell may affect only one portion of the new shoot. This may represent a sector running throughout the length of the shoot, in which case we have what is called a sectorial chimera or variation. Buds taken from that particular section will develop into plants showing the variation throughout.

Also, in certain plants mutations occur involving only the outer ring or rings of cells on the stem. These are termed periclinal chimeras. The thornless sports of blackberries are of this type. They reproduce true to the thornless type from propagations made from stem tissue as tip layers, since in this case the new bark develops as a continuation of the old, but not from root tissues, because in this case all the new tissues originate from deep-seated cells that carry genes for thorniness.

These mutations in the vegetative tissues may involve only one gene or they may involve several. Thus, not only color of fruit might be modified, but shape, texture, season of ripening, or chemical composition might be affected by such mutations. At rare intervals a doubling of some or all of the chromosomes may occur without nuclear division, followed by regular division thereafter. Such a mutation, which produces a permanent increase in the number of chromosomes in each cell, often results in marked variations in vigor, fruit size, quality, and other factors in the mutant tissue. The variations can be reproduced in practically identical form by vegetative propagation.

It is noteworthy, however, that in most plants these vegetative mutations occur very infrequently. Ten thousand buds taken from a grape variety may develop into as many individual vines with hardly an observable variation that can be attributed to a lack of perfectly regular genetic reproduction in the vegetative cells. The remarkable feature is not that occasional irregular cell divisions occur, but rather that the irregularities are so rare.

This fact is of tremendous importance from the standpoint of establishing fruit varieties. Once an individual plant is obtained, as a result either of hybridization or of selection, it is possible to reproduce that plant almost exactly by vegetative propagation. With seed-propagated plants, on the other hand, before a new variety can be established it is necessary not only to secure an individual plant that has the characteristics desired but to follow this with selfing or inbreeding until a group of plants is secured of proper genetic purity to come true in large proportion from seed. This long process of breeding to secure varieties that come true from seed is not necessary in the improvement of plants that are vegetatively propagated.

The fact that all fruit varieties are vegetatively propagated, however, is not an unmixed advantage to the breeder of fruit crops. The very fact that individuals can be reproduced by vegetative means has resulted in the selection of varieties without any regard to how nearly they reproduce true to type from seed. Furthermore, up to the present time much less study has been made of the hereditary make-up of our fruits as a group than of many of the seed-propagated crop plants. We can usually judge what characters will be transmitted in inheritance, in the case of seed-propagated varieties of sufficient purity, by the type of parent material. This is not always true of vegetatively propagated plants.

The Northern Spy apple, for example, in its vegetatively propagated form is large-fruited. Seed of this variety, however, produces mostly smaller apples. A particular variety of grape may be black, yet seed planted from this variety may produce white, red, or black grapes. The possibilities of our horticultural varieties as breeding stock can be determined only by trial. In actual experience it has sometimes been found that a variety having very valuable characteristics when vegetatively propagated does not tend to reproduce these characteristics in the seed offspring. On the other hand, certain rather mediocre varieties may prove superior as parents for the development of improved sorts by breeding methods.

Most of our tree fruits and some ornamentals are propagated by budding or grafting the desired variety on the roots of the same or closely related species. With our tree fruits, these roots are mainly developed from seedlings. With grapes and roses, the roots are also propagated vegetatively.

There is much need for investigations in the United States to determine the best rootstock to use with the various fruit and nut varieties. The use of the best rootstocks might greatly improve the vigor and longevity of orchards under certain conditions. For example, peach rootstocks resistant to nematodes in the South and in parts of California should result in longer lived and more vigorous trees. The development of grape rootstocks resistant to phylloxera has saved the vinifera grape industry of southern Europe and in parts of California. The development of apple stocks resistant to woolly aphis would be a great asset to apple growing in many parts of the world. The characters of the rootstock are second only to the characters of the variety in determining successful production of many of our fruit varieties.

DO VEGETATIVELY PROPAGATED VARIETIES "RUN OUT"?

Closely allied to this discussion of the relation of vegetative propagation to breeding is the question of whether or not such vegetatively propagated varieties last indefinitely. It was long held, even by horticultural authorities, that after a few generations of vegetative propagation, varieties gradually lose their superior characters, become less vigorous, and decrease in value until they are abandoned as commercial sorts. Andrew Knight, of England, probably the

Figure 1.—Potatoes in middle row were propagated from seed pieces infected with curly dwarf, one of the potato virus diseases. The rows on each side were propagated from healthy seed stock. Virus diseases transmitted by vegetative propagation undoubtedly account for the so-called "running out" of many varieties.

greatest horticultural authority at the beginning of the nineteenth century, believed that varieties "run out" under vegetative propagation. Potato growers strongly held to this view until recent years, because their varieties appeared to deteriorate rather rapidly. Until recently, most growers of vegetatively propagated plants believed that such propagation is a weakening process and that new varieties propagated from seed must be developed frequently if vigor, quality, and productiveness are to be maintained.

It is true that many vegetatively propagated varieties are popular for a plant generation or two and then pass out of the trade. However, there is no evidence that varieties have become progressively weaker owing to repeated vegetative multiplication. In some cases, varieties develop diseases that may be carried from the mother plant to the daughter through the bud, cutting, or runner plant. This is especially true of the virus group of diseases, and many varieties may have disappeared because of such transmitted infection. A number of virus diseases are known that affect potatoes (fig. 1), strawberries, raspberries, and other vegetatively propagated plants. An under-

standing of these diseases has come only in very recent years. Prior to a knowledge of these diseases it was natural that the grower would assume that the weakened or malformed plants, resulting from vegetative propagation from infected parent material, were "running out." By keeping the parent material for vegetative propagation free of disease, such deterioration can be prevented.

Other varieties are discarded because of changing preferences on the part of the consumer or because the plant may not be sufficiently

Figure 2.—Winesap apple trees still vigorous, productive, and producing good-quality fruit. The leading commercial apple variety of the United States, this variety has been propagated vegetatively since its origin almost 200 years ago.

hardy, vigorous, or disease-resistant to meet new demands. The Early Crawford peach is an excellent example of this. This variety, which originated about 100 years ago, is still identical with the original in all the characters that made it very popular 50 years ago. Today, however, it is little grown, despite its high quality. Other varieties have developed that are heavier yielders, that can be shipped and held on the market in better condition, and that are somewhat hardier.

The Esopus Spitzenburg apple is another example of a very high-quality dessert variety that is disappearing from American orchards because the tree is not hardy and is particularly susceptible to many diseases. Yet there is no reason to believe that this variety as propagated today is in any way inherently different from the parent tree of 150 years ago. It is still a vigorous tree and productive, if protected from low winter temperatures and diseases. In contrast, the most extensively grown apple in the United States today is the Winesap (fig. 2), which is believed to have originated at least 200 years ago.

Occasionally a variety may show a lack of stability under vegetative propagation, which leads to an abundance of vegetative mutations generally of one particular type. For example, in a number of strawberry varieties under vegetative propagation there has been a marked tendency to mutate to a yellow-foliage form (fig. 3). Such wholesale

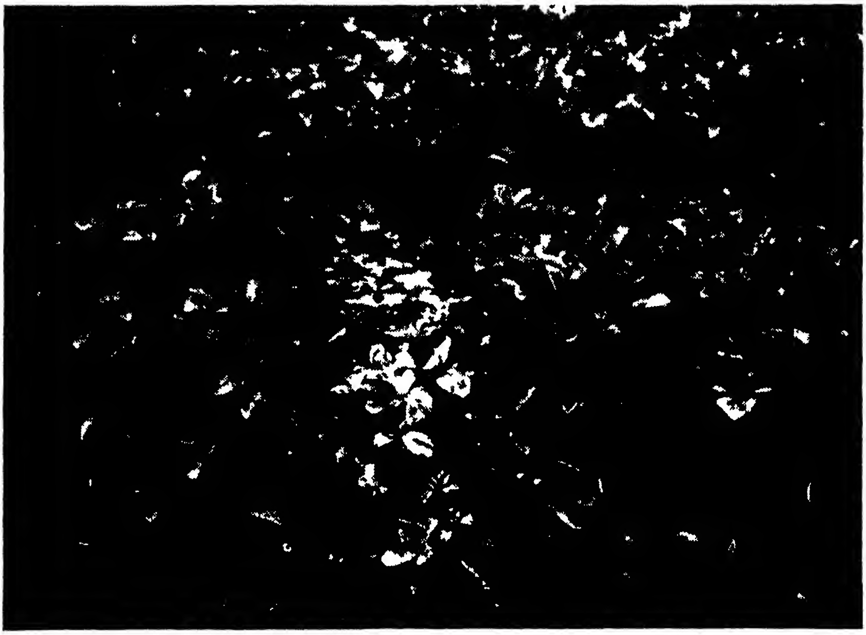

Figure 3.—The yellow-plant mutation (center) in the Blakemore strawberry. This mutation occurs very frequently in this variety and will result in the commercial deterioration of the variety unless propagating material is carefully selected to avoid it.

mutation has occurred in the Howard 17, or Premier, variety, and in recent years it has occurred in the Blakemore. Apparently some unstable gene occurs in the make-up of these varieties that develops a very high proportion of mutations. In certain strawberry varieties this has resulted in their passing out of commercial production.

The Washington Navel orange also appears to develop a rather large number of mutations under vegetative propagation. In most cases careful selection of the parent stock will permit the maintenance of such varieties. Perhaps this marked tendency to mutate, which occurs in a very few vegetatively propagated varieties, most nearly represents "running out" in the sense that the term has usually been employed. Even in this case, however, the selection of true-to-type parent material will usually maintain a variety indefinitely.

A CHRONOLOGY OF GENETICS

ROBERT COOK, Editor, Journal of Heredity

THE science of genetics as of 1937 has a long and rather involved history, which has not proved easy to treat as a chronology. Made up as it has been of a fusion of diverse specialties which have developed at different rates, a simple chronological listing of discoveries and developments necessarily gives a rather fragmentary picture of the unfolding of the modern science of heredity. Various plans were considered to avoid this difficulty, but the most satisfactory treatment seemed to be to combine everything in one simple chronology, which branches out into occasional summary paragraphs to suggest, without prohibitive chronological detail, the recent developments, and to buttress this with a graphic genetic family tree to give visually the relations of the various main components that have gone to make our modern genetic organism. The difficulties that have been encountered in determining many of the "first discoveries" noted in this chronology suggest that an exhaustive history of genetics will soon be necessary. Roberts and Zirkle have recently summarized the early publications on plant hybridization, but a connected story of the development of genetics as a whole remains to be written.

The compiler takes this opportunity to acknowledge invaluable help and suggestions from a group of about 35 geneticists who generously read and commented on a mimeographed first draft of this chronology. In the time allotted it would have been impossible without this freely given aid to have done nearly so complete a job as is here presented—which remains, it is regretfully realized, even with this help, only a very rough sketch. It was the wish of the editors to present in this Yearbook a bird's-eye view of genetic progress pointing out the important highlights but not in too much detail. Without overburdening this chronology with bibliographic references, and thereby reducing its readability to a minimum, and at the same time to make available authority for the dates given, a condensed list of references is included. A more detailed bibliography giving titles of articles cited and authors in full has been deposited in manuscript form in the United States Department of Agriculture library. Copies of this bibliography may be obtained from the library through the Biblioform Film Service. It is hoped that this will make all references reasonably easily available to all who are interested.

BEGINNINGS

FIRST hybrids were probably of species and varieties of cattle and dogs, by Neolithic people, possibly as much as 10,000 to 25,000 years ago.

Several varieties of dogs and of cattle and sheep are depicted on Egyptian and Babylonian monuments of 5,000 years ago. The bisexual nature of the date palm was also recognized by the early Babylonians and Assyrians 5,000 years ago. Mules are mentioned in Homer (B. C. 800) and in Herodotus (fifth century B. C.). The writings of Aristotle and other ancients abound in a wealth of observations, many of them confirmed by modern experiments. Unfortunately they also contain much very fanciful material—descriptions of astonishing and highly improbable hybrids between a great variety of animals. This very likely meant no more than that monstrosities were ascribed to hybridization, as the ancients generally looked upon the process of hybridization with abhorrence. Even angels and demons were reported on excellent authority to have produced hybrid progeny whose astonishing characteristics were limited only by the imagination of the narrator. Theories of heredity were not lacking, but facts that might verify these purely speculative fabrications were held in small esteem. Vergil tells us that the chosen seed, improved through years and labor, was seen to run back, unless man selected by hand the largest and fullest ears (Georgics I: 197). Columella and Varro also affirm the need for selection of cereal varieties. Theophrastus and Pliny discussed sex in plants but reported no experiments.

Allusions to the tendency of "like to beget like" are not hard to find in ancient literature. The Middle Ages enthusiastically added much to the fables but nothing to the factual background of the ancients. In spite of the lack of theoretical background, animal breeding, based on traditional methods ("like begets like" and various approximations to the progeny test), excellently exemplified in the New Testament aphorism "by their fruits ye shall know them", (Matthew 7: 20) made very considerable progress.

That primitive men have been not only persistent plant breeders but fairly successful ones is evidenced by the remarkable progress made in plant breeding in many parts of the world. The ancient Chinese are credited with breeding superior varieties of rice and hybrid flowers. Russian workers have recently published most interesting accounts of the wheat breeding on the southern slopes of the Caucasus Mountains. We have only to consider Indian corn, and the remarkable varieties produced by the American Indians, to realize the fact that man has been breeding plants from very early times.

The records left by the Babylonians and Egyptians leave no doubt that at least 5,000 years ago distinct breeds of domesticated animals were recognized. Certain of the types depicted on those ancient monuments bear a remarkable resemblance to modern breeds. Excellent types of beef cattle and of merinolike sheep are to be seen in some of these ancient relics, which mark the beginnings of recorded history. Jacob's famous agreement with Laban regarding "goats that were ringstraked and spotted" (Genesis 30: 35) has often been cited as evidence of an early belief in maternal impressions. But we read in the next verse that Jacob relied on "three days' journey" between Laban's solid-colored "cattle" and his own spotted flocks, and when it is explicitly stated that the rams used were spotted, it is clear that this ancient Hebrew herdsman did not depend entirely

on magic to produce results in animal breeding. Early Hindu writers also discussed these matters at length.

While the philosophers and scholars of the Middle Ages were piling one improbability on another, at least two great modern breeds were being formed—the Arab horse and the merino sheep. The desert horse had very remote beginnings, and it had reached or maintained such a state of excellence by the Middle Ages that it contributed greatly to the development of the horse of today. The English Thoroughbred breed traces to two Arab horses and a Barb imported into England about the time of Charles II. From very remote beginnings the Spanish merino had reached a perfection that gave Spain virtually a monopoly of the fine wool weaving industry by the fifteenth century. This monopoly was maintained by a strict embargo. Through royal courtesy the ban was lifted in 1765 to permit the export of merinos into Saxony. Within a few years merinos were exported from Spain to several other countries. In 1786 the famous merino herd at Rambouillet, France, was established. Maintained continuously since that time with only one importation of outside blood, this herd has formed the basis for the modern Rambouillet breed, which today is spread over all the world and is raised in greater numbers than any other type of sheep.

One other "root" of modern genetics also had a very early beginning. Mathematics was a subject intensively studied in Babylon, Egypt, and Greece. Some branches of the science of numbers were highly developed among the ancients, although algebra, so essential in modern genetic experiments, was not well developed until after the Crusades. This early science of numbers formed the groundwork for the later development of statistics, probability, and correlation, all necessary tools of modern genetics.

BACKGROUND

By the beginning of the seventeenth century a new spirit of scientific skepticism had begun to be manifest. The reaction of common sense against the cumulative absurdities of centuries of uncontrolled verbalism was reflected in the first stirrings of an age of scientific experiment. Nehemiah Grew in 1676 suggested the nature of ovules and pollen. A growing interest in biology culminated in the publication in 1694 of Camerarius' (Germany) famous 50-page letter on the sex of plants (De Sexu Plantarum Epistola), which put on record convincing evidence that plants are sexual organisms. This was followed early in the eighteenth century by the production of the first artificial plant hybrid by Thomas Fairchild (in England a short time before 1717). The practical implication of these discoveries is reflected in the founding in 1727 of the seed-breeding establishment today world-famous as Vilmorin-Andrieux et Cie. (One of the early great successes of the Vilmorins was the development of the sugar beet during the Napoleonic era.) In the next 50 years there was a veritable wave of hybridizing. Crosses between more than a dozen different plant genera were made by several investigators and reported with varying degrees of accuracy. This period culminated in the publication of J. G. Koelreuter's work (Germany, 1761–66), reporting the results of 136 experiments in artificial hybridization. This

mass of evidence definitely established plant hybridization as a scientific pursuit.

At the same time independent progress was being made in fields that after 1900 were to have a profound influence on genetics. M. Malphigi (Italy) was laying the groundwork for descriptive embryology (1650–70). A. von Leeuwenhock (Holland) was discovering the tiny world of the miscroscope, and with his pupil, Johan Ham (Holland), in 1677, was the first to see mammalian germ cells (spermatozoa). In 1780 L. Spallanzani (Italy) attempted to demonstrate by artificial insemination in dogs the essential part played by the male in fertilization.[1] The modern science of statistics had its beginnings at about the same time, in a treatise published in 1761 by a Prussian divine, J. P. Süssmilch, who undertook by appeal to vital statistics to prove the glory of God. The leisurely progress of scientific thought is suggested by the award to Linneaus (Sweden) in 1760 of a prize for an essay on sex in plants—nearly a century after Camerarius had rather conclusively laid the groundwork of this subject. Linnaeus' publication of Species Plantarum in 1753, which attempted to classify plants according to their assumed relationships, marks an important step in the development of evolution theory. In 1760 Robert Bakewell (England) took over the management of the Dishley Estate, where for 35 years he proved to his own satisfaction that inbreeding is not necessarily injurious and that it is the quickest way to fix type. His experiments laid the groundwork for the development of many of the modern breeds of livestock. In 1793 C. K. Sprengel (Prussia) observed the cross-pollination of plants by insects.

In the matter of human heredity some knowledge had also been accumulating. From the earliest times resemblance in relatives had been noted. The inheritance of such definite anatomical peculiarities as the "Hapsburg jaw" had frequently been recognized. Man has never been well adapted for laboratory study, and little exact progress was made. A notable exception has to do with sex-linked inheritance. The peculiar inheritance of color-blindness was reported to the Royal Society as long ago as 1779 by a British divine, Michael Lort. Forty years later C. T. Nasse (Germany) formulated a law of sex-linked inheritance based on hemophilia, a disease of unusual interest because of its occurence in the royal families of Europe.

By 1760 the stage was set for a century of biological progress that culminated in 1859 with the publication of Darwin's Origin of Species.

GENETICS IS BORN, 1760–1900

1760–1830—Foundation of important livestock breeds through inbreeding and selection practiced by English breeders—Bakewell, Bates, the Collings, and others.

1809—Publication of J. B. P. de Lamarck's Philosophie Zoologique (France) represented the first attempt to produce a comprehensive theory of evolution. Erasmus Darwin (England), G. L. L. de Buffon (France), and W. von Goethe (the German poet whose Metamorphosis of Plants, 1790, is a notable milestone in biological thinking) had dealt with various phases of the problem of organic development of individuals, species, and genera. Lamarck attempted to weld these observations and speculations into a coherent theory of evolution, an important step in biological progress.

[1] His "proof" that the fluid and not the spermatozoa was the fertilizing agent was unfortunately wrong. Not until 1824 did Prevost and Dumas correct this mistake.

1812—(1) Karl Friedrich Gauss (Germany), Theoria combinationis observationum erroribus minimis obnoxia (theory of least squares—basic in the statistical evaluation of data).

(2) Pierre Simon Laplace (France), Theorie analytiques des probabilités. Beginning of "the law of error concept."

1820—(1) Gauss, evolution of the probable error—for a century the almost universally used test of the significance of experimental data.

(2) C. F. Nasse (Germany), Nasse's law of male sex-linked inheritance, based on study of hemophilia.

1822—John Goss (England) reports but does not interpret dominance and recessiveness, and segregation in pea hybrids.

1823—Thomas Andrew Knight (England), Knight-Darwin law of cross-breeding (value of crossing to produce better plants). Dominance, recessiveness, and segregation observed in peas without mathematical relationships.

1826—A. Sageret (France) classifies contrasting characters in the parents of a cross in pairs, using muskmelons and cantaloups, cites unit characters in human eye color, and uses the term "dominant."

1835—(1) Division of cells described by H. von Mohl (Germany).

(2) Publication of K. F. von Gaertner's Memoir (Germany) reporting 25 years of hybridization experiments dealing with 107 species of plants; noted distinction between the uniformity of first hybrid generation and the diversity of later generations, and reported hybrid vigor.

1838–39—Cell theory, M. J. Schleiden and T. Schwann (Germany). First generalized statement of the theory that all organisms are made up of cells—one of the great generalizations of experimental biology.

1840—Word "protoplasm" coined by J. E. Purkinje (Bohemia), though used in a slightly different sense from that of today. A. Payen (France) and F. Cohn (Germany) suggested the essential similarity of protoplasm as the physical basis of all life (1846–50).

1841—R. A. von Kolliker (Switzerland) proves that spermatozoa arise from parent body and are not parasites as was previously believed.

1840–50—Louis de Vilmorin (France) develops the progeny test ("genealogical selection") in wheat, oat, and sugar-beet breeding.

1843—John Le Couteur (island of Jersey) publishes a summary of his work on wheat breeding. "This summary has been the basis and origin of variety testing" (De Vries). The same methods were independently developed somewhat earlier by Patrick Sheriff (Scotland), who produced many outstanding varieties.

1846—(1) A. Quetelet (Belgium), Lettres . . . sur la Theorie des Probabilités. Described biological phenomena in quantitative terms.

(2)Von Mohl recognizes nature and importance of protoplasm in its present sense.

1848—W. Hofmeister (Germany) figures the chromosomes as unstained bodies, but without appreciating their significance.

1849—(1) Sir Richard Owen (England) enunciates principle of the continuity of the germ plasm. This idea was developed by Virchow, Weismann, and others, and culminated in the modern gene theory.

(2) Union of sperm cell and egg cell (fertilization) first seen in seaweed (*Fucus*) by G. Thuret (France). A year later he showed that the egg would not develop without fertilization.

1858—R. Virchow (Germany) enunciates the principle: Omnis cellula e cellula (every cell from a cell), finally disposing of the theory of spontaneous generation—a basic biological generalization which completed the cell theory, establishing the continuity of all life from remote beginnings.

1859—Publication of Charles Darwin's Origin of Species (England). This contains extensive discussions of hybrids, but its contribution to genetics was mostly indirect. It marks a turning point in scientific thought and dates the beginning of the modern experimental approach to biological problems.

1861–62—M. J. S. Schultze (Germany) and H. A. de Bary (Germany) establish the essential unity of protoplasm in all living cells.

1863—D. A. Godron and C. V. Naudin (France) independently report experiments in plant hybridization. Naudin confirmed Sageret's work, in general discussed work of the early hybridizers, and reported dominance and segregation in *Datura* (jimsonweed) hybrids. He did not deal with single characters and reported no statistical observations on the second generation. His theoretical explanation of his facts was a forerunner of Mendel's ideas, but inferred rather than deduced.

1865—F. Schweigger-Seidel and A. von la Valette St. George (Germany) independently prove that a spermatozoon is a single cell and contains nucleus and cytoplasm.

It is impossible to tell how much of this earlier work was known to Gregor Mendel. Very likely most of it was. The work of Godron and Naudin was jointly awarded a prize by the French Academy of Sciences, so that it must have been fairly well known in scientific circles. Mendel had access to a rather extensive library, which included all of Darwin's works, and many other books on plant hybridization, etc. He was in contact with such eminent biologists as Nägeli, so that there is an excellent possibility that he had the benefit of this earlier work. But be that as it may:

1866—(1) Gregor Mendel (Austria) publishes in the Proceedings of the Brünn Natural History Society (Verhandlungen der Natur Forschenden Verein in Brunn) his investigations concerning plant hybrids, Versuche über Pflanzen-Hybriden, one of the oustandingly lucid and detailed expositions of a fundamental discovery. For 34 years Mendel's papers lay forgotten.
(2) E. Haeckel (Germany) predicts that the cell nucleus will play a star role in heredity.

1867—(1) Vilmorin tests immediate effect of pollen.
(2) H. S. Bidwell (United States) reports controlled pollination in maize.

1868—Darwin's pangen hypothesis—gemmules (hypothetical particles that float in the blood stream) are given off by cells and held to modify germ cells.

1873-4—L. Auerbach (Germany) begins experimental study of cell mechanics (fertilization).

1875—(1) E. Strasburger (Germany) describes the chromosomes.
(2) Oscar Hertwig (Germany) proves that fertilization consists of union of two parental nuclei contained in the sperm and ovum. This demonstration that sexual reproduction is a process contributed to essentially equally by the two sexes marked an important advance. It disposed of speculation regarding the role of the two sexes in inheritance, and it showed that genetics is basically a problem of cell physiology.

1878-81—W. J. Beal (United States) determines increased yields of corn hybrids between varieties and suggests their use in corn production.

1879-82—W. Flemming (Germany) describes the longitudinal splitting of the chromosomes.

1881—W. O. Focke (Germany) coins the term "xenia" to denote immediate effect of pollen on the endosperm in the maize seed.

1883—(1) P. J. van Beneden (Belgium) begins study of early history of animal egg. Reports reduction of the chromosome number in the egg cells to half that in body cells and holds that chromosomes have a genetic continuity throughout the life cycle—basically important concepts in genetic theory.
(2) E. L. Sturtevant (United States) observes without interpreting first linkage of genes now known as tunicate and sugary (*TuSu*) in maize.

1884—K. W. von Nägeli (Switzerland), ideoplasm concept—control of heredity seen as due to "ids", which were conceived to be solid particles. Nägeli's book was important as a precursor of Weismann's The Germ Plasm.

1884-5—(1) Identification of the cell nucleus as the basis of inheritance "made independently and almost simultaneously by Hertwig, Strasburger, Kölliker, and A. Weismann" (Germany).
(2) Halves of split chromosomes shown going to opposite poles by Flemming and others.

1885—C. Rabl (Austria) announces the individuality of the chromosomes.

1886—(1) Francis Galton (England) devises the correlation table—a most useful tool in applying statistical methods to many biological problems.

(2) Hugo de Vries (Holland) discovers aberrant evening primrose plants at Hilversum, Holland. Experiments with these extending over 15 years formed the basis for his mutation theory of evolution.

1885–87—Weismann publishes a theory of chromosome behavior during cell division and fertilization which explains earlier observations of Van Beneden, Strasburger, etc., and predicts that two kinds of cell division will be discovered—mitosis (already known) and reduction, in which the chromosome number will be reduced to half by an orderly separation of paternal and maternal chromosomes.

1887—W. Roux (Germany) suggests that the longitudinal splitting of the chromosomes when dividing means that many different qualities are arranged single file in the chromosome, and that these are all contributed by this method of division to each daughter cell.

1887-88—Th. Boveri (Germany) verifies Weismann's prediction of the reduction of the chromosomes by observing the phenomenon in *Ascaris*.

1888—Chromosomes named by W. Waldeyer (Germany).

1889—(1) De Vries revises the "pangen" theory of determiners floating in the blood stream, and denies any transfer of gemmules (determiners) from body cells to gametes.

(2) Francis Galton (England) publishes Natural Inheritance, which formulates his law of ancestral inheritance—a statistical statement of the relative influence of parents, grandparents, etc , in determining characteristics in offspring.

1890—(1) Law of numerical equality of paternal and maternal chromosomes at fertilization in animals and plants (Boveri, Germany; L. Guignard, France).

(2) Babcock test for butterfat percentages (United States). Beginnings of dairy-cattle selection for butterfat production on scientific basis.

1891—(1) Willett M. Hays (United States) develops the centgener progeny test, thereby recognizing that the test of the genetic quality of an individual can be adequately evaluated only by a study of its progeny. At about the same time the New York (Cornell) Agricultural Experiment Station develops rod-row method of small grain testing.

(2) W. A. Kellerman and W. T. Swingle (United States) make first count on a segregating ear of maize.

1892—With publication of Das Keimplasma (The Germ Plasm) Weismann enunciates the then very radical principle of noninheritance of acquired characters, and expands Nägeli's idioplasm theory to bring cell theory and "genetic theory" into organic relationship. Basing his theory on Van Beneden's observations. Weismann explains the reduction division as a method of exactly distributing the chromosome material.

1894—(1) W. Bateson (England) emphasizes the importance of the study of "discontinuous variation" (an approach toward the idea of Mendelian units) in solving the problem of heredity.

(2) Karl Pearson (England) publishes first of Contributions to the Mathematical Theory of Evolution, developing methods of dealing statistically with skew frequency curves.

(3) A. Millardet (France) notes "false hybrids" entirely resembling pollen parent (patrogenesis).

1897—(1) G. Udny Yule (England), publications On the Theory of Correlation.

(2) First egg-laying contests (England).

1898—(1) Pearson develops Galton's Law of Ancestral Heredity and also introduces the standard deviation, an improved method of determining the significance of deviations of observed data from theoretical perfection.

(2) S. G. Navashin (Russia) discovers double fertilization in higher plants.

(3) W. J. Spillman (United States) notes segregation in wheat, which he reported in 1901 in an independent statement of Mendelian principles.

(4) G. M. Gowell (United States) installs 52 trap nests and initiates scientific breeding for egg production.

(5) Flemming counts human chromosomes, finding 24 in corneal (eye) tissue. (Later work with improved technique shows 24 pairs.)

1899—(1) L. Cuénot (France) working with animals, and Strasburger (Germany, working with plants, advance theory that sex is controlled within the germ cell, not by environment.

(2) De Vries and C. F. J. E. Correns (Germany) publish almost simultaneously an explanation of xenia in corn as due to double fertilization

(3) First International Conference of Hybridization (the later conferences in this series were called Congresses of Genetics) held in London

EARLY DAYS OF GENETICS

THE TURN of the century was an epochal year in the experimenta study of heredity. The almost simultaneous rediscovery of Mendel'. paper independently by three investigators (who had, when they reac' Mendel's paper, experimental material of their own to verify hi: conclusions), was a striking symptom of an even wider trend. Batesor had for years been attacking the problem of discontinuous variation and Haldane says that had not Mendel's paper been discovered, Bateson would undoubtedly have been buried in Westminster Abbey as the discoverer of atomic heredity. Spillman's wheat work in the United States had reached a point where he appears to have been just on the brink of making the same illuminating generalization. Other workers also were hot on the trail of the gene, and the time was ripe for a veritable explosion of genetic progress. Within 3 years of the triple De Vries-Correns-Von Tschermak announcements, abundant verification of Mendel's work had been made by many workers, and the universality of the Mendelian principles had been demonstrated in plants, animals, and man. The fecund pomace fly, *Drosophila*, was about to enter his milk-bottle kingdom and populate acres of banana-agar nutrient medium with an ever-growing progeny of mutant forms. Into the hands of the research investigator had been given the key to unlock that perennial mystery of the ages, heredity

1900—Rediscovery and verification of Mendel's principles independently b De Vries (Holland), Correns (Germany), and E. von Tschermak (Austria) marking the beginning of modern genetics.

1901—(1) H. Henking (Germany), F. C. Paulmier (United States), and other report an "accessory chromosome" in spermatozoa (later identified with se determination), based on work begun in 1891.

(2) Bateson publishes a translation of Mendel's paper.

1902—(1) Terms allelomorph, homozygote, heterozygote, F_1, F_2, coined by Bateson. In their report to the evolution committee, Bateson and Saunders list 26 instances of allelomorphism which had been "actually provedt to exist, or may be inferred from the published record." This included cases in peas, wheat, maize, *Datura*, *Oenothera*, snapdragon, mouse, fowl, catle. The Mendelian nature of polydactylism (an extra finger) in man was suggested.

(2) De Vries—The Mutation Theory of Evolution, based on studies of evening primrose.

(3) T. H. Montgomery (United States) announces the pairing of homologous maternal and paternal chromosomes during synapsis (joining and separation prior to formation of germ cells with reduced chromosome number).

(4) E. C. McClung (United States) relates an accessory chromosome found in some insects to sex determination—first attempt to connect a specific character with a particular chromosome. The concept of specific sex chromosomes, which have a major influence in determining sex, has been verified, with modifications, in a range of organisms extending from the pomace fly to man.

(5) Cuénot first demonstrates Mendelism in animals (normal and albino mice).

1902—(6) Bateson defends Mendelism against attacks of W. F. R. Weldon and Karl Pearson (England). This heated clash regarding the utility of experimental versus statistical approaches to biological problems continued intermittently until 1904. Publication of first number of Biometrika, the leading journal dealing with the statistical aspects of genetics.

1902–3—W. W. Sutton (United States) shows that body chromosomes are individually recognizable and points out the mutual interrelations between cytological observations and Mendelian phenomena, closing the gap between cytology and genetics.

1903—(1) Pure-line concept (variations in the progeny of a single plant of a self-fertilized species are not due to inheritance) first put forward by W. L. Johannsen (Denmark). Phenotype and genotype defined. Modern concept of "selection" born.

(2) R. H. Biffen (England) reports that resistance to stripe rust of wheat is governed by a single Mendelian recessive factor.

(3) Bateson (walnut, rose, and single comb in fowl) and Cuénot (albino and pigmented mice) note interaction of nonallelomorphic factors (later called epistacy).

1904—(1) C. B. Davenport (United States) confirms Mendelian inheritance of polydactylism in man.

(2) American Breeders Association founded under Secretary of Agriculture James Wilson, with Willett M. Hays as secretary.

(3) Thomas Hunt Morgan becomes professor of zoology at Columbia University. This represents the beginning of the former "Columbia group" of genetic research workers, which included many of the names outstanding in genetics today. Other centers also had their origin about this time, at Harvard University, the University of Chicago, the University of Indiana, and Leland Stanford University.

(4) Station for Experimental Evolution established by the Carnegie Institution of Washington.

(5) A. F. Blakeslee (United States) reports isolation of sex-different strains of molds. First called "plus" and "minus", these were later called "male" and "female" though no morphological differences could be found between them.

1905—(1) G. H. Shull and E. M. East (United States) begin independent experiments on inbreeding in maize that opens up a field of the utmost theoretical and practical importance.

(2) N. M. Stevens and E. B. Wilson (United States) confirm McClung's sex-determination theory.

(3) "Coupling" (linkage) in sweet pea analyzed by Bateson, E. R. Saunders, and R. C. Punnett (England). Bateson and Punnett explain the walnut comb in the fowl as being due to two dominant factors, one of which alone produces pea combs, and the other, rose combs—the double recessive being single combs. This first report of interaction of Mendelian factors marked a very important advance.

(4) O. F. Cook and W. T. Swingle (United States) publish diagram and propose names for the sexual cycle (sporophyte-gametophyte) in plants.

1906—(1) Term "genetics" coined by Bateson.

(2) C. W. Woodworth and W. E. Castle (United States) "discover" *Drosophila*. "More has been learned concerning heredity from this one species since 1910 than had been learned from all sources before that time." It produces 25 generations a year and has but 4 pairs of chromosomes, so that it is ideally suited to make linkage studies. The modern gene theory is based largely on studies of *Drosophila*.

(3) Possible relation between linkage and the chromosomes pointed out by R. H. Lock (England).

(4) George Rommel begins U. S. Department of Agriculture inbreeding experiments with guinea pigs, which have been continued ever since.

1907—(1) Correns advances theory of two kinds of male gametes (male-determining and female-determining).

(2) J. B. Norton (United States) publishes rod-row system of breeding, first put into general use by him in 1902.

(3) Strasburger uses terms haploid and diploid for reduced and double number of chromosomes.

1907—(4) A. M. Lutz (United States) shows that the gigas mutation of the evening-primrose has double number of chromosomes of *Oenothera lamarckiana* Ser.

The discovery of a tetraploid in the evening-primrose opened up the subject of variation of chromosome number in general, and of polyploidy in particular. This discovery that organisms might vary in their chromosome constitution by an entire set of chromosomes has today developed a very extensive branch of cyto-genetics. Discoveries of polyploid series in wheat, the roses, the *Daturas* and *Solanums*, and elsewhere have marked a distinct advance in our understanding of the development of species. The artificial production of polyploids by heat treatment and by other means has been a more recent development of great promise. Even greater in its possibilities may be the production of generic polyploids (amphidiploids) having one or more complete chromosome complements from each parent species. These forms are generally self-fertile but are usually sterile with the parent species or genera.

(5) Bateson coins terms "epistatic" and "hypostatic" to describe interrelations of non-allelomorphic genes.

1908—(1) Cuénot discovers that the yellow gene (*Y*) in mice is lethal, suggesting that it kills the embryo early in development when inherited from both parents.

(2) Zeitschrift fur induktive Abstammungs-und Vererbungslehre (Journal for Inductive Descendence and Inheritance Theory) founded.

(3) Delaware Agricultural Experiment Station begins inbreeding experiments with swine.

Many practical breeders before this time had used intensive inbreeding in their operations, but the degree of inbreeding actually practiced is very hard to determine. Several instances are on record of herds being maintained for a number of generations without the introduction of new blood. N. H. Gentry's work with Berkshire swine in Missouri was a notably successful example of the use of inbreeding in breed improvement. The Delaware experiment represents the first attempt to attack this problem in a scientific manner with farm animals. All of the swine inbreeding experiments (and they are practically the only experiments in the intense inbreeding of livestock, by brother×sister matings, that have been undertaken, though considerably more has been done with poultry) have been only partially successful from a practical standpoint. The hoped-for production of highly inbred lines of swine that could be crossed to utilize to the full the principle of hybrid vigor in the first generation has failed to materialize because of the practical difficulties encountered in maintaining the inbred lines. Theoretically there appears to be no reason why robust inbred lines cannot be produced as has been done with rats and guinea pigs. Among the outstanding later experiments are those at the University of California, the Oklahoma Agricultural Experiment Station, Iowa State College (poultry), the Minnesota Agricultural Experiment Station, and the United States Department of Agriculture.

Many less direct attempts to produce highly inbred herds of livestock have been started and are continuing. Notable among these is the United States Department of Agriculture's development in dairy-cattle breeding, which has continued since 1912. The intention is to produce dairy sires pure or homozygous for high production by

line breeding as intense as possible to the foundation sire of the herd. While many practical breeders have used this method with livestock for short periods, this continuing project, with accurate records for many generations, is unique.

(4) H. Nilsson-Ehle (Sweden) explains that inheritance of color of seed in wheat is largely due to three Mendelian factors—multiple factors and blending inheritance begin to be added to Mendelian concepts. This principle was confirmed a year later by East in corn.

1909—(1) Crossing-over hypothesis (exchange of segments in paired chromosomes) advanced by F. A. Janssens (Belgium).

(2) R. A. Emerson (United States) reports multiple allelomorphs (more than one alternative factor) in beans and maize.

(3) Sir Francis Galton's bequest to found the Galton Laboratory at the University of London establishes the first laboratory devoted to the study of human heredity.

(4) Shull suggests use of first-generation hybrids between inbred lines as a basis of practical corn breeding.

1910—(1) L. Epstein and R. Ottenberg (United States) point out that human blood groups (discovered by K. Landsteiner, Austria, in 1900 and classified by Jansky, Germany, in 1907) follow Mendelian principles in inheritance.

(2) Morgan proposes explanation of sex-linked inheritance; publishes first gene mutation in *Drosophila* (white eye).

(3) Announcement of the gene theory by Morgan, which includes the principle of linkage of genes resident on the same chromosome. This brilliant hypothesis has been upheld in a multitude of experiments. Beginning of chromosome maps compiled by linkage and cross-over data.

(4) A. B. Bruce, and F. W. Keeble, and C. Pellew (England) suggest that hybrid vigor is due to dominant favorable growth factors.

(5) A. Lang (Switzerland) suggests multiple factor hypothesis to account for size differences in rabbits.

(6) H. Winkler (Germany) publishes method of producing *Solanum* chimaeras artificially. The explanation of these chimaeras as layers (periclinal) and sectors (sectorial) of cells from stock and cion was furnished by Erwin Baur (Germany) 1914.

1911—(1) Journal of Genetics (England) established

(2) Raymond Pearl (United States) publishes the first of his studies of egg production in the fowl.

(3) G. N. Collins and J. H. Kempton (United States) report first linkage in maize.

(4) Baur publishes the first edition of his Introduction to the Experimental Study of Heredity, Einfuhrung in die experimentelle Vererbungslehre.

(5) Richard Goldschmidt (Germany) publishes the first edition of his Einfuhrung in die Vererbungswissenschaft (Introduction to the Science of Heredity), which summarizes his theory of sex determination as a matter of rate of developmental expression of sex-determining genes—demonstrated by the production of intersexual forms in hybrids of the gypsy moth.

(6) W. E. Castle and J. C. Philips (United States), ovary transplantation experiment in the guinea pig, showing nonmodification of genetic characters through change in embryo environment.

(7) Cuénot, explanation of multiple allelomorphism in mice.

1912—(1) R. R. Gates (England) identifies *Oenothera semi-gigas* Vries as a triploid—the first to be recognized (triploids have three sets of chromosomes).

(2) H. S. Jennings (United States) shows that with self-fertilization the percentage of heterozygosis is halved in each successive generation.

This principle was elaborated by H. D. Fish (United States 1914) and Pearl 1913–17, and expanded by Jennings in 1917. In 1923 Sewell Wright (United States) published a general inbreeding coefficient applicable to irregular systems of mating. Since that time the evolutionary implications of Mendelian heredity have been developed by Wright, R. A. Fisher, J. B. S. Haldane, and others.

1913—(1) C. B. Bridges (United States) reports nondisjunction of sex chromosomes (both sex chromosomes going to one gamete and none to the other). Important confirmation of chromosome theory.

(2) Nils Hansson (Sweden) publishes first formula for a sire index, an improvement in the progeny test for characters not expressed by the sire.

More recently the sire-index idea has been elaborated by a number of suggested modifications of Hansson's original idea. All of these are based on the concept that the sire's transmitting ability for a character he does not himself show (such as milk or egg production) can be measured by comparing the production of his daughters with that of their dams. This concept is one of the bases of the "proved-sire movement" started in 1918 by the United States Department of Agriculture, which attempts to discover and to utilize to the maximum the sires that transmit desirable qualities to the greatest degree.

1915—Morgan, A. H. Sturtevant, Bridges, and H. J. Muller (United States) publish The Mechanism of Mendelian Heredity—an epoch-making book.

1916—(1) Castle confirms Lang's multiple-factor hypothesis of blending inheritance in rabbits.

(2) Winkler produces polyploid forms from the callus tissue of decapitated grafts

This method of doubling, tripling, and quadrupling the chromosome number has been rather widely used in experimental procedures by other workers. By applying it to haploid tomatoes, E. W. Lindstrom (United States, 1927) was able to obtain a pure line by doubling of identical chromosome complements—a procedure of considerable value in genetics and plant breeding.

(3) Castle and Wright discover first linkage in a mammal (rat).

(4) Pearl demonstrates effectiveness of pedigree selection contrasted with mass selection in the fowl.

(5) Shull suggests the word "heterosis" to designate the vigor of first-generation hybrids.

1917—(1) O. Winge (Denmark) elaborates theory of polyploid origin of new species by multiplication of a basic chromosome complex.

(2) Emerson finds variegated pericarp in maize due to an unstable gene.

(3) The Connecticut Agricultural Experiment Station produces the first commercial "crossed corn."

Following the early experiments of Beal, and the inbreeding experiments of Shull and East, inbreeding experiments with maize enjoyed a considerable vogue. It was found that where some of these uniform but usually rather unpromising inbred lines were crossed, an extremely vigorous and uniform first-generation hybrid was produced, which exceeded the yields of commercial varieties by 30 percent or even more. The production of this crossed corn seed on a commercial basis was first attempted at the Connecticut Station. Unfortunately the lack of vigor and the small quantities of seed produced by the inbred strains made seed production difficult and expensive. To obviate this difficulty the system of "double-crossed corn" (suggested by D. F. Jones in 1919, first commercial production attempted in 1921 by George S. Carter, Clinton, Conn.) was perfected, whereby four inbred lines were used. These lines (designated A, B, C, D) are crossed in pairs (A×B and C×D), and the resulting two extremely vigorous hybrids are crossed to produce the commercial seed. These varieties have great vigor and uniformity, and production of seed in commercial quantities is entirely feasible. Many workers have con-

tributed notably to this development, among them D. F. Jones, H. A. Wallace, F. D. Richey, and M. T. Jenkins, and many others in the United States Department of Agriculture and in the Corn Belt experiment stations.

The concepts developed by inbreeding have been applied in other ways, such as that of shifting a single desirable character from one variety to another by crossing and then by repeatedly back-crossing, to the other parental variety with the majority of desirable characteristics, those segregates that have the one desired character. H. V. Harlan and M. L. Martini (United States) first used this technique in barley in 1922, and it has been applied with equal success by several other workers.

(4) W. B. Kirkham, H. L. Ibsen, and E. Steigleder (United States) prove the lethal action of the yellow gene in the mouse by embryological studies.

The attempt to trace the beginnings of gene effects in the earliest possible stages of development (and to follow through to maturity the developmental history of a gene) has grown into a new and promising but often very difficult branch of genetic research—the "genetics and development" studies. The problem has also been approached by experiments in the transplantation of tissues and organs, by hormone injections, and by studies of the gene chemistry involved in color development of hair, etc. The field is just beginning to be explored.

(5) J. Jeswiet (Netherlands) working in Java proves that the Kassoer sugarcane (used in breeding mosaic-resistant P. O. J. hybrid sugarcane) is a second-generation hybrid of true sugarcane with a wild grass, *Saccharum spontaneum* L., that contains little or no sugar. This initiated large-scale sugarcane breeding in many countries, with wild relatives used to secure disease resistance. Later researches showed that the vigorous, disease-resistant, high-yielding sugarcane hybrids all showed a much higher chromosome count than true sugarcane (polyploidy).

1918—H. D. King (United States) reports results of inbreeding rats for 25 consecutive generations, showing that close inbreeding is not necessarily deleterious, and that fertility and vigor can be maintained in some lines.

1919—Morgan and others publish The Physical Basis of Heredity, setting forth in detail the gene theory, and summarizing *Drosophila* genetics.

RECENT DEVELOPMENTS

Even from the safe vantage of a third of a century it is not easy to evaluate the developments that followed the rediscovery of Mendel's work. As we advance nearer to the present our task becomes more difficult, for discoveries that now seem not especially revolutionary may, in the light of later work, be as epochal as Mendel's pioneer contribution. The time is too short to place a final value on many advances, and progress is being made on too many fronts to attempt to cover adequately the multitudinous work in genetics and related sciences. Some recent developments that may have been overlooked may be much more important 20 years hence than they seem today. Thus the compiler is sure only that in this most hazardous part of his journey he is treading on very dangerous ground indeed.

It was planned in compiling this chronology to avoid mention of any names in this final part, simply citing significant developments and trends, letting the perspective of the years determine more fairly

those who have made fundamental contributions to genetic progress. In practice this has proved difficult, because some names are so closely linked to certain discoveries that anonymity seems unfair. Thus radiation genetics and salivary-gland chromosomes immediately bring to mind the names of the pioneers whose work has very recently led the way to new bonanzas of genetic facts. Certain developments have been so interesting and significant that to stop the chronology 10 or 15 years ago purely through the promptings of the instinct of self-preservation would destroy much of its interest and value. The following compromise, which attempts to maintain perspective at very short range, is put forth with many misgivings and with a painful realization of the hazards involved. In the short summary paragraphs frequently interspersed with names and dates, an attempt has been made to suggest the extent and significance of some of the important developments.

1920—(1) Tobacco variety "made to order" by genetic methods (East and Jones in the United States).

(2) H. D. Goodale's (United States) studies of effects of selection on egg production.

(3) E. B. Babcock (United States) begins *Crepis* investigations, which are adding much to our knowledge of chromosome evolution within a genus.

(4) G. Tackholm (Sweden), monograph on polyploid series in *Rosa*, suggesting how a genus may have evolved through changes in chromosome number.

1921—(1) Triploid discovered in *Drosophila* by Bridges.

(2) Morgan estimates that the gene has a diameter between 20 and 70 microns.

Since Morgan first attempted to estimate the size of the gene several other approximations have been attempted. These have been based on the volume of the chromosomes, the number of genes known to to reside in the chromosomes, and the number of mutations that have been known to occur in a given chromosome; or on the number of mutations alone. As our knowledge of the number of genes increases, the maximum estimated size of the individual gene is necessarily reduced. Very recently the problem of gene action has begun to be attacked from the angle of the physical chemist by D. Wrinch (England) and other biochemists. It is thus shown that the giant protein molecules of which the chemists have built mental pictures through X-ray analysis and by other means come within the range of size postulated for the individual gene. At the present time no experimental evidence exists to prove the speculations that the gene in fact consists of a single molecule.

(3) East makes genetic analysis of partial sterility in tobacco hybrids.

1922—(1) Haploid *Datura* discovered by A. F. Blakeslee, J. Belling, M. E. Farnham, and A. D. Bergner (United States). This is the first discovery of a flowering plant developing with single instead of paired chromosomes.

(2) R. E. Cleland (United States) shows that characteristic arrangement of chromosome chains (rings) in *Oenothera* are typical of different species.

1923—(1) K. Sax (United States) demonstrates linkage between quantitative and qualitative characters in the garden bean.

(2) F. A. E. Crew (Great Britain) presents evidence to show that the "bulldog" calf, a nonliving monster frequently appearing in crosses of Dexter and Kerry cattle, is due to a lethal factor.

While other workers had suggested the inheritable nature of this defect, Crew was the first worker to suggest the possibility of its being

a lethal Mendelian character, the first lethal character identified as such in the livestock breeds. Since that time many other lethals have been recorded. C. Wriedt (Norway) has noted a tendency for outstanding dairy sires to transmit lethal factors, suggesting a linkage between such lethals and factors of economic value. They are thus a matter of some importance to the practical breeder. Their genetic interest is considerable because of the studies they have made possible in the developmental history of genes, from fertilization to adult organisms—the first of these being the study of L. C. Dunn and W. Landauer (United States) on the "creeper" fowl.

1924—(1) Blakeslee and Belling produce pure-line *Datura* by self-fertilization of a haploid.

(2) W. R. Taylor adapts smear technique to plant cytology, simplifying previous cumbersome methods and making possible the study of a much larger amount of material.

(3) Blakeslee, Belling, and Farnham explain certain *Datura* mutants as being plants with an extra chromosome. Blakeslee suggests the term "simple trisomic" for such forms in a classification of chromosomal types.

(4) W. T. Swingle and R. W. Nixon (United States) coin the term "metaxenia" to describe the effect of the pollen on maternal tissue outside the embryo. They confirm earlier observations, hitherto generally discredited, that date pollen has a profound effect on time of ripening and some other genetic characters.

1925—(1) T. H. Goodspeed and R. E. Clausen (United States) publish an analysis of their "artificial species", *Nicotiana digluta*, showing that this form (which arose as a fertile seedling from a normally sterile first-generation hybrid) contains a complete diploid set of chromosomes of each parent species of the original cross (*N. glutinosa* L.×*N. tabacum* L.). This amphidiploid ("double diploid") is self-fertile but is sterile with the parent species. This mechanism for the production of fertile polyploids by doubling the chromosome number of sterile first-generation hybrids has been found to be of rather wide occurrence in plants.

Primula kewensis W. Wats. was the first of the amphidiploids to be noted. It arose as a fertile branch of a sterile hybrid. The phenomenon remained an enigma until Goodspeed's and Clausen's publication. *Nicotiana digluta* explained the origin of a considerable number of such "artificial new species." Among forms recognized as amphidiploids on the basis of Clausen's and Goodspeed's work are Karpetchenko's *Raphano-Brassica*, C. A. Jorgensen's *Solanum luteonigrum*, wheat-agropyron hybrids of the Russian workers, etc. Other true-breeding interfertile forms, essentially new species, have been produced by chromosomal rearrangement in *Datura*.

(2) E. S. McFadden (United States) produces the two wheats, Hope and H–44, from a cross betwen Marquis wheat and Yaroslav Emmer. In the mature plant stage these wheats have been found to be nearly immune from almost all the physiological races of stem rust now known.

(3) J. A. Clark and E. R. Ausemus (United States) point out that the near-immune reaction in Hope wheat is a new character in common hard red spring wheat, inherited as a dominant character. The Hope and H–44 wheats have since become successfully and extensively used in further breeding for stem-rust control.

(4) East and A. J. Mangelsdorf (United States) offer a genetic interpretation of self-sterility in *Nicotiana* as due to rate-of-growth genes affecting the pollen tubes.

1926—(1) Belling advances the segmental interchange theory of chromosome evolution (exchange of segments between chromosomes that are not homologous).

(2) J. Percival (England) publishes explanation of polyploid origin of 14 and 21 chromosome wheats.

1927—(1) Artificial (X-ray) transmutation of the gene, Muller in *Drosophila* and L. J. Stadler in plants (United States).

The discovery made almost simultaneously by Muller and Stadler and Goodspeed that X-rays, and by F. B. Hanson (United States) that radium produces abundant gene mutations is one of the great bonanzas of modern genetic research. In the short time since this discovery was made it has been shown that X-rays produce a variety of effects ranging from mutations in a single gene to profound rearrangements and reassortments of entire chromosomes. Since Muller's original announcement the radiation technique has been extended to other forms of wave energy. It is impossible to give in any detail the development in this very widespread and fertile field of research.

(2) T. S. Painter (United States) finds a chromosome deficiency in mice which, with associated genetic evidence, establishes the first case in mammals of locating a definite gene on a definite chromosome.

(3) J. H. Craigie (Canada) reports hybridization of rust fungi to produce new pysiological forms; reports mutation in rust fungi.

The discovery by Craigie that hybridization of rust fungi is possible has opened up a wide field of most interesting research in microgenetics. Other workers have shown that the disease-producing fungi that attack plants mutate rather frequently in respect to their ability to infect and affect a given strain. The problem of the plant breeder seeking resistance has been enormously increased in complexity by these discoveries, which necessitate methods of protection by breeding against an enemy whose physiological reactions change with no visible outward alteration.

(4) Belling, iron-aceto-carmine technique of chromosome staining, makes possible more detailed studies of chromosome structure.

(5) B. O. Dodge (United States) publishes first report on the genetics of *Ascomycetes* (fungi), which have some advantages for genetic research because their haploid nature makes direct observation of all gene effects possible. With this material C. L. Lindegren (United States) has recently produced the first chromosome map of genes in a lower plant.

1930—(1) Stadler finds that maize genes vary widely in rate of mutation (no mutation in 1½ million waxy gametes, 492 per million in red pericarp [*P*] gametes).

(2) H. A. Timofeeff-Ressovsky (Union of Soviet Socialist Republics) reports induced reverse gene variations in *Drosophila*, demonstrating that X-ray effects are not purely destructive.

1930–37—The perfecting of the gene-frequency technique for the analysis of human inheritance by F. Bernstein (Germany), L. Hogben, J. B. S. Haldane, and L. S. Penrose (England), A. S. Wiener and L. S. Snyder (United States) makes possible much greater precision in the use of pedigree data, when the samples are too small to allow statistical treatment by older methods.

1931—(1) B. McClintock and H. Creighton (United States) in maize, and C. Stern (Germany) in *Drosophila*, prove crossing-over cytologically.

(2) McClintock and others of the Cornell group relate maize linkage groups to specific chromosomes by use of trisomics (diploid plants with one extra chromosome).

(3) Cleland and Blakeslee unify *Oenothera* and *Datura* cyto-genetic observations through segmental interchange theory.

(4) Wright gives first comprehensive picture of evolution in Mendelian terms, with stress on the balance and interplay between selection intensity, mutation rates, inbreeding, isolation, and migration.

1932—(1) L. F. Randolph (United States) produces tetraploid maize by heat treatment.

(2) Th. Dobzhansky (United States), and Muller and Painter show that "chromosome map" distance and actual (cytological) distance do not coincide.

(3) Variegation in *Drosophila* shown to be dependent on chromatin not organized into chromosomes (heterochromatin) by J. W. Gowen and and E. H. Gay (United States).

(4) J. M. Rasmusson (Norway) formulates hypothesis of interaction of genes to interpret certain observations of quantative character inheritance.

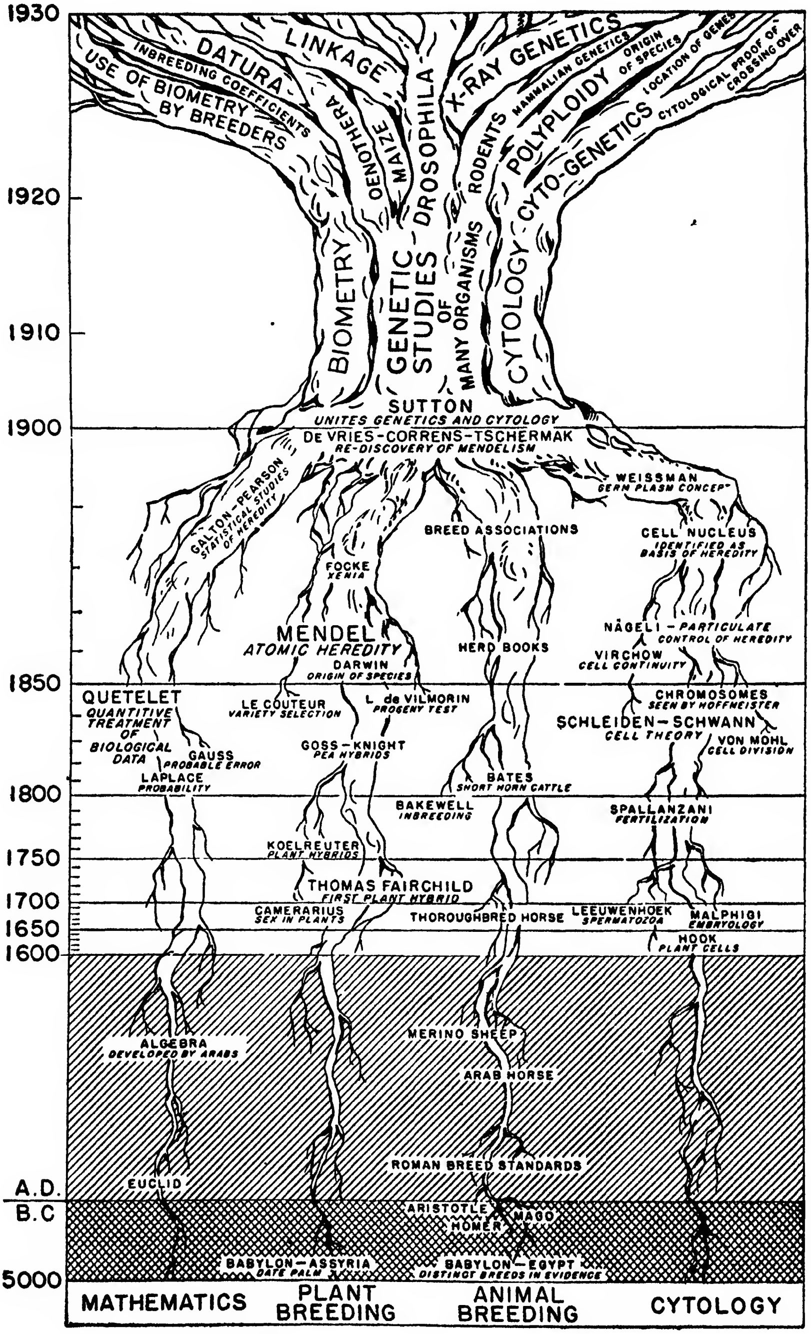
1934—Painter discovers genetic value of giant salivary gland chromosomes (discovered many years earlier, but considered a cytological curiosity), making possible detailed studies of chromosome structure, and leading to very exact location of genes.

THE FAMILY TREE OF GENETICS

It is customary to visualize historical development by analogy to a tree, whose roots go back into the distant past, whose trunk symbolizes a nicely unified development, and whose spreading branches denote the wide ramifications of our pet discipline at the moment we are considering it. Under any circumstances such an analogy is probably hazardous, and with some misgivings we shall symbolize genetics as a tree which has drawn its sustenance from four main roots.

These four taproots of modern genetics are: (1) The genetics root, leading back through Morgan, Bateson, De Vries, Mendel, Koelreuter, etc.: (2) the cytological root, tracing through Belling, McClung, Wilson, Sutton, Van Beneden, Leeuwenhoek, to Hooke, who first saw and named the cell; (3) the biometrical root, tracing through Wright, Fisher, Pearson, Galton, Laplace; and (4) the animal-breeding root, tracing through the stud and herd books, through the breed founders (such as Bakewell, the Collings, and Bates of a century ago) to Mago the Carthagenian, who is to be credited with compiling the first recorded score card—which is still used, with surprisingly little modification. Other "roots" could also be thought of.

It should be borne clearly in mind that these roots have generally been entirely distinct through much of their developmental history. No experimental connection existed between the observational work of the hybridizers and that of the microscopists until Sutton in 1902 confirmed Haeckel's prediction (1866) that the nucleus would prove to be the vehicle of heredity. The observed facts of Mendelian heredity fitted the cytologists' finding that meiosis and fertilization were a method for keeping the chromosome complement constant. The heretofore independent concepts were thus mutually confirmatory and together made a complete picture. Since that time it has been increasingly difficult to ignore cytology in studying strictly genetic phenomena. Without the cytologist's aid much genetic work would remain purely speculative. In the case of polyploidy, for instance, cytological counts of chromosome number and observation of chromosomal behavior at the reduction division have been of tremendous importance. Similarly the mathematical root developed entirely independently until Galton and Pearson bridged a gap that previously had been so wide that few students of the subjects involved would have admitted any close relationship.



The family tree of genetics.

What of future developments? The chronologer can do no better than quote one of the greatest geneticists, T. H. Morgan:

> I have been challenged recently to state on this occasion what seemed to be the most important problems for genetics in the immediate future. I have decided to try, although I realize only too well that my own selection may only serve to show to future generations how blind we are (or I have been, at least) to the significant events of our own time.
>
> First, then, the physical and physiological processes involved in the growth of genes and their duplication (or as we say their "division") are obviously phenomena on which the whole process of reproduction rests. The ability of the new genes to retain the property of duplication is the background of all genetic theory. Whether the solution will come from a frontal attack by cytologists, geneticists, and chemists, or by flank movements, is difficult to predict.
>
> Second: An interpretation in physical terms of the changes that take place during and after the conjugation of the chromosomes. This includes several separate but interdependent phenomena—the elongation of the threads, their union in pairs, crossing over, and the separation of the four strands. Here is a problem on the biological level, as we say, whose solution may be anticipated only by a combined attack of geneticists and cytologists.
>
> Third: The relation of genes to characters. This is the explicit realization of the implicit power of the genes, and includes the physiological action of the gene on the rest of the cell. This is the gap in our knowledge to which I referred already at some length.
>
> Fourth: The nature of the mutation process—perhaps I may say the chemico-physical changes involved when a gene changes to a new one. Emergent evolution, if you like, but as a scientific problem, not one of metaphysics.
>
> Fifth: The application of genetics to horticulture and to animal husbandry, especially in two essential respects—more intensive work on the physiological rather than the morphological aspects of inheritance; and the incorporation of genes from wild varieties into strains of domesticated types.
>
> Should you ask me how these discoveries are to be made, I should become vague and resort to generalities. I should then say: By industry, trusting to luck for new openings. By the intelligent use of working hypotheses (by this I mean a readiness to reject any such hypotheses unless critical evidence can be found for their support). By a search for favorable material, which is often more important than plodding along the well-trodden path hoping that something a little different may be found. And lastly, by not holding genetics congresses too often.

It is probable that we are even now witnessing the development of another major branch of the genetic tree—the biochemical branch. It has long been guessed that genes must be chemical in their action, and the molecular nature of the gene has more than once been suggested and speculated on. Studies of the analysis and synthesis of the sex hormones, of growth hormones and cancer-producing substances, and of the filterable viruses are bringing to light effects that closely resemble the action of genes. The next great important advance may be to link the gene with the newer biochemistry, which will make it necessary to revise our "genetic tree" and to add another important root tracing through Wilstetter, Mendeleeff, Dalton, and Lavoisier, to the alchemists of the Middle Ages!

Thus while specialization has been essential to promote the progress of science, it is distinctly a danger that too much specialization may endanger continued progress, if it prevents the formation of such fruitful graft-hybrids in ideas as those that have contributed so greatly to the progress of genetics. The geneticist and the breeder of the future must be intelligently cognizant of many fields of knowledge that are more and more impinging on their chosen specialty. Synthesis of these increasingly complicated factors seems essential if progress is to continue.
